Triggers can be nested up to 32 levels. If a trigger changes a table on which another trigger exists, the second trigger is fired and can then fire a third trigger, and so on. If the nesting level is exceeded, the trigger is canceled, and the transaction is rolled back.

The following error message is returned if the nesting level is exceeded:

```
Server: Msg 217, Level 16, State 1, Procedure ttt2, Line 2
Maximum stored procedure nesting level exceeded (limit 32).
```

You can disable nested triggers by setting the `nested triggers` option of `sp_configure` to 0 (off):

```
EXEC sp_configure 'nested triggers', 0
GO
RECONFIGURE WITH OVERRIDE
GO
```

After the `nested triggers` option is turned off, the only triggers to fire are those that are part of the original data modification: the top-level triggers. If updates to other tables are made via the top-level triggers, those updates are completed, but the triggers on those tables do not fire. For example, say you have an UPDATE trigger on the `jobs` table in the `BigPubs2008` database and an UPDATE trigger on the `employee` table as well. The trigger on the `jobs` table updates the `employee` table. If an update is made to the `jobs` table, the `jobs` trigger fires and completes the updates on the `employee` table. However, the trigger on the `employee` table does not fire.

The default configuration is to allow nested triggers, but there are reasons for turning off the `nested triggers` option. For example, you might want triggers to fire on direct data modifications but not on modifications that are made by another trigger. Say you have a trigger on every table that updates the audit time. You might want the audit time for a table to be updated by a trigger when that table is being updated directly, but you might not want the audit date updated on any of the other tables that are part of the nested trigger executions. This can be accomplished by turning off the `nested triggers` option.

Using Recursive Triggers

Recursive triggers were introduced in SQL Server 7.0. If a trigger modifies the same table where the trigger was created, the trigger does not fire again unless the `recursive triggers` option is turned on. `recursive triggers` is a database option turned off by default.

The first command in the following example checks the setting of `recursive triggers` for the `BigPubs2008` database, and the second sets `recursive triggers` to `TRUE`:

```
EXEC sp_dboption BigPubs2008, 'recursive triggers'
```

```
EXEC sp_dboption BigPubs2008, 'recursive triggers', TRUE
```

If you turn off nested triggers, recursive triggers are automatically disabled, regardless of how the database option is set. The maximum nesting level for recursive triggers is the same as for nested triggers: 32 levels.

You should use recursive triggers with care. It is easy to create an endless loop, as shown in Listing 30.24, which creates a recursive trigger on a new test table in the `BigPubs2008` database.

LISTING 30.24 The Error Message Returned for an Endless Loop with Recursive Triggers

```
--The first statement is used to disable the previously created
--DDL trigger which would prevent any changes.
DISABLE TRIGGER ALL ON DATABASE
EXEC sp_configure 'nested triggers', 1
RECONFIGURE WITH OVERRIDE
EXEC sp_dboption BigPubs2008, 'recursive triggers', TRUE
CREATE TABLE rk_tr_test (id int IDENTITY)
GO
CREATE TRIGGER rk_tr ON rk_tr_test FOR INSERT
AS INSERT rk_tr_test DEFAULT VALUES
GO
INSERT rk_tr_test DEFAULT VALUES
```

```
Server: Msg 217, Level 16, State 1, Procedure rk_tr, Line 2
Maximum stored procedure nesting level exceeded (limit 32).
```

The recursion described thus far is known as *direct recursion*. Another type of recursion exists as well: indirect recursion. With *indirect recursion*, a table that has a trigger fires an update to another table, and that table, in turn, causes an update to happen to the original table on which the trigger fired. This action causes the trigger on the original table to fire again.

With indirect recursion, setting the `recursive_triggers` database setting to `FALSE` does not prevent the recursion from happening. The only way to prevent this type of recursion is to set the `nested_triggers` setting to `FALSE`, which, in turn, prevents all recursion.

Summary

Triggers are among the most powerful tools for ensuring the quality of data in a database. The range of commands that can be executed from within triggers and their capability to automatically fire give them a distinct role in defining sound database solutions.

Chapter 31, “Transaction Management and the Transaction Log,” looks at the methods for defining and managing transactions within SQL Server 2008.

This page intentionally left blank

CHAPTER 31

Transaction Management and the Transaction Log

Transaction management is an important area in database programming. The transactions you construct and issue can have a huge impact on the performance of SQL Server and the consistency of your databases. This chapter looks at the methods for defining and managing transactions in SQL Server 2008.

What's New in Transaction Management

Not much has really changed in SQL Server 2008 related to transactions, transaction logging, and transaction management. About the only real change is the removal of the `WITH TRUNCATE_ONLY` and `WITH NO_LOG` options from the `BACKUP LOG` command. These options are no longer available in SQL Server 2008 to prune the transaction log. The alternative is to switch the database to simple recovery model.

What Is a Transaction?

A *transaction* is one or more SQL statements that must be completed as a whole or, in other words, as a single logical unit of work. Transactions provide a way of collecting and associating multiple actions into a single all-or-nothing multiple-operation action. All operations within the transaction must be fully completed or not performed at all.

Consider a bank transaction in which you move \$1,000 from your checking account to your savings account. This

IN THIS CHAPTER

- ▶ What's New in Transaction Management
- ▶ What Is a Transaction?
- ▶ How SQL Server Manages Transactions
- ▶ Defining Transactions
- ▶ Transactions and Batches
- ▶ Transactions and Stored Procedures
- ▶ Transactions and Triggers
- ▶ Transactions and Locking
- ▶ Coding Effective Transactions
- ▶ Transaction Logging and the Recovery Process
- ▶ Long-Running Transactions
- ▶ Bound Connections
- ▶ Distributed Transactions

transaction is, in fact, *two* operations: a decrement of your checking account and an increment of your savings account. Consider the impact on your finances if the bank's server went down after it completed the first step and never got to the second! When the two operations are combined, as a transaction, they either both succeed or both fail as a single, complete unit of work.

A transaction is a logical unit of work that has four special characteristics, known as the ACID properties:

- ▶ **Atomicity**—Associated modifications are an all-or-nothing proposition; either all are done or none are done.
- ▶ **Consistency**—After a transaction finishes, all data is in the state it should be in, all internal structures are correct, and everything accurately reflects the transaction that has occurred.
- ▶ **Isolation**—One transaction cannot interfere with the processes of another transaction.
- ▶ **Durability**—After the transaction has finished, all changes made are permanent.

The responsibility for enforcing the ACID properties of a transaction is split between T-SQL developers and SQL Server. The developers are responsible for ensuring that the modifications are correctly collected together and that the data is going to be left in a consistent state that corresponds with the actions being taken. SQL Server ensures that the transaction is isolated and durable, undertakes the atomicity requested, and ensures the consistency of the final data structures. The transaction log of each database provides the durability for the transaction. As you see in this chapter, you have some control over how SQL Server handles some of these properties.

How SQL Server Manages Transactions

SQL Server uses the database's transaction log to record the modifications that occur within the database. Each log record is labeled with a unique log sequence number (LSN), and all log entries that are part of the same transaction are linked together so that they can be easily located if the transaction needs to be undone or redone. The primary responsibility of logging is to ensure transaction durability—either ensuring that the completed changes make it to the physical database files or ensuring that any unfinished transactions are rolled back in the event of an error or a server failure.

What is logged? Obviously, the start and end of a transaction are logged, but SQL Server also logs the actual data modification, page allocations and de-allocations, and changes to indexes. SQL Server keeps track of a number of pieces of information, all with the aim of ensuring the ACID properties of the transaction.

After a transaction has been committed, it cannot be rolled back. The only way to undo a committed transaction is to write another transaction to reverse the changes made. A transaction can be rolled back before it is committed, however.

SQL Server provides transaction management for all users, using the following components:

- ▶ Transaction-control statements to define the logical units of work
- ▶ A write-ahead transaction log
- ▶ An automatic recovery process
- ▶ Data-locking mechanisms to ensure consistency and transaction isolation

Defining Transactions

You can carry out transaction processing with Microsoft SQL Server in three ways:

- ▶ **AutoCommit**—Every T-SQL statement is its own transaction and automatically commits when it finishes. This is the default mode in which SQL Server operates.
- ▶ **Explicit**—This approach provides programmatic control of the transaction, using the `BEGIN TRAN` and `COMMIT/ROLLBACK TRAN/WORK` commands.
- ▶ **Implicit**—In this mode, when you issue certain SQL commands, SQL Server automatically starts a transaction. You must finish the transaction by explicitly issuing the `COMMIT/ROLLBACK TRAN/WORK` commands.

Each of these methods is discussed in the following sections.

NOTE

The terms for explicit and implicit transactions can be somewhat confusing. The way to keep them straight is to think of how a multistatement transaction is initiated, not how it is completed. AutoCommit transactions are in a separate category because they are both implicitly started and committed.

Implicit and explicit transactions have to be explicitly ended, but explicit transactions must also be explicitly started with the `BEGIN TRAN` statement, whereas no `BEGIN TRAN` is necessary to start a multistatement transaction when in implicit transaction mode.

AutoCommit Transactions

AutoCommit is the default transaction mode for SQL Server. Each individual T-SQL command automatically commits or rolls back its work at the end of its execution. Each SQL statement is considered to be its own transaction, with begin and end control points implied. Following is an example:

```
[implied begin transaction]
UPDATE account
    SET balance = balance + 1000
    WHERE account_no = "123456789"
[implied commit or rollback transaction]
```

If an error is present in the execution of the statement, the action is undone (that is, rolled back); if no errors occur, the action is completed, and the changes are saved.

Now let's consider the banking transaction mentioned at the beginning of this chapter that involved moving money from a savings account to a checking account. Assume that it is written as follows in T-SQL:

```
declare @checking_account char(10),
        @savings_account char(10)
select @checking_account = '0003456321',
       @savings_account = '0003456322'
update account
    set balance = balance - $1000
    where account_number = @checking_account
update savings_account
    set balance = balance + $1000
    where account_number = @savings_account
```

What would happen if an error occurred in updating the savings account? With AutoCommit, each statement is implicitly committed after it completes successfully, so the update for the checking account has already been committed. You would have no way of rolling it back except to write another separate update to add the \$1,000 back to the account. If the system crashed during the updates, how would you know which updates, if any, completed, and whether you need to undo any of the changes because the subsequent commands were not executed? You would need some way to group the two commands together as a single logical unit of work so they can complete or fail as a whole. SQL Server provides transaction control statements that allow you to explicitly create multistatement user-defined transactions.

Explicit User-Defined Transactions

To have complete control of a transaction and define logical units of work that consist of multiple data modifications, you need to write explicit user-defined transactions. Any SQL Server user can make use of the transaction control statements; no special privileges are required.

To start a multistatement transaction, use the `BEGIN TRAN` command, which optionally takes a transaction name:

```
BEGIN TRAN[SACTION] [transaction_name] [WITH MARK ['description']]
```

The transaction name is essentially meaningless as far as transaction management is concerned, and if transactions are nested (which is discussed later in this chapter), the name is useful only for the outermost `BEGIN TRAN` statement. Rolling back to any other name, besides a savepoint name (savepoints are covered in the next section), generates an error message similar to the following error message and does not roll back the transaction:

Msg 6401, Level 16, State 1, Line 5

Cannot roll back t2. No transaction or savepoint of that name was found.

Naming transactions is really useful only when you use the `WITH MARK` option. If the `WITH MARK` option is specified, a transaction name must be specified. `WITH MARK` allows for restoring a transaction log backup to a named mark in the transaction log. (For more information on restoring database and log backups, see Chapter 14, “Database Backup and Restore.”) This option allows you to restore a database to a known state or to recover a set of related databases to a consistent state. However, you need to be aware that `BEGIN TRAN` records are written to the log only if an actual data modification occurs within the transaction.

You complete an explicit transaction by issuing either a `COMMIT TRAN` or `COMMIT [WORK]` statement, and you can undo an explicit transaction by using either `ROLLBACK TRAN` or `ROLLBACK [WORK]`. The syntax of these commands is as follows:

```
COMMIT [TRAN[SACTION] [transaction_name]] | [WORK]
```

```
ROLLBACK [TRAN[SACTION] [transaction_name | savepointname]] | [WORK]
```

The `COMMIT` statement marks the successful conclusion of a transaction. This statement can be coded as `COMMIT`, `COMMIT WORK`, or `COMMIT TRAN`. The only difference is that the first two versions are SQL-92 ANSI compliant.

The `ROLLBACK` statement unconditionally undoes all work done within the transaction. This statement can also be coded as `ROLLBACK`, `ROLLBACK WORK`, or `ROLLBACK TRAN`. The first two commands are ANSI-92 SQL compliant and do not accept user-defined transaction names. `ROLLBACK TRAN` is required if you want to roll back to a savepoint within a transaction.

The following example shows how you could code the previously mentioned banking example as a single transaction in SQL Server:

```
declare @checking_account char(10),
        @savings_account char(10)
select @checking_account = '0003456321',
       @savings_account = '0003456322'
begin tran
update account
  set balance = balance - $1000
  where account_number = @checking_account
if @@error != 0
begin
  rollback tran
  return
end
update savings_account
  set balance = balance + $1000
  where account_number = @savings_account
if @@error != 0
```

```

begin
    rollback tran
    return
end
commit tran

```

Certain commands cannot be specified within a user-defined transaction, primarily because they cannot be effectively rolled back in the event of a failure. In most cases, because of their long-running nature, you would not want them to be specified within a transaction anyway. Following are the commands you cannot specify in a user-defined transaction:

```

ALTER DATABASE
ALTER FULLTEXT CATALOG
ALTER FULLTEXT INDEX
BACKUP DATABASE
BACKUP LOG
CREATE DATABASE
CREATE FULLTEXT CATALOG
CREATE FULLTEXT INDEX
DROP DATABASE
DROP FULLTEXT CATALOG
DROP FULLTEXT INDEX
RESTORE DATABASE
RECONFIGURE
RESTORE LOG
UPDATE STATISTICS

```

Savepoints

A savepoint allows you to set a marker in a transaction that you can roll back to undo a portion of the transaction but commit the remainder of the transaction. The syntax is as follows:

```
SAVE TRAN[SACTION] savepointname
```

Savepoints are not ANSI-SQL 92 compliant, so you must use the SQL Server-specific transaction management commands that allow you to specify a named point within the transaction and then recover back to it.

The following code illustrates the differences between the two types of syntax when using the `SAVE TRAN` command:

SQL-92 Syntax

```

BEGIN TRAN mywork
  UPDATE table1...
  SAVE TRAN savepoint1
  INSERT INTO table2...
  DELETE table3...
  IF @@error = -1
    ROLLBACK WORK
COMMIT WORK

```

SQL Server–Specific Syntax

```

BEGIN TRAN mywork
  UPDATE table1...
  SAVE TRAN savepoint1
  INSERT INTO table2...
  DELETE table3...
  IF @@error = -1
    ROLLBACK TRAN savepoint1
COMMIT TRAN

```

Note the difference between the SQL-92 syntax on the left and the SQL Server–specific syntax on the right. In the SQL-92 syntax, when you reach the `ROLLBACK WORK` command, the *entire* transaction is undone rather than undoing only to the point marked by the savepoint. You have to use the SQL Server–specific `ROLLBACK TRAN` command and specify the savepoint name to roll back the work to the savepoint and still be able to subsequently roll back or commit the rest of the transaction.

Nested Transactions

As a rule, you can't have more than one active transaction per user session within SQL Server. However, suppose you have a SQL batch that issues a `BEGIN TRAN` statement and then subsequently invokes a stored procedure, which also issues a `BEGIN TRAN` statement. Because you can have only one transaction active, what does the `BEGIN TRAN` inside the stored procedure accomplish? In SQL Server, this leads to an interesting anomaly referred to as *nested transactions*.

To determine whether transactions are open and how deep they are nested within a connection, you can use the global function `@@trancount`. If no transaction is active, the transaction nesting level is `0`. As a transaction is initiated, the transaction nesting level is incremented; as a transaction completes, the transaction nesting is decremented. The overall transaction remains open and can be entirely rolled back until the transaction nesting level returns to `0`.

You can use the `@@trancount` function to monitor the current status of a transaction. For example, what would SQL Server do when encountering the following transaction (which produces an error because of the reference constraint on the `titles` table)?

```

use BIGPUBS2008
go
BEGIN TRAN
  DELETE FROM publishers
  WHERE pub_id = '0736'
go

```

```

Msg 547, Level 16, State 0, Line 2
The DELETE statement conflicted with the REFERENCE constraint
"FK_pub_info_pub_id_2BDE8E15". The conflict occurred in database
"bigpubs2008", table "dbo.pub_info", column 'pub_id'.
The statement has been terminated.

```

Is the transaction still active? You can find out by using the @@trancount function:

```
select @@trancount
go
```

```
-----
          1
```

In this case, @@trancount returns a value of 1, which indicates that the transaction is still open and in progress. This means that you can still issue commands within the transaction and commit the changes, or you can roll back the transaction. Also, if you were to log out of the user session from SQL Server before the transaction nesting level reached 0, SQL Server would automatically roll back the transaction.

Although nothing prevents you from coding a BEGIN TRAN within another BEGIN TRAN, doing so has no real benefit, even though such cases might occur. However, if you nest transactions in this manner, you must execute a COMMIT statement for each BEGIN TRAN statement issued. The reason is that SQL Server modifies the @@trancount with each transaction statement and considers the transaction finished only when the transaction nesting level returns to 0. Table 31.1 shows the effects that transaction control statements have on @@trancount.

TABLE 31.1 Transaction Statements' Effects on @@trancount

Statement	Effect on @@trancount
BEGIN TRAN	+1
COMMIT	-1
ROLLBACK	Sets to 0
SAVE TRAN <i>savepoint</i>	No effect
ROLLBACK TRAN <i>savepoint</i>	No effect

Following is a summary of how transactional control relates to the values reported by:

- ▶ When you log in to SQL Server, the value of @@trancount for your session is initially 0.
- ▶ Each time you execute begin transaction, SQL Server increments @@trancount.
- ▶ Each time you execute commit transaction, SQL Server decrements @@trancount.
- ▶ Actual work is committed only when @@trancount reaches 0 again.
- ▶ When you execute ROLLBACK TRANSACTION, the transaction is canceled and @@trancount returns to 0. Notice that ROLLBACK TRANSACTION cuts straight through

any number of nested transactions, canceling the overall main transaction. This means that you need to be careful how you write code that contains a ROLLBACK statement. You need to be sure to check for the return status up through all levels and exit accordingly so you don't continue executing data modifications that were meant to be part of the larger overall transaction.

- ▶ Setting savepoints and rolling back to a savepoint do not affect @@trancount or transaction nesting in any way.
- ▶ If a user connection is lost for any reason when @@trancount is greater than 0, any pending work for that connection is automatically rolled back. SQL Server requires that multistatement transactions be explicitly committed.
- ▶ Because the BEGIN TRAN statement increments @@trancount, each BEGIN TRAN statement must be paired with a COMMIT for the transaction to complete successfully.

Let's look at some sample code to see the values of @@trancount as the transaction progresses. This first example is a simple explicit transaction with a nested BEGIN TRAN:

SQL Statement	@@trancount Value
SELECT "Starting...."	0
BEGIN TRAN	1
DELETE FROM table1	1
BEGIN TRAN	2
INSERT INTO table2	2
COMMIT	1
UPDATE table3	1
COMMIT	0

Transactions are nested *syntactically only*. The only commit tran statement that has an impact on real data is the last one, the statement that returns @@trancount to 0. That statement fully commits the work done by the initial and nested transactions. Until that final COMMIT TRAN is encountered, all the work can be rolled back with a ROLLBACK statement.

As a general rule of thumb, if a transaction is already active, you shouldn't issue another BEGIN TRAN statement. You should check the value of @@trancount to determine whether a transaction is already active. If you want to be able to roll back the work performed within a nested transaction without rolling back the entire transaction, you can set a savepoint instead of issuing a BEGIN TRAN statement. Later in this chapter, you see an example showing how to check @@trancount within a stored procedure to determine whether the stored procedure is being invoked within a transaction and then issue a BEGIN TRAN or SAVE TRAN, as appropriate.

Implicit Transactions

AutoCommit transactions and explicit user-defined transactions, which are the default transaction mode in SQL Server 2008, are not ANSI-92 SQL compliant. The ANSI-92 SQL standard states that any data retrieval or modification statement issued should implicitly

begin a multistatement transaction that remains in effect until an explicit ROLLBACK or COMMIT statement is issued. Microsoft refers to this transaction mode as IMPLICIT_TRANSACTIONS.

To enable implicit transactions for a connection in SQL Server 2008, you need to enable the IMPLICIT_TRANSACTIONS session setting using the following command:

```
SET IMPLICIT_TRANSACTIONS ON
```

After this option is turned on, transactions are implicitly started, if they are not already in progress, whenever any of the following commands are executed:

```
ALTER TABLE
CREATE
DELETE
DROP
FETCH
GRANT
INSERT
OPEN
REVOKE
SELECT
TRUNCATE TABLE
UPDATE
```

Note that neither the ALTER VIEW nor ALTER PROCEDURE statement starts an implicit transaction.

You must explicitly complete implicit transactions by issuing a COMMIT or ROLLBACK; a new transaction is started again on the execution of any of the preceding commands. If you plan to use implicit transactions, the main issue to be aware of is that locks are held until you explicitly commit the transaction. This can cause problems with concurrency and the system's capability to truncate the transaction log.

Even when using implicit transactions, you can still issue the BEGIN TRAN statement and create transaction nesting. In the following example, IMPLICIT_TRANSACTIONS ON is turned on to see the effect this has on the value of @@trancount.

SQL Statements	@@trancount Value
SET IMPLICIT_TRANSACTIONS ON	0
go	0
INSERT INTO table1	1
UPDATE table2	1
COMMIT	0

```

go
SELECT * FROM table1          1
BEGIN TRAN                    2
DELETE FROM table1           2
COMMIT                        1
go
DROP TABLE table1           1
COMMIT                        0

```

As you can see in this example, if a `BEGIN TRAN` is issued while a transaction is still active, transaction nesting occurs, and a second `COMMIT` is required to finish the transaction. The main difference between this example and the preceding one is that here, a `BEGIN TRAN` is *not* required to start the transaction. The first `INSERT` statement initiates the transaction. When you are running in implicit transaction mode, you don't need to issue a `BEGIN TRAN` statement; in fact, you should avoid doing so to prevent transaction nesting and the need for multiple commits.

The following example shows the previous banking transaction using implicit transactions:

```

set implicit_transactions on
go

declare @checking_account char(10),
        @savings_account char(10)
select @checking_account = '0003456321',
       @savings_account = '0003456322'
update account
   set balance = balance - $1000
   where account_number = @checking_account
if @@error != 0
begin
   rollback
   return
end
update savings_account
   set balance = balance + $1000
   where account_number = @savings_account
if @@error != 0
begin
   rollback

```

```

return
end
commit

```

This example is nearly identical to the explicit transaction example except for the lack of a `BEGIN TRAN` statement. In addition, when in implicit transaction mode, you cannot roll back to a named transaction because no name is assigned when the transaction is invoked implicitly. You can, however, still set savepoints and roll back to savepoints to partially roll back work within an implicit transaction.

TIP

If you need to know within your SQL code whether implicit transactions are enabled so you can avoid issuing explicit `BEGIN TRAN` statements, you can check the `@@options` function. `@@options` returns a bitmap that indicates which session-level options are enabled for the current session. If bit 2 is on, implicit transactions are enabled. The following code snippet can be used in stored procedures or SQL batches to check this value and decide whether to issue a `BEGIN TRAN` statement:

```

if @@options & 2 != 2 — if bit 2 is not turned on
    BEGIN TRAN —a begin tran can be issued since implicit transactions
are off
...

```

Implicit Transactions Versus Explicit Transactions

When would you want to use implicit transactions versus explicit transactions? If you are porting an application from another database environment, such as DB2 or Oracle, that uses implicit transactions, that application converts over to SQL Server more easily and with fewer code changes if you run in implicit transaction mode. Also, if the application you are developing needs to be ANSI compliant and run across multiple database platforms with minimal code changes, you might want to use implicit transactions.

If you use implicit transactions in your applications, you need to be sure to issue `COMMIT` statements as frequently as possible to prevent leaving transactions open and holding locks for an extended period of time, which can have an adverse impact on concurrency and overall system performance.

If an application is going to be hosted only on SQL Server, it is recommended that you use `AutoCommit` and explicit transactions so that changes are committed as quickly as possible and so that only those logical units of work that are explicitly defined contain multiple commands within a transaction.

Transactions and Batches

There is no inherent transactional quality to batches. As you have seen already, unless you provide the syntax to define a single transaction made up of several statements, each individual statement in a batch is its own separate transaction, and each statement is carried to completion or fails individually.

The failure of a transaction within a batch does not cause the batch to stop processing. In other words, transaction flow does not affect process flow. After a `ROLLBACK TRAN` statement, processing continues with the next statement in the batch or stored procedure. For this reason, you should be sure to check for error conditions after each data modification within a transaction and exit the batch or stored procedure, as appropriate.

Consider the banking transaction again, this time removing the `RETURN` statements:

```
declare @checking_account char(10),
        @savings_account char(10)
select @checking_account = '0003456321',
       @savings_account = '0003456322'
begin tran
update account
    set balance = balance - $1000
    where account_number = @checking_account
if @@error != 0
    rollback tran
update savings_account
    set balance = balance + $1000
    where account_number = @savings_account
if @@error != 0
    rollback tran
commit tran
```

Assume that a check constraint on the account prevents the balance from being set to a value less than 0. If the checking account has less than \$1,000 in it, the first update fails, and the T-SQL code catches the error condition and rolls back the transaction. At this point, the transaction is no longer active, but the batch still contains additional statements to execute. Without a return after the rollback, SQL Server continues with the next statement in the batch, which in this case is the update to the savings account. However, this now executes as its own separate transaction, and it automatically commits if it completes successfully. This is not the result you want because now that second update is its own separate unit of work, so you have no way to roll it back.

The key concept to keep in mind here is that transaction flow does not affect program flow. In the event of an error within a transaction, you need to make sure you have the proper error checking and a means to exit the transaction in the event of an error. This

prevents the batch from continuing with any remaining modifications that were meant to be a part of the original transaction. As a general rule, a RETURN statement should almost always follow a rollback.

In addition to being able to define multiple transactions within a batch, you can also have transactions that span multiple batches. For example, you could write an application that begins a transaction in one batch and then asks for user verification during a second batch. The SQL might look like this:

First batch:

```
use bigpubs2008
go
begin transaction
insert publishers (pub_id, pub_name, city, state)
    values ('1111', 'Joe and Marys Books', 'Northern Plains', 'IA')
if @@error = 0
    print 'publishers insert was successful. Please go on.'
else
    print 'publisher insert failed. Please roll back'
```

Second batch:

```
update titles
    set pub_id = '1111'
    where pub_id = '1234'
delete authors
    where state = 'CA'
commit transaction
```

Writing transactions that span multiple batches is almost always a bad idea. The locking and concurrency problems can become complicated, with awful performance implications.

What if the application prompted for user input between batches, and the user went out to lunch? Locks would be held until the user got back and continued the transaction. In general, you want to enclose each transaction in a single batch, using conditional programming constructs to handle situations like the preceding example. Following is a better way to write that code:

```
begin transaction
insert publishers (pub_id, pub_name, city, state)
    values ('1111', 'Joe and Marys Books', 'Northern Plains', 'IA')
if @@error = 0
begin
    print 'publishers insert was successful. Continuing.'
    update titles
        set pub_id = '1111'
        where pub_id = '1234'
    delete authors
```

```
        where state = 'CA'  
    commit transaction  
end  
else  
begin  
    print 'publisher insert failed. rolling back transaction'  
    rollback transaction  
end
```

The important point in this example is that the transaction now takes place within a single batch for better performance and consistency. As you see in the next section, it is usually best to encode transactions in stored procedures for even better performance and to avoid the possibility of unfinished transactions.

Transactions and Stored Procedures

Because SQL code in stored procedures runs locally on the server, it is recommended that entire transactions be completely encapsulated within stored procedures to speed transaction processing. This way, the entire transaction executes within a single stored procedure call from the client application, rather than being executed across multiple requests. The less network traffic that occurs between the client application and SQL Server during transactions, the faster they can finish.

Another advantage of using stored procedures for transactions is that doing so helps you avoid the occurrence of partial transactions—that is, transactions that are started but not fully committed. Using stored procedures this way also avoids the possibility of user interaction within a transaction. The stored procedure keeps the transaction processing completely contained because it starts the transaction, carries out the data modifications, completes the transaction, and returns the status or data to the client.

Stored procedures also provide the additional benefit that if you need to fix, fine-tune, or expand the duties of the transaction, you can do all this at one time, in one central location. Your applications can share the same stored procedure, providing consistency for the logical unit of work across your applications.

Although stored procedures provide a useful solution to managing transactions, you need to know how transactions work within stored procedures and code for them appropriately. Consider what happens when one stored procedure calls another, and they both do their own transaction management. Obviously, they now need to work in concert with each other. If the called stored procedure has to roll back its work, how can it do so correctly without causing data integrity problems?

The issues you need to deal with go back to the earlier topics of transaction nesting and transaction flow versus program flow. Unlike a rollback in a trigger (see the next section), a rollback in a stored procedure does not abort the rest of the batch or the calling procedure.

For each `BEGIN TRAN` encountered in a nested procedure, the transaction nesting level is incremented by 1. For each `COMMIT` encountered, the transaction nesting level is decremented by 1. However, if a rollback other than to a named savepoint occurs in a nested procedure, it rolls back all statements to the outermost `BEGIN TRAN`, including any work performed inside the nested stored procedures that has not been fully committed. It then continues processing the remaining commands in the current procedure as well as the calling procedure(s).

To explore the issues involved, you can work with the sample stored procedure shown in Listing 31.1. The procedure takes a single integer argument, which it then attempts to insert into a table (`test_table`). All data entry attempts—whether successful or not—are logged to a second table (`auditlog`). Listing 31.1 contains the code for the stored procedure and the tables it uses.

LISTING 31.1 Sample Stored Procedure and Tables for Transaction Testing

```
CREATE TABLE test_table (col1 int)
go
CREATE TABLE auditlog (who varchar(128), valentered int null)
go
CREATE PROCEDURE trantest @arg INT
AS
BEGIN TRAN
    IF EXISTS( SELECT * FROM test_table WHERE col1 = @arg )
        BEGIN
            RAISERROR ('Value %d already exists!', 16, -1, @arg)
            ROLLBACK TRANSACTION
        END
    ELSE
        BEGIN
            INSERT INTO test_table (col1) VALUES (@arg)
            COMMIT TRAN
        END
END

INSERT INTO auditlog (who, valentered) VALUES (USER_NAME(), @arg)
return
```

Now explore what happens if you call this stored procedure in the following way and check the values of the two tables:

```
set nocount on
EXEC trantest 1
EXEC trantest 2
SELECT * FROM test_table
SELECT valentered FROM auditlog
go
```

The execution of this code gives the following results:

```
col1
-----
1
2

valentered
-----
1
2
```

These would be the results you would expect because no errors would occur, and nothing would be rolled back.

Now, if you were to run the same code a second time, `test_table` would still have only two rows because the procedure would roll back the attempted insert of the duplicate rows. However, because the procedure and batch are not aborted, the code would continue processing, and the rows would still be added to the `auditlog` table. The result would be as follows:

```
set nocount on
EXEC trantest 1
EXEC trantest 2
SELECT * FROM test_table
SELECT valentered FROM auditlog
go
```

```
Msg 50000, Level 16, State 1, Procedure trantest, Line 6
Value 1 already exists!
```

```
Msg 50000, Level 16, State 1, Procedure trantest, Line 6
Value 2 already exists!
```

```
col1
-----
1
2

valentered
-----
1
2
1
2
```

Now explore what happens when you execute the stored procedure from within a transaction:

```
set nocount on
BEGIN TRAN
EXEC trantest 3
EXEC trantest 1
EXEC trantest 4
COMMIT TRAN
SELECT * FROM test_table
SELECT valentered FROM auditlog
go
```

The execution of this code gives the following results:

```
Msg 50000, Level 16, State 1, Procedure trantest, Line 6
Value 1 already exists!
```

```
Msg 266, Level 16, State 2, Procedure trantest, Line 0
Transaction count after EXECUTE indicates that a COMMIT or ROLLBACK TRANSACTION
statement is missing. Previous count = 1, current count = 0.
```

```
Msg 3902, Level 16, State 1, Line 6
The COMMIT TRANSACTION request has no corresponding BEGIN TRANSACTION.
```

```
col1
-----
1
2
4

valentered
-----
1
2
1
2
1
4
```

A number of problems are occurring now. For starters, you get a message telling you that the transaction nesting level was messed up. More seriously, the results show that the value 4 made it into the `test_table` table anyway and that the `auditlog` table picked up the inserts of 1 and the 4 but lost the fact that you tried to insert a value of 3. What happened?

Let's examine this example one step at a time. First, you start the transaction and insert the value 3 into `trantest`. The stored procedure starts its own transaction, adds the value to `test_table`, commits that, and then adds a row to `auditlog`. Next, you execute the procedure with the value 1. This value already exists in the table, so the procedure raises an error and rolls back the transaction. Remember that a `ROLLBACK` undoes work to the outermost `BEGIN TRAN`—which means the start of this batch. This rolls back everything, including the insert of 3 into `trantest` and `auditlog`. The `auditlog` entry for the value 1 is inserted and not rolled back because it occurred after the transaction was rolled back and is a standalone, automatically committed statement now.

You then receive an error regarding the change in the transaction nesting level because a transaction should leave the state of a governing procedure in the same way it was entered; it should make no net change to the transaction nesting level. In other words, the value of `@@trancount` should be the same when the procedure exits as when it was entered. If it is not, the transaction control statements are not properly balanced.

Also, because the batch is not aborted, the value 4 is inserted into `trantest`, an operation that completes successfully and is automatically committed. Finally, when you try to commit the transaction, you receive the last error regarding a mismatch between `BEGIN TRAN` and `COMMIT TRAN` because no transaction is currently in operation.

The solution to this problem is to write the stored procedures so that transaction nesting doesn't occur and so the stored procedure rolls back only its own work. When a rollback occurs, it should return an error status so that the calling batch or procedure is aware of the error condition and can choose to continue or abort the work at that level. You can manage this by checking the current value of `@@trancount` and determining what needs to be done. If a transaction is already active, the stored procedure should not issue a `BEGIN TRAN` and nest the transaction; rather, it should set a savepoint. This allows the procedure to perform a partial rollback of its work. If no transaction is active, the procedure can safely begin a new transaction. The following SQL code fragment is an example of using this approach:

```
DECLARE @trancount INT
/* Capture the value of the transaction nesting level at the start */
SELECT @trancount = @@trancount
IF (@trancount = 0) — no transaction is currently active, start one
    BEGIN TRAN mytran
ELSE — a transaction is active, set a savepoint only
    SAVE TRAN mytran
.
.
/* This is how to trap an error. Roll back either to your
own BEGIN TRAN or roll back to the savepoint. Return an
error code to the caller to indicate an internal failure.
How the caller handles the transaction is up to the caller.*/
```

```

IF (@@error <> 0)
BEGIN
    ROLLBACK TRAN mytran
    RETURN -1969
END
.
.
/* Once you reach the end of the code, you need to pair the BEGIN TRAN,
   if you issued it, with a COMMIT TRAN. If you executed the SAVE TRAN
   instead, you have nothing else to do...end of game! */
IF (@trancount = 0)
    COMMIT TRAN

RETURN 0

```

If you apply these concepts to all stored procedures that need to incorporate transaction processing as well as the code that calls the stored procedures, you should be able to avoid problems with transaction nesting and inconsistency in your transaction processing. You just need to be sure to check the return value of the stored procedure and determine whether the whole batch should be failed or whether that one call is of little importance to the overall outcome and the transaction can continue.

For additional examples of and discussion about coding guidelines for stored procedures in transactions, see Chapter 44, “Advanced Stored Procedure Programming and Optimization.”

Transactions and Triggers

SQL Server 2008 provides two types of Data Manipulation Language (DML) triggers: `AFTER` and `INSTEAD OF`. `INSTEAD OF` triggers perform their actions before any modifications are made to the actual table the trigger is defined on.

Whenever a trigger is invoked, it is *always* invoked within another transaction, whether it’s a single-statement `AutoCommit` transaction or a user-defined multistatement transaction. This is true for both `AFTER` triggers and `INSTEAD OF` triggers. Even though an `INSTEAD OF` trigger fires before, or “instead of,” the data modification statement itself, if a transaction is not already active, an `AutoCommit` transaction is still automatically initiated as the data modification statement is invoked and prior to the invocation of the `INSTEAD OF` trigger. (For more information on `AFTER` and `INSTEAD OF` triggers, see Chapter 30, “Creating and Managing Triggers.”)

NOTE

Although the information presented in this section applies to both `AFTER` and `INSTEAD OF` triggers, the examples presented pertain primarily to `AFTER` triggers.

Because the trigger is already operating within the context of a transaction, the only transaction control statements you should ever consider using in a trigger are `ROLLBACK` and

SAVE TRAN. You don't need to issue a BEGIN TRAN because a transaction is already active; a BEGIN TRAN would only serve to increase the transaction nesting level, and that would complicate things further.

Triggers and Transaction Nesting

To demonstrate the relationship between a trigger and the transaction nesting level, you can use the following SQL code to create a trigger on the employee table:

```
use bigpubs2008
go
CREATE TRIGGER tD_employee ON employee
FOR DELETE
AS
    DECLARE @msg VARCHAR(255)

    SELECT @msg = 'Trancount in trigger = ' + CONVERT(VARCHAR(2), @@trancount)

    PRINT @msg

    RETURN
go
```

The purpose of this trigger is simply to show the state of the @@trancount within the trigger as the deletion is taking place.

If you now execute code for implied and explicit transactions, you can see the values of @@trancount and behavior of the batch. First, here's the implied transaction:

```
set nocount on
print 'Trancount before delete = ' + CONVERT(VARCHAR(2), @@trancount)
DELETE FROM employee WHERE emp_id = 'PMA42628M'
print 'Trancount after delete = ' + CONVERT( VARCHAR(2), @@trancount)
go
```

The results of this are as follows:

```
Trancount before delete = 0
Trancount in trigger = 1
Trancount after delete = 0
```

Because no transaction starts until the DELETE statement executes, the first value of @@trancount indicates this with a value of 0. Within the trigger, the transaction count has a value of 1; you are now inside the implied transaction caused by the DELETE. After the trigger returns, the DELETE is automatically committed, the transaction is finished, and @@trancount returns to 0 to indicate that no transaction is currently active.

Now explore what happens within an explicit transaction:

```

begin tran
print 'Trancount before delete = ' + CONVERT(VARCHAR(2), @@trancount)
DELETE FROM employee WHERE emp_id = 'PMA42628M'
print 'Trancount after delete = ' + CONVERT( VARCHAR(2), @@trancount)
commit tran
print 'Trancount after commit = ' + CONVERT( VARCHAR(2), @@trancount)
go

```

This code gives the following results:

```

Trancount before delete = 1
Trancount in trigger = 1
Trancount after delete = 1
Trancount after commit = 0

```

In this example, a transaction is already active when the DELETE is executed. The BEGIN TRAN statement initiates the transaction, and @@trancount is 1 before the DELETE is executed. The trigger becomes a part of that transaction, which is not committed until the COMMIT TRAN statement is executed.

What would happen, however, if the trigger performed a rollback? You can find out by modifying the trigger to perform a rollback as follows:

```

ALTER TRIGGER tD_employee ON employee
FOR DELETE
AS
print 'Trancount in trigger = ' + CONVERT(VARCHAR(2), @@trancount)

ROLLBACK TRAN

return

```

Now rerun the previous batch. The outcome this time is as follows:

```

Trancount before delete = 1
Trancount in trigger = 1
Msg 3609, Level 16, State 1, Line 3
The transaction ended in the trigger. The batch has been aborted.

```

Notice in this example that the batch did not complete, as evidenced by the missing output from the last two print statements. When a rollback occurs within a trigger, SQL Server aborts the current transaction, continues processing the commands in the trigger, and after the trigger returns, aborts the rest of the batch and returns error message 3609 to indicate that the batch has been aborted because the transaction ended within the trigger. A ROLLBACK TRAN statement in a trigger rolls back all work to the first BEGIN TRAN statement. It is not possible to roll back to a specific named transaction, although you can roll back to a named savepoint, as discussed later in this section.

Again, the batch and transaction are aborted when the trigger rolls back; any subsequent statements in the batch are not executed. The key concept to remember is that the trigger becomes an integral part of the statement that fired it and of the transaction in which that statement occurs.

It is important to note, however, that although the batch is aborted immediately after the trigger that performed a rollback returns, any statements within the trigger that follow the `ROLLBACK TRAN` statement but before it returns are executed. For example, you can modify the previous trigger further to include a print statement after the `ROLLBACK TRAN` statement:

```
ALTER TRIGGER tD_employee ON employee
FOR DELETE
AS
print 'Trancount in trigger = ' + CONVERT(VARCHAR(2), @@trancount)

ROLLBACK TRAN

print 'Trancount in trigger after rollback = ' + CONVERT(VARCHAR(2), @@trancount)

return
```

Now, if you rerun the previous batch, you can see the print statement after the `ROLLBACK TRAN` but before the `RETURN` statement is executed:

```
Trancount before delete = 1
Trancount in trigger = 1
Trancount in trigger after rollback = 0
Msg 3609, Level 16, State 1, Line 3
The transaction ended in the trigger. The batch has been aborted.
```

Notice that the Trancount after the `ROLLBACK TRAN` in the trigger is now 0. If the trigger subsequently performed any data modifications following the `ROLLBACK TRAN`, they would now be running as AutoCommit transactions. For this reason, you must be sure to issue a `RETURN` statement to exit the trigger after a `ROLLBACK TRAN` is issued to avoid the trigger performing any operations that would then be automatically committing, leaving no opportunity to roll them back.

Triggers and Multistatement Transactions

Now let's look at another example. First, you need to create a trigger to enforce referential integrity between the `titles` table and `publishers` table:

```
--The first statement is used to disable any previously created
--DDL triggers in the database which would prevent creating a new trigger.
```

```

DISABLE TRIGGER ALL ON titles
go
create trigger tr_titles_i on titles for insert as
declare @rows int -- create variable to hold @@rowcount
select @rows = @@rowcount
if @rows = 0 return
if update(pub_id) and (select count(*)
    from inserted i, publishers p
    where p.pub_id = i.pub_id ) != @rows
begin
    rollback transaction
    raiserror ('Invalid pub_id inserted', 16, 1)
end
return
go

```

Next, for the trigger to take care of the referential integrity, you might first need to disable the foreign key constraint on the `titles` table with a command similar to the following:

```
alter table titles nocheck constraint FK__titles__pub_id__0F424F67
```

NOTE

The system-generated name for the foreign key constraint may possibly be different on your database. You can use `sp_helpconstraint titles` to verify the name of the foreign key constraint on the `pub_id` column of the `titles` table and use it in place of the constraint name specified in this example.

Now, run a multistatement transaction with an invalid `pub_id` in the second insert statement:

```

/* transaction inserts rows into a table */
begin tran add_titles
insert titles (title_id, pub_id, title)
    values ('XX1234', '0736', 'Tuning SQL Server')
insert titles (title_id, pub_id, title)
    values ('XX1235', 'abcd', 'Tuning SQL Server')
insert titles (title_id, pub_id, title)
    values ('XX1236', '0877', 'Tuning SQL Server')
commit tran
go

```

```

Msg 50000, Level 16, State 1, Procedure tr_titles_i, Line 10
Invalid pub_id inserted
Msg 3609, Level 16, State 1, Line 4
The transaction ended in the trigger. The batch has been aborted.

```

How many rows are inserted if 'abcd' is an invalid `pub_id`? In this example, no rows are inserted because the `ROLLBACK TRAN` in the trigger rolls back all modifications made by the trigger, including the insert with the bad `pub_id` and all statements preceding it within the transaction. After the `RETURN` statement is encountered in the trigger, the rest of the batch is aborted.

CAUTION

You should never issue a `BEGIN TRAN` statement in a trigger because a transaction is already active at the time the trigger is executed. Rolling back to a named transaction in a trigger is illegal and generates a runtime error, rolling back the transaction and immediately terminating processing of the trigger and batch. The only transaction control statements you should ever consider including in a trigger are `ROLLBACK TRAN` and `SAVE TRAN`.

Using Savepoints in Triggers

Although `BEGIN TRAN` statements are not recommended within a trigger, you can set a savepoint in a trigger and roll back to the savepoint. This technique rolls back only the operations within the trigger subsequent to the savepoint. The trigger and transaction it is a part of are still active until the transaction is subsequently committed or rolled back. The batch continues processing.

Savepoints can be used to avoid a trigger's arbitrarily rolling back an entire transaction. You can roll back to the named savepoint in the trigger and then issue a `raiserror` and return immediately to pass the error code back to the calling process. The calling process can then check the error status of the data modification statement and take appropriate action, either rolling back the transaction, rolling back to a savepoint in the transaction, or ignoring the error and committing the data modification.

The following example shows a trigger that uses a savepoint:

```
alter trigger tr_titles_i on titles for insert as
declare @rows int -- create variable to hold @@rowcount
select @rows = @@rowcount
if @rows = 0 return
save tran titlestrig
if update(pub_id) and (select count(*)
    from inserted i, publishers p
    where p.pub_id = i.pub_id ) != @rows
begin
    rollback transaction titlestrig
    raiserror ('Invalid pub_id inserted', 16, 1)
end
return
```

This trigger rolls back all work since the savepoint and returns an error number of 50000. In the transaction, you can check for the error number and make the decision about whether to continue the transaction, roll back the transaction, or, if savepoints were set in the transaction, roll back to a savepoint and let the transaction continue. The following example rolls back the entire transaction if either of the first two inserts fail, but it rolls back to the named savepoint only if the third insert fails, allowing the first two to be committed:

```
begin tran add_titles
insert titles (title_id, pub_id, title)
    values ('XX1234', '0736', 'Tuning SQL Server')
if @@error = 50000 — roll back entire transaction and abort batch
    begin
        rollback tran add_titles
        return
    end
insert titles (title_id, pub_id, title)
    values ('XX1236', '0877', 'Tuning SQL Server')
if @@error = 50000 — roll back entire transaction and abort batch
    begin
        rollback tran add_titles
        return
    end
save tran keep_first_two — set savepoint for partial rollback
insert titles (title_id, pub_id, title)
    values ('XX1235', 'abcd', 'Tuning SQL Server')
if @@error = 50000 — roll back to save point, continue batch
    begin
        rollback tran keep_first_two
    end
commit tran
```

TIP

When you use a savepoint inside a trigger, the trigger does not roll back the transaction. Therefore, the batch is not automatically aborted. You must explicitly return from the batch after rolling back the transaction to prevent subsequent statements from executing.

NOTE

Don't forget to reenable the constraint on the titles table when you are finished testing:

```
alter table titles check constraint FK_titles__pub_id__0F424F67
```

Transactions and Locking

SQL Server issues and holds on to locks for the duration of a transaction to ensure the isolation and consistency of the modifications. Data modifications that occur within a transaction acquire exclusive locks, which are then held until the completion of the transaction. Shared locks, or read locks, are held for only as long as the statement needs them; usually, a shared lock is released as soon as data has been read from the resource (for example, row, page, table). You can modify the length of time a shared lock is held by using keywords such as `HOLDLOCK` in a query or setting the `REPEATABLE_READ` or `SERIALIZABLE` lock isolation levels. If one of these options is specified, shared locks are held until the completion of the transaction.

What this means for you as a database application developer is that you should try to hold on to as few locks or as small a lock as possible for as short a time as possible to avoid locking contention between applications and to improve concurrency and application performance. The simple rule when working with transactions is to keep them short and keep them simple. In other words, you should do what you need to do in the most concise manner, in the shortest possible time. You should keep any extraneous commands that do not need to be part of the logical unit of work—such as `SELECT` statements, commands for dropping temporary tables, commands for setting up local variables, and so on—outside the transaction.

To modify the manner in which a transaction and its locks can be handled by a `SELECT` statement, you can issue the `SET TRANSACTION ISOLATION LEVEL` statement. This statement allows the query to choose how much it is protected against other transactions modifying the data being used. The `SET TRANSACTION ISOLATION LEVEL` statement has the following mutually exclusive options:

- ▶ **READ COMMITTED**—This setting is the default for SQL Server. Modifications made within a transaction are locked exclusively, and the changes cannot be viewed by other user processes until the transaction completes. Commands that read data only hold shared locks on the data for as long as they are reading it. Because other transactions are not blocked from modifying the data after you have read it within your transaction, subsequent reads of the data within the transaction might encounter *nonrepeatable reads* or *phantom data*.
- ▶ **READ UNCOMMITTED**—With this level of isolation, one transaction can read the modifications made by other transactions prior to being committed. This is, therefore, the least restrictive isolation level, but it is one that allows the reading of dirty and uncommitted data. This option has the same effect as issuing `NOLOCK` within `SELECT` statements, but it has to be set only once for your connection. This option should never be used in an application in which accuracy of the query results is required.
- ▶ **REPEATABLE READ**—When this option is set, as data is read, locks are placed and held on the data for the duration of the transaction. These locks prevent other transactions from modifying the data you have read so that you can carry out multiple passes across the same information and get the same results each time. This isolation

level is obviously more restrictive than `READ COMMITTED` and `READ UNCOMMITTED`, and it can block other transactions. However, although it prevents nonrepeatable reads, it does not prevent the addition of new rows or *phantom rows* because only *existing* data is locked.

- ▶ **SERIALIZABLE**—This option is the most restrictive isolation level because it places a range lock on the data. This prevents any modifications to the data being read from until the end of the transaction. It also avoids phantom reads by preventing rows from being added or removed from the data range set.
- ▶ **SNAPSHOT**—Snapshot isolation specifies that data read by any statement will see only data modifications that were committed before the start of the transaction. The effect is as if the statements in a transaction see a snapshot of the committed data as it existed at the start of the transaction. The `ALLOW_SNAPSHOT_ISOLATION` database option must be set to `ON` for a transaction to specify the `SNAPSHOT` isolation level.

READ_COMMITTED_SNAPSHOT Isolation

In addition to the `SNAPSHOT` isolation level, SQL Server also supports a special form of read-committed isolation, referred to as `READ_COMMITTED_SNAPSHOT`. This form of isolation is similar to snapshot isolation, but unlike snapshot isolation, which sees the version of the data at the start of the transaction, read committed snapshot queries see the version of the data at the start of the statement.

To enable the `READ_COMMITTED_SNAPSHOT` isolation level for queries, you need to enable the `READ_COMMITTED_SNAPSHOT` database option. Any queries that normally would run at the standard `READ_COMMITTED` isolation level automatically run at the `READ_COMMITTED_SNAPSHOT` isolation level, without requiring any code changes.

For more information on transaction isolation levels and their effect on lock types, locking behavior, and performance, see Chapter 37, “Locking and Performance.”

Coding Effective Transactions

Poorly written or inefficient transactions can have a detrimental effect on concurrency of access to data and overall application performance. SQL Server can hold locks on a number of resources while the transaction is open; modified rows acquire exclusive locks, and other locks might also be held, depending on the isolation level used. To reduce locking contention for resources, transactions should be kept as short and efficient as possible. During development, you might not even notice that a problem exists; the problem might become noticeable only after the system load is increased and multiple users are executing transactions simultaneously. Following are some guidelines to consider when coding transactions to minimize locking contention and improve application performance:

- ▶ Do not return result sets within a transaction. Doing so prolongs the transaction unnecessarily. Perform all data retrieval and analysis outside the transaction.

- ▶ *Never* prompt for user input during a transaction. If you do, you lose all control over the duration of the transaction. (Even the best programmers miss this one on occasion.) On the failure of a transaction, be sure to issue the rollback before putting up a message box telling the user that a problem occurred.
- ▶ Keep the start and end of a transaction together in the same batch or, better yet, use a stored procedure for the operation.
- ▶ Keep the transaction short. Start the transaction at the point where you need to do the modifications. Do any preliminary work beforehand.
- ▶ Make careful use of different locking schemes and transaction isolation levels.
- ▶ If user input is unavoidable between data retrieval and modification and you need to handle the possibility of another user modifying the data values read, use optimistic locking strategies or snapshot isolation rather than acquiring and holding locks by using `HOLDLOCK` or other locking options. Chapter 37 covers optimistic locking methods and snapshot isolation in more detail.
- ▶ Collect multiple transactions into one transaction, or batch transactions together, if appropriate. This advice might seem to go against some of the other suggestions, but it reduces the amount of overhead SQL Server will encounter to start, finish, and log the transactions.

Transaction Logging and the Recovery Process

Every SQL Server database has its own transaction log that keeps a record of all data modifications in a database (for example, `insert`, `update`, `delete`) in the order in which they occur. This information is stored in one or more log files associated with the database. The information stored in these log files cannot be modified or viewed effectively by any user process.

SQL Server uses a write-ahead log. The buffer manager guarantees that changes are written to the transaction log before the changes are written to the database. The buffer manager also ensures that the log pages are written out in sequence so that transactions can be recovered properly in the event of a system crash.

The following is an overview of the sequence of events that occurs when a transaction modifies data:

1. Writes a `BEGIN TRAN` record to the transaction log in buffer memory.
2. Writes data modification information to transaction log pages in buffer memory.
3. Writes data modifications to the database in buffer memory.
4. Writes a `COMMIT TRAN` record to the transaction log in buffer memory.
5. Writes transaction log records to the transaction log file(s) on disk.
6. Sends a `COMMIT` acknowledgment to the client process.

The end of a typical transaction is indicated by a `COMMIT` record in the transaction log. The presence of the `COMMIT` record indicates that the transaction must be reflected in the database or be redone, if necessary. A transaction aborted during processing by an explicit roll-back or a system error has its changes automatically undone.

Notice that the data records are not written to disk when a `COMMIT` occurs. This is done to minimize disk I/O. All log writes are done synchronously to ensure that the log records are physically written to disk and in the proper sequence. Because all modifications to the data can be recovered from the transaction log, it is not critical that data changes be written to disk right away. Even in the event of a system crash or power failure, the data can be recovered from the log if it hasn't been written to the database.

SQL Server ensures that the log records are written before the affected data pages by recording the log sequence number (LSN) for the log record making the change on the modified data page(s). Modified, or "dirty," data pages can be written to disk only when the LSN recorded on the data page is less than the LSN of the last log page written to the transaction log.

When and how are the data changes written to disk? Obviously, they must be written out at some time; otherwise, it could take an exceedingly long time for SQL Server to start up if it had to redo all the transactions contained in the transaction log. Also, how does SQL Server know during recovery which transactions to reapply, or roll forward, and which transactions to undo or roll back? The following section looks at the mechanisms involved in the recovery process.

The Checkpoint Process

During recovery, SQL Server examines the transaction log for each database and verifies whether the changes reflected in the log are also reflected in the database. In addition, it examines the log to determine whether any data changes that were written to the data were caused by a transaction that didn't complete before the system failure.

As discussed earlier, a `COMMIT` writes the log records for a transaction to the transaction log (see Figure 31.1). Dirty data pages are written out either by the Lazy Writer or checkpoint process. The Lazy Writer process runs periodically to check whether the number of free buffers has fallen below a certain threshold, reclaims any unused pages, and writes out any dirty pages that haven't been referenced recently.

The checkpoint process also scans the buffer cache periodically and writes all dirty log pages and dirty data pages to disk (see Figure 31.2). The purpose of the checkpoint is to sync up the data stored on disk with the changes recorded in the transaction log. Typically, the checkpoint process finds little work to do because most dirty pages have been written out previously by the worker threads or Lazy Writer process.

FIGURE 31.1 A commit writes all “dirty” log pages from cache to disk.

FIGURE 31.2 A checkpoint writes log pages from cache to disk and then writes all “dirty” data pages.

SQL Server performs the following steps during a checkpoint:

1. Writes a record to the log file to record the start of the checkpoint.
2. Stores information recorded for the checkpoint in a chain of checkpoint log records.
3. Records the minimum recovery LSN (MinLSN), which is the first log image that must be present for a successful database-wide rollback. The MinLSN is either the LSN of the start of the checkpoint, LSN of the oldest active transaction, or LSN of the oldest transaction marked for replication that hasn't yet been replicated to all subscribers.
4. Writes a list of all outstanding, active transactions to the checkpoint records.
5. Writes all modified log pages to the transaction log on disk.

6. Writes all dirty data pages to disk. (Data pages that have not been modified are not written back to disk to save I/O.)
7. Writes a record to the log file, indicating the end of the checkpoint.
8. Writes the LSN of the start of the checkpoint log records to the database boot page. (This is done so that SQL Server can find the last checkpoint in the log during recovery.)

Figure 31.3 shows a simplified version of the contents of a transaction log after a checkpoint. (For simplicity, the checkpoint records are reflected as a single log entry.)

FIGURE 31.3 A simplified view of the end of the transaction log with various completed and active transactions, as well as the last checkpoint.

The primary purpose of a checkpoint is to reduce the amount of work the server needs to do at recovery time to redo or undo database changes. A checkpoint can occur under the following circumstances:

- ▶ When a checkpoint statement is executed explicitly for the current database.
- ▶ When ALTER DATABASE is used to change a database option. ALTER DATABASE automatically checkpoints the database when database options are changed.
- ▶ When an instance of SQL Server is shut down gracefully either due to the execution of the SHUTDOWN statement or because the SQL Server service was stopped.

NOTE

The SHUTDOWN WITH NOWAIT statement does not perform what is considered a graceful shutdown of SQL Server. This statement forces a shutdown of SQL Server without waiting for current transactions to complete and *without* executing a checkpoint of each database. This type of shutdown may cause the subsequent restart of SQL Server to take a longer time to recover the databases on the server.

- ▶ When SQL Server periodically generates automatic checkpoints in each database to reduce the amount of time the instance would take to recover the database.

Automatic Checkpoints

The frequency of automatic checkpoints is determined by the setting of the recovery interval for SQL Server. However, the determination of when to perform a checkpoint is based on the number of records in the log, not a specific period of time. The time interval between the occurrences of automatic checkpoints can be highly variable. If few modifications are made to the database, the time interval between automatic checkpoints could be quite long. Conversely, automatic checkpoints can occur quite frequently if the update activity on a database is high.

The recovery interval does not state how often automatic checkpoints should occur. The recovery interval is actually related to an estimate of the amount of time it would take SQL Server to recover the database by applying the number of transactions recorded since the last checkpoint. By default, the recovery interval is set to 0, which means SQL Server determines the appropriate recovery interval for each database. It is recommended that you keep this setting at the default value unless you notice that checkpoints are occurring too frequently and are impairing performance. You should try increasing the value in small increments until you find one that works well. You need to be aware that if you set the recovery interval higher, fewer checkpoints will occur, and the database will likely take longer to recover following a system crash.

If the database is using either the full or bulk-logged recovery model, an automatic checkpoint occurs whenever the number of log records reaches the number that SQL Server estimates it can process within the time specified by the recovery interval option.

If the database is using the simple recovery model, an automatic checkpoint occurs whenever the number of log records reaches the number that SQL Server estimates it can process during the time specified by the recovery interval option or the log becomes 70% full and the database is in log truncate mode. A database is considered to be in log truncate mode when the database is using the simple recovery model and one of the following events has occurred since the last full backup of the database:

- ▶ A minimally logged operation is performed in the database, such as a minimally logged bulk copy operation or a minimally logged `WRITETEXT` statement.
- ▶ An `ALTER DATABASE` statement is executed that adds or deletes a file in the database.
- ▶ A `BACKUP LOG` statement referencing the database is executed with either the `NO_LOG` or `TRUNCATE_ONLY` option.

When a database is configured to use the simple recovery model, the automatic checkpoint also truncates the unused portion of the transaction log prior to the oldest active transaction.

Manual Checkpoints

In addition to automatic checkpoints, a checkpoint can be explicitly initiated by members of the `sysadmin` fixed server role or the `db_owner` or `db_backupoperator` fixed database roles. The syntax for the `CHECKPOINT` command is as follows:

```
CHECKPOINT [ checkpoint_duration ]
```

To minimize the performance impact on other applications, SQL Server 2008 by default adjusts the frequency of the writes that a checkpoint operation performs. SQL Server uses this strategy for automatic checkpoints and for any `CHECKPOINT` statement that does not specify the *checkpoint_duration* value.

You can use the *checkpoint_duration* option to request the amount of time, in seconds, for the checkpoint to complete. When *checkpoint_duration* is specified, SQL Server attempts to perform the checkpoint within the requested duration. The performance impact of using *checkpoint_duration* depends on the number of dirty pages, the activity on the system, and the actual duration specified. For example, if the checkpoint would normally complete in 120 seconds, specifying a *checkpoint_duration* of 60 seconds causes SQL Server to devote more resources to the checkpoint than would be assigned by default to be able to complete the checkpoint in half the time. In contrast, specifying a *checkpoint_duration* of 240 seconds causes SQL Server to assign fewer resources than would be assigned by default. In other words, a short *checkpoint_duration* increases the resources devoted to the checkpoint, and a longer *checkpoint_duration* reduces the resources devoted to the checkpoint.

Regardless of the checkpoint duration specified, SQL Server always attempts to complete a checkpoint when possible. In some cases, a checkpoint may complete sooner than the specified duration, and at times it may run longer than the specified duration.

The Recovery Process

When SQL Server is started, it verifies that completed transactions recorded in the log are reflected in the data and that incomplete transactions whose changes are reflected in the data are rolled back out of the database. This is the recovery process. Recovery is an automatic process performed on each database during SQL Server startup. Recovery must be completed before the database is made available for use.

The recovery process guarantees that all completed transactions recorded in the transaction log are reflected in the data and all incomplete transactions reflected in the data are rolled back. During recovery, SQL Server looks for the last checkpoint record in the log.

Only the changes that occurred or were still open since the last checkpoint need to be examined to determine the need for any transactions to be redone (that is, rolled forward) or undone (that is, rolled back). After all the changes are rolled forward or rolled back, as necessary, the database is checkpointed, and recovery is complete.

The recovery algorithm has three phases centered around the last checkpoint record in the transaction log, as shown in Figure 31.4.

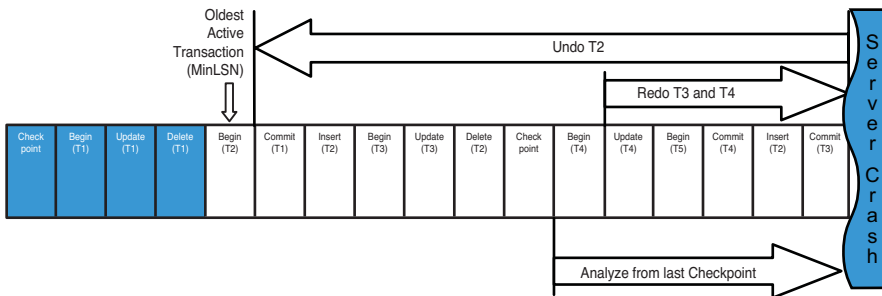

FIGURE 31.4 The phases of the recovery process.

These phases are as follows:

1. **Analysis phase**—SQL Server reads forward from the last checkpoint record in the transaction log. This pass identifies a list of pages (the dirty page table [DPT]) that might have been dirty at the time of the system crash or when SQL Server was shut down, as well as a list of the uncommitted transactions at the time of the crash.
2. **Redo (roll-forward) phase**—During this phase, SQL Server rolls forward all the committed transactions recorded in the log since the last checkpoint. This phase returns the database to the state it was in at the time of the crash. The starting point for the redo pass is the LSN of the oldest committed transaction within the DPT, so that only changes not previously checkpointed (only the committed dirty pages) are reapplied.
3. **Undo (rollback) phase**—This phase moves backward from the end of the log to the oldest active transaction at the time of the system crash or shutdown. All transactions that were not committed at the time of the crash but had pages written to the database are undone so that none of their changes are actually reflected in the database.

Now let's examine the transactions in the log in Figure 31.4 and determine how they will be handled during the recovery process:

- Transaction T1 is started and committed prior to the last checkpoint. No recovery is necessary.

- ▶ Transaction T2 started before the last checkpoint but had not completed at the time of the system crash. The changes written out by the checkpoint process for this transaction have to be rolled back.
- ▶ Transaction T3 started before the last checkpoint was issued and committed after that checkpoint but prior to the system crash. The changes made to the data after the checkpoint need to be rolled forward.
- ▶ Transaction T4 started and committed after the last checkpoint. This entire transaction needs to be rolled forward.
- ▶ Transaction T5 started after the last checkpoint, but no changes to the data were recorded in the log, so no data changes were written to the data. (Remember that changes must be written to the log before they can be written to the data.) No undo action is required for this transaction.

In a nutshell, this type of analysis is pretty much the same analysis the recovery process would do. To identify the number of transactions rolled forward or rolled back during recovery, you can examine the SQL Server error log and look at the recovery startup messages for each database. Following is a sample fragment of the recovery messages you might see in the SQL Server error log:

```

Managing the Transaction Log

Each database in SQL Server has at least one transaction log file. The transaction log file contains the transaction log records for all changes made in that database. By default, transaction log files have the file extension `.ldf`.

A database can have several log files, and each log file can have a maximum size of 32TB. A log file cannot be part of a filegroup. No information other than transaction log records can be written to a log file.

Regardless of how many physical files have been defined for the transaction log, SQL Server treats it as one contiguous file. The transaction log for a database is actually managed as a set of virtual log files (VLFs). VLFs have no fixed size, and there is no fixed number of VLFs for a physical log file. The size and number of VLFs is not configurable. SQL Server determines the size of the VLFs dynamically, based on the total size of all the log files and the growth increment specified for the log. Figure 31.5 shows an example of a physical log file divided into multiple virtual log files.

The transaction log is essentially a wrap-around file. Initially, the logical log file begins at the start of the physical log file. As transactions are committed, new log records are added to the end of the logical log, and the logical log expands toward the end of the physical log. When the logical log reaches the end of the physical log file, SQL Server attempts to wrap around and start writing log records back at the beginning of the physical log file, as shown in Figure 31.6.

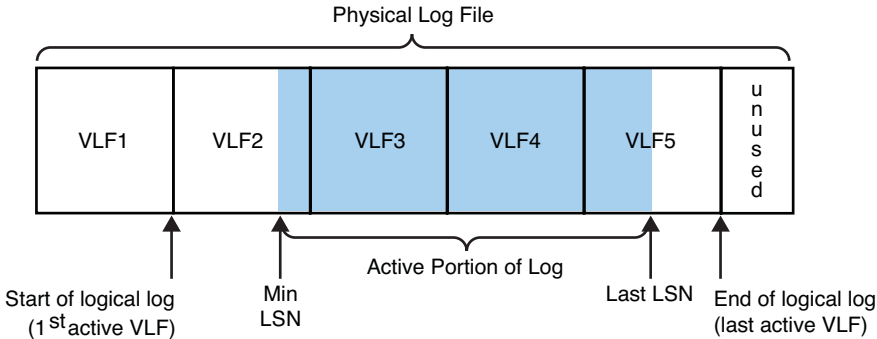

FIGURE 31.5 The structure of a physical log file showing VLFs.

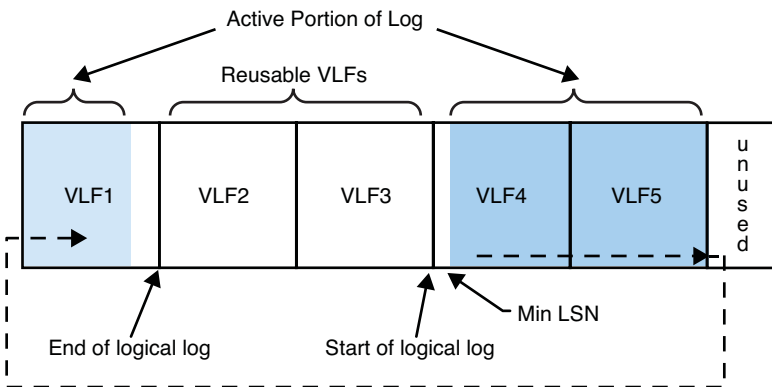

FIGURE 31.6 An example of the active portion of a log cycling around to reusable VLF at the beginning of a log file.

SQL Server, however, can reuse only the first VLF if it is no longer part of the logical log; that is, the VLF does not contain any active log records, and the contents of the inactive VLFs have been truncated. Log truncation frees any virtual logs whose records all appear before the MinLSN. The MinLSN is the log sequence number of the oldest log record required for a successful database recovery.

In environments where the log is not being maintained, SQL Server automatically truncates and reuses the space in the VLFs at the beginning of the log file as soon as it reaches the end of the log file. This can occur as long as the VLFs at the beginning of the log file do not contain the MinLSN. SQL Server assumes that the log is not being maintained

when the database is in simple recovery mode, or when you have never performed a full backup of the database.

If the database is configured to use the bulk-logged or full recovery models so that the log is being maintained, the reusable portion of the log prior to the MinLSN cannot be truncated or purged until the transaction log has actually been backed up.

If the first VLF cannot be reused because it contains the MinLSN or it hasn't been truncated yet, SQL Server needs to expand the log file. This is done by adding a new VLF to the end of the physical log (as long as the log file is still configured to grow automatically). SQL Server can then continue writing log records to the new VLF. However, if the log file is not configured to auto-grow, a 9002 error is generated, indicating that the log file is out of space.

Certain conditions can cause log records to remain active, preventing the MinLSN from moving out of the first VLF, which in turn prevents the VLFs at the beginning of the physical log file from being reused. Some of the conditions that can lead to the log space not being reused include, but are not limited to, the following:

- ▶ No checkpoint has taken place yet since the log was last truncated, and the log records are needed for database recovery.
- ▶ A database or log backup is in progress.
- ▶ A long-running transaction is still active.
- ▶ Database mirroring is paused. (For more information, see Chapter 20, "Database Mirroring.")
- ▶ The database is the primary database for transactional replication, and transactions relevant to the publications have not yet been delivered to the distribution database. (For more information on replication, see Chapter 19, "Replication.")
- ▶ A database snapshot is being created (for more information, see Chapter 32, "Database Snapshots").

If something is preventing the log from being truncated, SQL Server 2008 provides information in the system catalogs to determine what is preventing log truncation. This information is available in the `log_reuse_wait_desc` column of the `sys.databases` catalog view, which you can display by using a query similar to the following:

```
select name, log_reuse_wait_desc
  from sys.databases
 where name = db_name()
```

When a log file is configured to auto-grow and there is significant update activity against the database and the inactive portion of the transaction log is not being truncated frequently enough (or at all) to allow for the reuse of VLFs, the log file size can become excessive. This can lead to insufficient disk space in the file system that contains the log

file. This can subsequently also lead to a 9002 out-of-space error if the log file needs to grow and not enough disk space is available. At times, you might need to shrink the log file to reduce its size.

Shrinking the Log File

After the log has been backed up and the active portion of the log has wrapped around to the beginning of the log file, the VLFs at the end of the physical log can be deleted from the log file, and the log file can be reduced in size.

When you shrink a log file, the space freed can only come from the end of the log file. The unit of size reduction is the size of the virtual log file. For example, if you have a 1GB log file that has been divided into five 200MB virtual log files, the log file can only be shrunk in 200MB increments. The file size can be reduced to sizes such as 800MB or 400MB, but the file cannot be reduced to sizes such as 333MB or 750MB.

SQL Server 2008 provides the DBCC SHRINKFILE command for shrinking the transaction log file. Its syntax is as follows:

```
DBCC SHRINKFILE ( { 'file_name' } { [,EMPTYFILE] | [,target_size ] } )
    [ WITH NO_INFOMSGS ]
```

If no target size is specified for the DBCC SHRINKFILE command, SQL Server removes as many of the inactive virtual log files from the end of the physical log file as possible to restore the transaction log file to its default size. The default size of the transaction log file is the size specified when the log file was created or the last size set by using the ALTER DATABASE command.

If a target size is specified for DBCC SHRINKFILE, SQL Server attempts to remove as many VLFs from the end of the log file as possible to reduce the log file to as close to the target size as possible without making the log smaller than the specified target size. After shrinking, the log file is typically somewhat larger than the target size, especially if the target size is not a multiple of the VLF size.

If no VLFs beyond the *target_size* mark contain an active portion of the log, all the VLFs that come after the *target_size* mark are freed, and the DBCC SHRINKFILE statement completes successfully, with no messages. However, if any VLF beyond the *target_size* mark does contain an active portion of the log, SQL Server frees from the end of the physical log file as many of the VLFs as possible that do not contain active portions of the log. When this occurs, the DBCC SHRINKFILE command returns an informational message indicating that not all the requested space was freed. When the active portion of the log moves off the VLF(s) at the end of the physical log file, you can reissue the DBCC SHRINKFILE statement again to free the remaining space.

You can also use SQL Server Management Studio (SSMS) to shrink the transaction log file. In the Object Browser, expand the Databases folder and right-click the target database. Then select Tasks, Shrink, and Files. The Shrink File dialog appears, as shown in Figure 31.7.

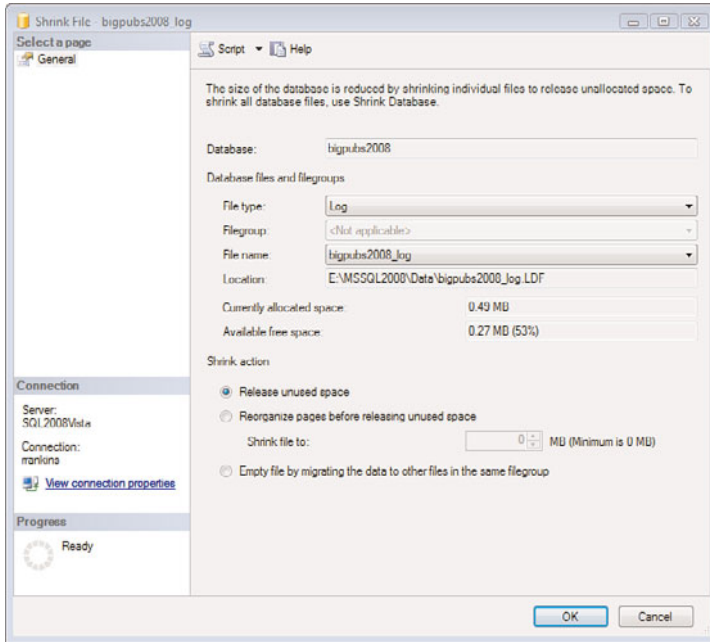

FIGURE 31.7 The SSMS Shrink File dialog.

In the File Type drop-down list, select Log. To shrink the log file to its default size, click the radio button next to Release Unused Space in the Shrink Action area of the dialog box. To shrink the log file to a desired size, click the radio button next to Reorganize Pages Before Releasing Unused Space and specify the desired target size. After you choose the desired shrink option, click OK.

In addition to manually shrinking the transaction log, SQL Server also provides a database option, `AUTO_SHRINK`, that can be enabled to shrink the log and database files automatically when space is available at the end of the file. If you are regularly backing up or truncating the log, the `AUTO_SHRINK` option keeps the size of the log file in check. The auto-shrink process runs periodically and determines whether the log file can be shrunk. The Log Manager keeps track of how much log space has been used since the auto-shrink process last ran. The auto-shrink process then shrinks the log either to 125% of the maximum log space used since auto-shrink last ran or the default size of the transaction log file, whichever is larger.

TIP

Repeated growing and shrinking of the log file can lead to excessive file fragmentation, which can have an adverse impact on the file I/O performance. It is recommended that instead of using AUTO_SHRINK, you set the transaction log to the size it is expected to grow to during normal processing and enable the auto-grow option so that it doesn't run out of space if something prevents the log from being truncated. By doing so, you help avoid the need for the log file to be constantly expanded during normal processing and also avoid excessive fragmentation of the log file. If something causes the log file to auto-grow and exceed the normal log file size, you can always manually shrink the file back to its normal size.

Long-Running Transactions

As you have already seen, transaction information is recorded in each database's transaction log. However, long-running transactions can be a cause of consternation to a system administrator who is attempting to back up and prune the transaction log. Only the inactive portion of the log can be truncated during this operation. The inactive portion of the log is the pages that contain log records for all completed transactions prior to the first log record of the oldest still-active transaction (see Figure 31.8). Even if completed transactions follow the first record of the oldest active transaction, they cannot be removed from the log until the oldest active transaction completes. The reason is that the log is pruned by clearing out entire pages of information prior to the oldest active transaction. Pages after that point cannot be cleared because they might contain records for the active transaction that would be needed in the event of a rollback or database recovery.

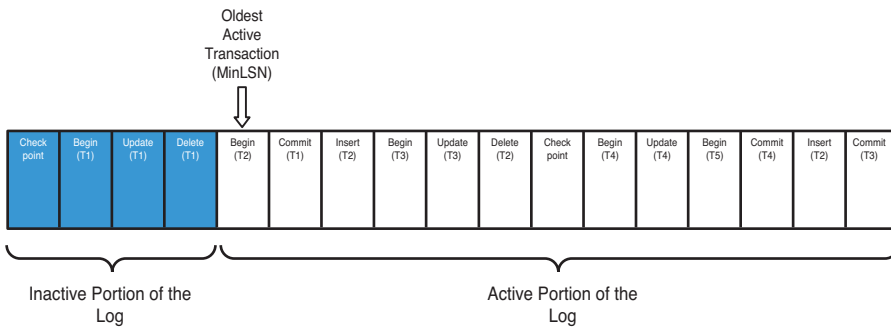

FIGURE 31.8 The inactive portion of the log is the pages in the log prior to the oldest active transaction.

In addition to preventing the log from being pruned, long-running transactions can degrade concurrency by holding locks for an extended period of time, preventing other users from accessing the locked data.

To get information about the oldest active transaction in a database, you can use the DBCC OPENTRAN command, whose syntax is as follows:

```
DBCC OPENTRAN [( 'DatabaseName' | DatabaseId)]
[WITH TABLERESULTS [, NO_INFOMSGS]]
```

The following example displays a sample of the oldest active transaction for the bigpubs2008 database:

```
DBCC OPENTRAN (bigpubs2008)
go
```

```
Transaction information for database 'bigpubs2008'.
```

```
Oldest active transaction:
```

```
  SPID (server process ID): 56
  UID (user ID) : -1
  Name           : add_titles
  LSN            : (1926:170:6)
  Start time     : May 26 2009 12:17:09:220AM
  SID            : 0xe6810e075514c744bc8d03b34c27b004
```

DBCC execution completed. If DBCC printed error messages, contact your system administrator.

DBCC OPENTRAN returns the server process ID (SPID) of the process that initiated the transaction, user ID, name of the transaction (naming transactions are helpful here because the names might help you identify the SQL code that initiated the transaction), LSN of the page containing the initial BEGIN TRAN statement for the transaction, and, finally, time the transaction was started.

If you specify the TABLERESULTS option, this information is returned in two columns that you can load into a table for logging or comparison purposes. The NO_INFOMSGS option suppresses the display of the 'DBCC execution completed...' message. The following example runs DBCC OPENTRAN and inserts the results into a temp table:

```
CREATE TABLE #opentran_results
( result_label VARCHAR(30), result_value VARCHAR(46))

insert #opentran_results
      exec ('dbcc opentran (bigpubs2008) WITH TABLERESULTS, no_infomsgs')

select * from #opentran_results
go
```

If no open transactions exist for the database, you receive the following message from DBCC OPENTRAN:

```
No active open transactions.
```

DBCC execution completed. If DBCC printed error messages, contact your system administrator.

DBCC OPENTRAN provides a means for you to identify which transactions are potential problems, based on their longevity. If you capture the process information at the same time, using `sp_who`, you can identify who or what application is causing the longest-running transaction(s). Using this information, you can terminate the process, if necessary, or you can just have a quiet word with the user if the query is ad hoc or with the application developers if it is SQL code generated by a custom application.

Bound Connections

During the course of a transaction, the process that initiated the transaction acquires exclusive locks on the data that is modified. These locks prevent other user processes or connections from seeing any of these changes until they are committed. However, it is common for some SQL Server applications to have multiple connections to SQL Server. Even though each connection might be for the same user, SQL Server treats each connection as an entirely separate SQL Server process, and by default, one connection cannot see the uncommitted changes of another nor modify records locked by the other connection.

Bound connections provide a means of linking multiple connections together to share the same lock space and participate in the same transaction. This capability can be useful, especially if an application makes use of extended stored procedures. Extended stored procedures, although invoked from within a user session, run externally in a separate session. An extended stored procedure might need to call back into the database to access data. Without bound connections between the original process and extended stored procedure, the extended stored procedure would be blocked by the locks held on the data by the originating process.

NOTE

In earlier versions of SQL Server, bound sessions were primarily used in developing extended stored procedures that needed to execute T-SQL statements on behalf of the process calling them. In SQL Server 2008, it is recommended that extended stored procedures be replaced with stored procedures written using the common language runtime (CLR). CLR-stored procedures are more secure, scalable, and stable than extended stored procedures. In addition, CLR-stored procedures use the `SqlContext` object to join the context of the calling session rather than bound connections.

Bound connections are of two types: local and distributed. Local bound connections are two or more connections within a single server that are bound into a single transaction space. Distributed bound connections make use of the Microsoft Distributed Transaction Coordinator (MS DTC; described in more detail in the following section, “Distributed Transactions”) to share a transaction space across connections from more than one server.

Distributed Transactions

Typically, transaction management controls only the data modifications made within a single SQL Server instance. However, the increasing interest and implementation of distributed systems brings up the need to access and modify data distributed across multiple SQL Server instances within a single unit of work.

What if in the banking example, the checking accounts reside on one SQL Server instance and the savings accounts on another? Moving money from one account to another would require updates to two separate SQL Server instances. How do you modify data on two different instances and still treat it as a single unit of work? You need some way to ensure that the distributed transaction retains the same ACID properties as a local transaction. To provide this capability, SQL Server ships with the MS DTC service, which provides the capability to control and manage the integrity of multiserver transactions. MS DTC uses the industry-standard two-phase commit protocol to ensure the consistency of all parts of any distributed transaction passing through SQL Server and any referenced linked servers.

Chapter 54, “Managing Linked and Remote Servers” (on the CD), covers the process of configuring servers and writing SQL code to support distributed transactions.

Summary

A transaction is a logical unit of work as well as a unit of recovery. The successful control of transactions is of the utmost importance to the correct modification of related information. In this chapter, you learned how to define and control transactions, examined different transaction-management schemes, learned how the recovery process works, and discovered how to correctly code transactions within triggers and stored procedures. You also learned methods for optimizing transactions to improve application performance, and you got an overview of locking and distributed transactions. Locking is covered in more detail in Chapter 37, and distributed transactions are covered in more detail in Chapter 54. In addition, this chapter discussed the snapshot isolation options available in SQL Server 2008. Snapshot isolation provides the capability to keep versions of row data that existed prior to the start of a transaction.

Chapter 32 discusses the concept of database snapshots, which provide a way to keep a read-only, static view of a database.

CHAPTER 32

Database Snapshots

Database snapshots have been a feature of competing database products (Oracle and DB2) for years. Database snapshots are great for fulfilling point-in-time reporting requirements, reverting a database back to a point in time (recoverability and availability), and for potentially reducing the processing impact of querying against your primary transactional databases (via database mirroring and database snapshots).

Keep in mind that database snapshots are point in time and read-only. Database snapshots are not materialized views. Materialized views become part of the data object (table) that they are touching (that is, that are bound to them); when data changes in the base tables, materialized views change (that is, are updated). Database snapshots are point-in-time reflections of an entire database and are not bound to the underlying database objects from which they pull their data. They provide a full, read-only copy of the database at a specific point in time. Because of this point-in-time aspect, data latency must be well understood for all users of this feature: snapshot data is only as current as at the time the snapshot was made.

Database snapshots make huge use of Microsoft's copy-on-write technology. In fact, the copy-on-write technology is the primary enabling mechanism for snapshots. If you recall from Chapter 20, "Database Mirroring," the copy-on-write technology is what enables database mirroring. Database snapshots can also be used in conjunction with database mirroring to provide a highly available transactional system and a reporting platform that is created from the database mirror and offloads the reporting away from

the primary transactional database, without any data loss impact whatsoever. This is a very powerful reporting and availability configuration.

What's New with Database Snapshots

With SQL Server 2005, everything about database snapshots was new because this was a completely new feature for SQL Server. With SQL Server 2008, there is little new to this feature other than under-the-cover improvements to the copy-on-write mechanisms and three more years of production implementations under their belt. One hundred percent of the SQL code you have set up for creating and managing snapshots will work perfectly with SQL Server 2008. No upgrade pain here.

Database snapshots have solved many companies' reporting, data safeguarding, and performance issues and directly contributed to higher availability across the board. Be aware, though, there are plenty of restrictions with doing database snapshots. In fact, these restrictions may prohibit you from using snapshots at all. We talk about these restrictions and when you can safely do database snapshots in a bit.

NOTE

The examples in this chapter are based on the SQL Server 2005 version of the AdventureWorks database rather than the newer AdventureWorks2008 or AdventureWorks2008R2 sample databases used for many of the examples in the other chapters in this book. The reason for this is because of the examples presented that create a snapshot from a Database Mirror. Database Mirroring cannot be implemented on a database that is also configured for FILESTREAM storage. The 2008 and 2008R2 versions of the AdventureWorks database make use of FILESTREAM storage.

Fortunately, the 2005 version of the AdventureWorks database can be installed using the same installer that installs the AdventureWorks2008 or AdventureWorks2008R2 database. If you didn't install AdventureWorks when you installed either of these sample databases, simply relaunch the installer and choose to install the AdventureWorks OLTP database.

For more information on downloading and installing the AdventureWorks sample databases, see the Introduction chapter.

What Are Database Snapshots?

Microsoft has kept up its commitment of providing a database engine foundation that can be highly available 7 days a week, 365 days a year. Database snapshots contribute to this goal in several ways:

- ▶ They decrease recovery time of a database because you can restore a troubled database with a database snapshot—referred to as *reverting*.
- ▶ They create a security blanket (safeguard) prior to running mass updates on a critical database. If something goes wrong with the update, the database can be reverted in a very short amount of time.

- ▶ They provide a read-only, point-in-time reporting database for ad hoc or canned reporting needs quickly (thus, increasing reporting environment availability).
- ▶ They create a read-only, point-in-time reporting and off-loaded database for ad hoc or canned reporting needs quickly from a database mirror (again, increasing reporting environment availability and also offloading reporting impact away from your production server/principal database server).
- ▶ As a bonus, database snapshots can be used to create testing or QA synchronization points to enhance and improve all aspects of critical testing (thus decreasing bad code from going into production that directly affects the stability and availability of that production implementation).

A database snapshot is simply a point-in-time full database view. It's not a copy—at least not a full copy when it is originally created. We talk about this more in a moment. Figure 32.1 shows conceptually how a database snapshot can be created from a source database on a single SQL Server instance.

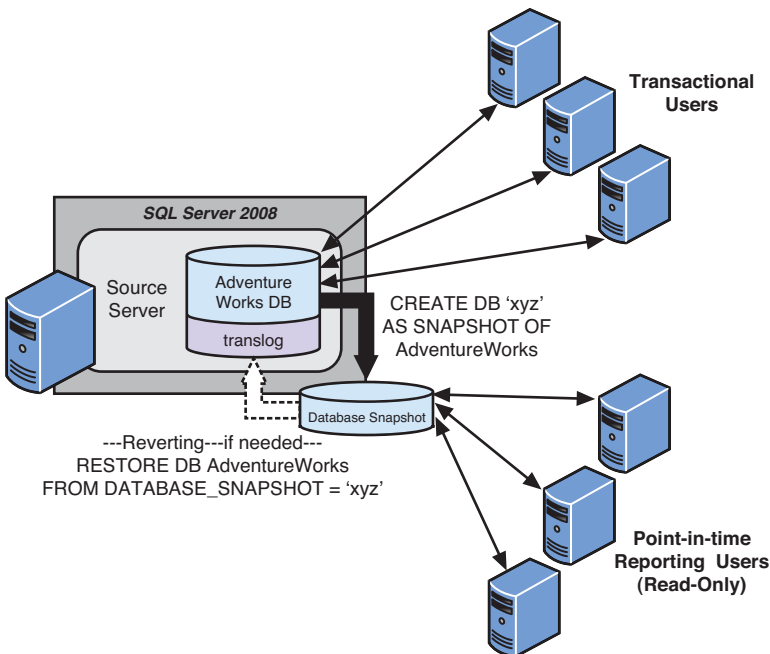

FIGURE 32.1 Basic database snapshot concept: a source database and its database snapshot, all on a single SQL Server instance.

This point-in-time view of a database's data never changes, even though the data (data pages) in the primary database (the source of the database snapshot) may change. It is truly a snapshot at a point in time. For a snapshot, it always simply points to data pages that were present at the time the snapshot was created. If a data page is updated in the

source database, a copy of the original source data page is moved to a new page chain termed the *sparse file*. This utilizes copy-on-write technology. Figure 32.2 shows the sparse file that is created, alongside the source database itself.

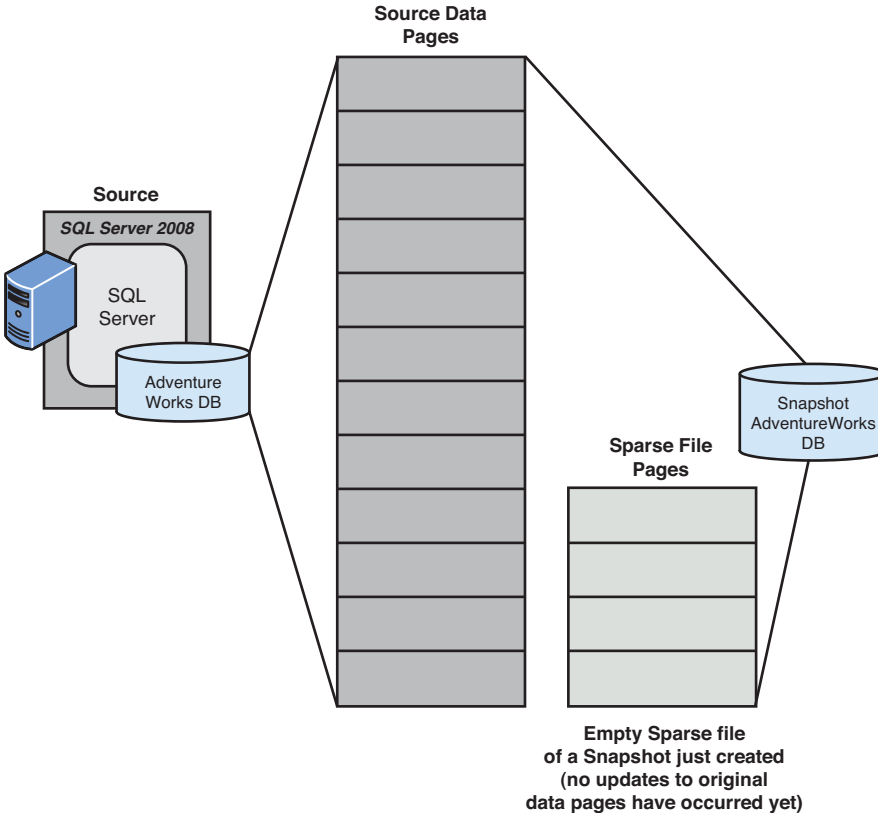

FIGURE 32.2 Source database data pages and the sparse file data pages that comprise the database snapshot.

A database snapshot really uses the primary database's data pages up until the point that one of these data pages is updated (changed in any way). As already mentioned, if a data page is updated in the source database, the original copy of the data page (which is referenced by the database snapshot) is written to the sparse file page chain as part of an update operation, using the copy-on-write technology. It is this new data page in the sparse file that still provides the correct point-in-time data to the database snapshot that it serves. Figure 32.3 illustrates that as more data changes (updates) occur in the source database, the sparse file gets larger and larger with the old original data pages.

Eventually a sparse file could contain the entire original database if all data pages in the primary database were changed. As you can also see in Figure 32.3, which data pages the database snapshot uses from the original (source) database and which data pages are used

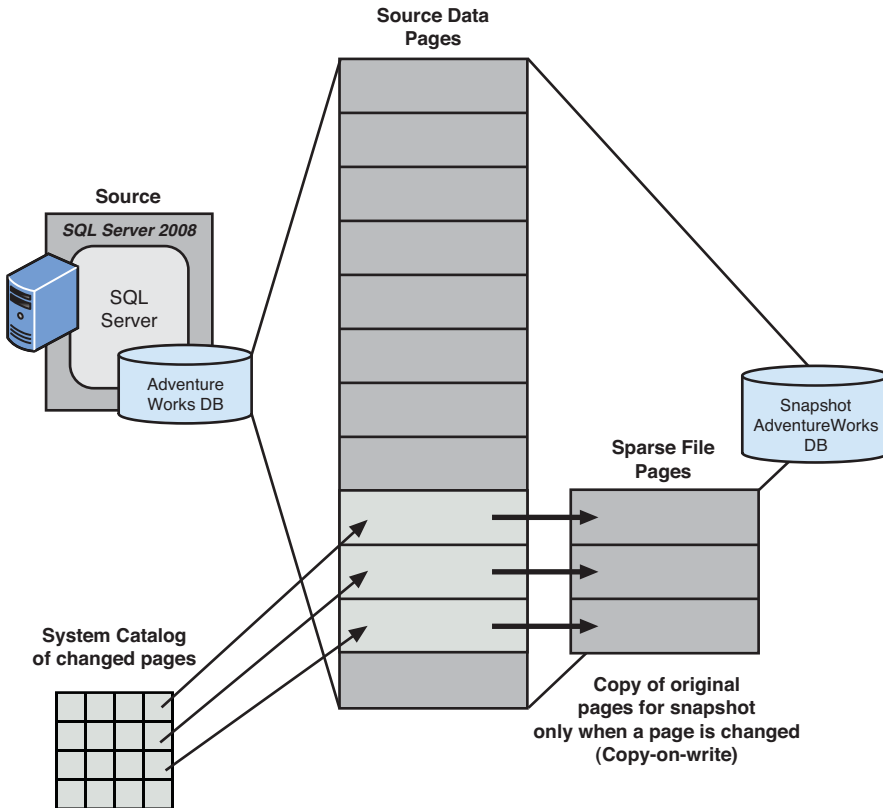

FIGURE 32.3 Data pages being copied to the sparse file for a database snapshot as pages are being updated in the source database.

from the sparse file are all managed by references in the system catalog for the database snapshot. This setup is incredibly efficient and represents a major breakthrough of providing data to others. Because SQL Server is using the copy-on-write technology, a certain amount of overhead is used during write operations. This is one of the critical factors you must sort through if you plan on using database snapshots. Nothing is free. The overhead includes the copying of the original data page, the writing of this copied data page to the sparse file, and then the subsequent metadata updating to the system catalog that manages the database snapshot data page list. Because of this sharing of data pages, it should also be clear why database snapshots must be within the same instance of a SQL Server: both the source database and snapshot start out as the same data pages and then diverge as source data pages are updated. In addition, when a database snapshot is created, SQL Server rolls back any uncommitted transactions for that database snapshot; only the committed transactions are part of a newly created database snapshot. And, as you might expect of something that shares data pages, database snapshots become unavailable if the source database becomes unavailable (for example, if it is damaged or goes offline).

NOTE

You might plan to do a new snapshot after about 30% of the source database has changed to keep overhead and file sizes in the sparse file at a minimum. The most frequent problem that occurs with database snapshots is related to sparse file sizes and available space. Remember, the sparse file has the potential of being as big as the source database itself (if all data pages in the source database eventually get updated). Plan ahead for this situation!

There are, of course, alternatives to database snapshots, such as data replication, log shipping, and even materialized views, but none are as easy to manage and use as database snapshots.

The most common terms associated with database snapshots are

- ▶ **Source database**—This is the database on which the database snapshot is based. A database is a collection of data pages. It is the fundamental data storage mechanism that SQL Server uses.
- ▶ **Snapshot databases**—There can be one or more database snapshots defined against any one source database. All snapshots must reside in the same SQL Server instance.
- ▶ **Database snapshot sparse file**—This new data page allocation contains the original source database data pages when updates occur to the source database data pages. One sparse file is associated with each database data file. If you have a source database allocated with one or more separate data files, you have corresponding sparse files of each of them.
- ▶ **Reverting to a database snapshot**—If you restore a source database based on a particular database snapshot that was done at a point in time, you are reverting. You are actually doing a database RESTORE operation with a FROM DATABASE_SNAPSHOT statement.
- ▶ **Copy-on-write technology**—As part of an update transaction in the source database, a copy of the source database data page is written to a sparse file so that the database snapshot can be served correctly (that is, still see the data page as of the snapshot point in time).

As Figure 32.4 illustrates, any data query using the database snapshot looks at both the source database data pages and the sparse file data pages at the same time. And these data pages always reflect the unchanged data pages at the point in time the snapshot was created.

Limitations and Restrictions of Database Snapshots

Many restrictions or limitations are involved with using database snapshots in SQL Server. Some of them are pretty restrictive and may determine whether you can consider using snapshots. With the current release of SQL Server Management Studio, you cannot even

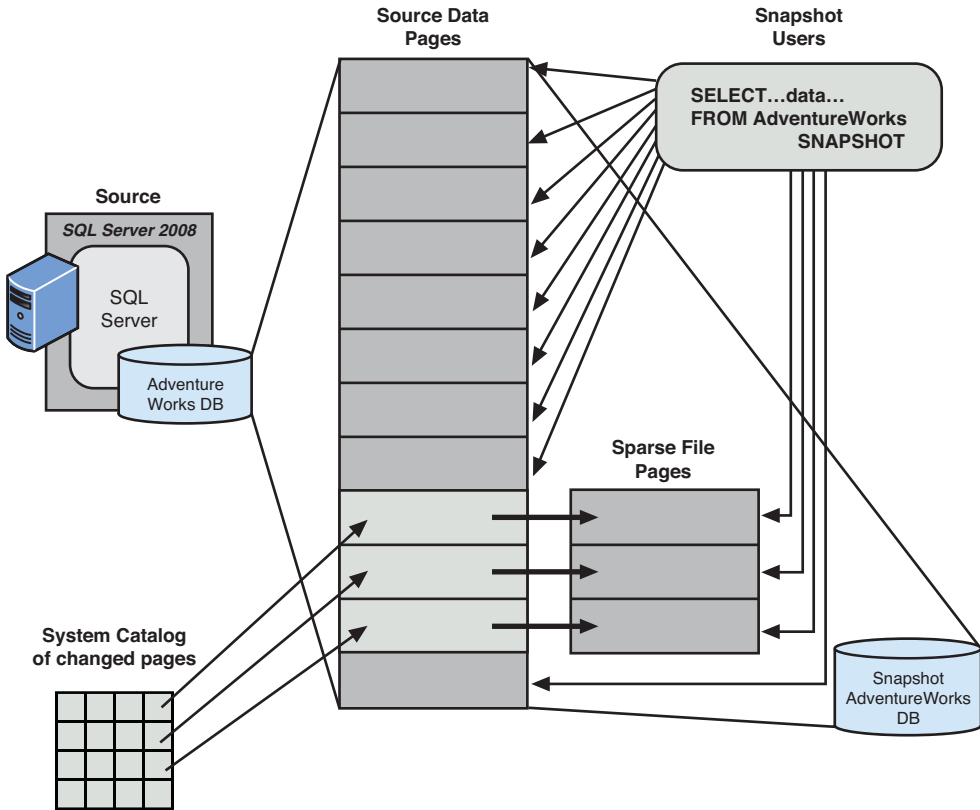

FIGURE 32.4 A query using the database snapshot touches both source database data pages and sparse file data pages to satisfy a query.

set up database snapshots with this GUI or a wizard; it must all be done using T-SQL statements (which is not that bad a deal). The following are some of the other restrictions:

- ▶ You must drop all other database snapshots when using a database snapshot to revert a source database.
- ▶ You lose visibility to the source database's uncommitted transactions in the database snapshot when it is created.
- ▶ The more updates to pages in the source database, the bigger your database snapshot sparse files become.
- ▶ A database snapshot can be done only for an entire database, not for a subset of the database.
- ▶ No additional changes can be made to a database snapshot. It is read-only and can't even have additional indexes created for it to make reporting queries run faster.
- ▶ Additional overhead is incurred on update operations on the source database due to the copy-on-write technique (not with SELECT statements).

- ▶ If you're using a database snapshot to revert (restore) a source database, neither the snapshot nor source database is available.
- ▶ The source database cannot be dropped, detached, or restored until the database snapshot is dropped first.
- ▶ Files on the source database or the snapshot cannot be dropped.
- ▶ For the database snapshot to be used, the source database must also be online (unless the source database is a mirrored database).
- ▶ The database snapshot must be on the same SQL Server instance as the source database.
- ▶ Snapshots are read-only.
- ▶ Database snapshot files must be on NTFS only (not FAT 32 or RAW partitions).
- ▶ Full-text indexing is not supported.
- ▶ If a source database ever goes into a `RECOVERY_PENDING` status, the database snapshot also becomes unavailable.
- ▶ If a database snapshot ever runs out of disk space, it must be dropped; it is actually marked as `SUSPECT`.

This may seem like a lot of restrictions—and it is. But look to Microsoft to address many of these restrictions in future releases. These current restrictions may disqualify many folks from getting into the database snapshot business. Others will thrive in its use out of the box.

Copy-on-Write Technology

The copy-on-write technology that Microsoft first introduced with SQL Server 2005 is at the core of both database mirroring and database snapshot capabilities. How it is used in database mirroring is explained in Chapter 20. In this section, we walk through a typical transactional user's update of data in a source database.

As you can see in Figure 32.5, an update transaction is initiated against the AdventureWorks database (labeled A). As the data is being updated in the source database's data page and the change is written to the transaction log (labeled B), the copy-on-write technology also copies the original source database data page in its unchanged state to the sparse data file (also labeled B) and updates the metadata page references in the system catalog (also labeled B) with this movement.

The original source data page is still available to the database snapshot. This adds extra overhead to any transaction that updates, inserts, or deletes data from the source database. After the copy-on-write technology finishes its write on the sparse file, the original update transaction is properly committed, and acknowledgment is sent back to the user (labeled C).

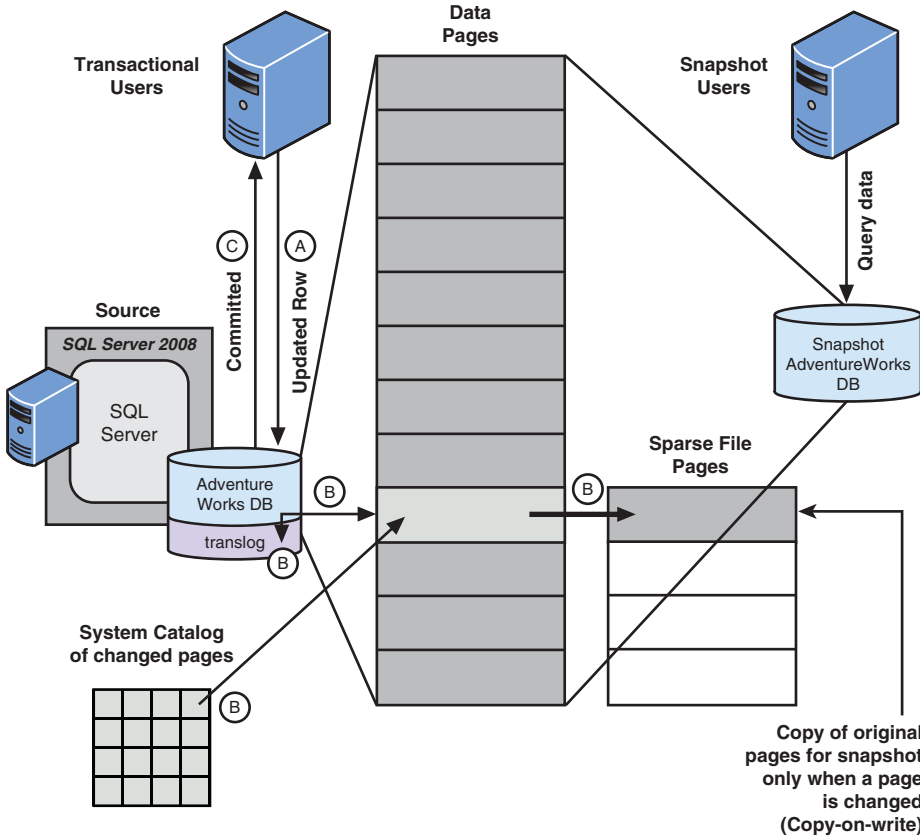

FIGURE 32.5 Using the copy-on-write technology with database snapshots.

NOTE

Database snapshots cannot be used for any of SQL Server’s internal databases—tempdb, master, msdb, or model. Also, database snapshots are supported only in the Enterprise Edition of SQL Server 2008.

When to Use Database Snapshots

As mentioned previously, there are a few basic ways you can use database snapshots effectively. Each is for a particular purpose, and each has its own benefits. After you have factored in the limitations and restrictions mentioned earlier, you can consider these uses. Let’s look at each of them separately.

Reverting to a Snapshot for Recovery Purposes

Probably the most basic usage of database snapshots is decreasing recovery time of a database by restoring a troubled database with a database snapshot—referred to as *reverting*. As Figure 32.6 shows, one or more regularly scheduled snapshots can be generated during a 24-hour period, effectively providing you with data recovery milestones that can be rapidly used. As you can see in this example, four database snapshots are six hours apart (6:00 a.m., 12:00 p.m., 6:00 p.m., and 12:00 a.m.). Each is dropped and re-created once per day, using the same snapshot name. Any one of these snapshots can be used to recover the source database rapidly in the event of a logical data error (such as rows deleted or a table being dropped). This technique is not supposed to take the place of a good maintenance plan that includes full database backups and incremental transaction log dumps. However, it can be extremely fast to get a database back to a particular milestone.

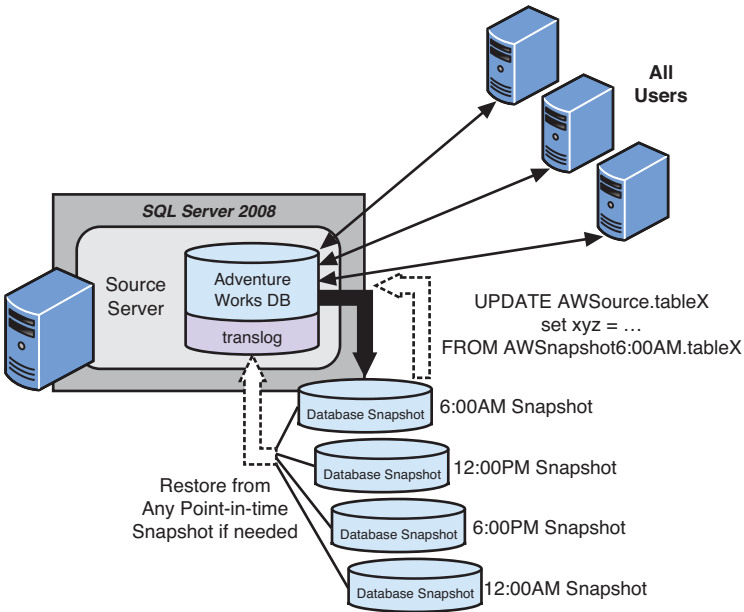

FIGURE 32.6 Basic database snapshot configuration: a source database and one or more database snapshots at different time intervals.

To revert to a particular snapshot interval, you simply use the `RESTORE DATABASE` command with the `FROM DATABASE_SNAPSHOT` statement. This is a complete database restore; you cannot limit it to just a single database object. In addition, you must drop all other database snapshots before you can use one of them to restore a database.

As you can also see in Figure 32.6, a targeted SQL statement variation from a complete database restore from a snapshot could be used instead if you knew exactly what you wanted to restore at the table and row level. You could simply use SQL statements (such as

an UPDATE SQL statement or an INSERT SQL statement) from one of the snapshots to selectively apply only the fixes you are sure need to be recovered (reverted). In other words, you don't restore the whole database from the snapshot, you only use some of the snapshots' data with SQL statements and bring the messed-up data row values back in line with the original values in the snapshot. This is at the row and column level and usually requires quite a bit of detailed analysis before it can be applied to a production database.

It is also possible to use a snapshot to recover a table that someone accidentally dropped. There is a little data loss since the last snapshot, but it is a simple INSERT INTO statement from the latest snapshot before the table drop. So be careful here, but consider the value as well.

Safeguarding a Database Prior to Making Mass Changes

Often, you plan regular events against your database tables that result in some type of mass update being applied to big portions of the database. If you do a quick database snapshot *before* any of these types of changes, you are essentially creating a nice safety net for rapid recovery in the event you are not satisfied with the mass update results. Figure 32.7 illustrates this type of safeguarding technique.

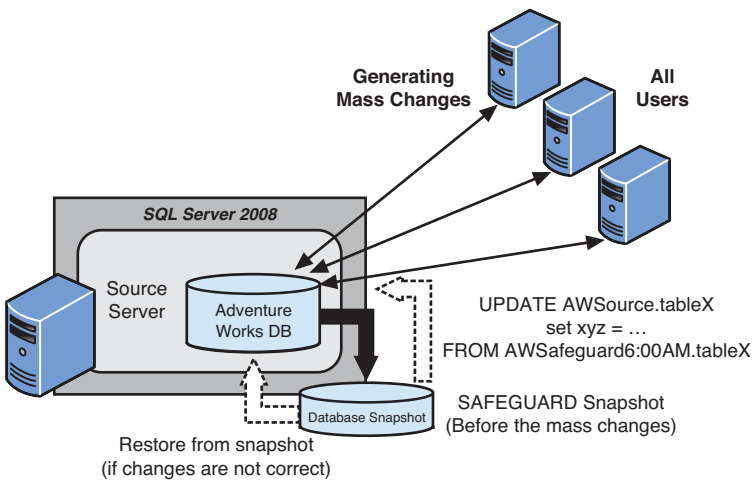

FIGURE 32.7 Creating a before database snapshot prior to scheduled mass updates to a database.

If you are not satisfied with the entire update operation, you can use RESTORE DATABASE from the snapshot and revert it to this point. Or, if you are happy with some updates but not others, you can use the SQL statement UPDATE to selectively update (restore) particular values back to their original values using the snapshot.

Providing a Testing (or Quality Assurance) Starting Point (Baseline)

In testing and the QA phases of your development life cycle, you often need to conduct tests over and over. These are either logic tests or even performance tests. To aid testing and QA, database snapshots can be made of a test database prior to full testing (create a testing baseline database snapshot) and then the test database can be reverted back to its original state at a moment's notice, using that baseline snapshot. This procedure can be done any number of times. Figure 32.8 shows how easy it is to simply create a testing reference point (or synchronization point) with a database snapshot.

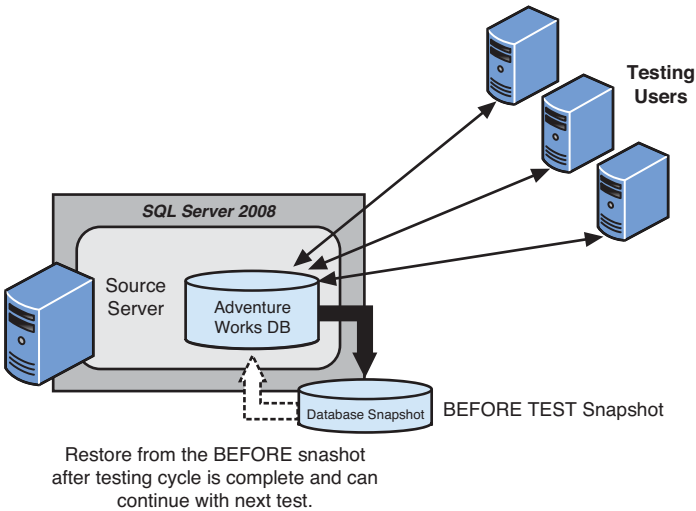

FIGURE 32.8 Establishing a baseline testing database snapshot before running tests and then reverting when finished.

You then just run your test scripts or do any manual testing—as much as you want—and then revert back to this starting point rapidly. Then you run more tests again.

Providing a Point-in-Time Reporting Database

If what you really need is a true point-in-time reporting database from which you can run ad hoc or canned reports, often a database snapshot can serve this purpose much better than resorting to log shipping or data replication. Key to determining when you can use this database snapshot technique is whether the reporting load on this database server instance can easily support the reporting workload and whether the update transactions against this database are adversely affected by the database snapshot overhead of each

transaction. Figure 32.9 shows the typical database snapshot configuration for one or more database snapshots that are to be used for reporting.

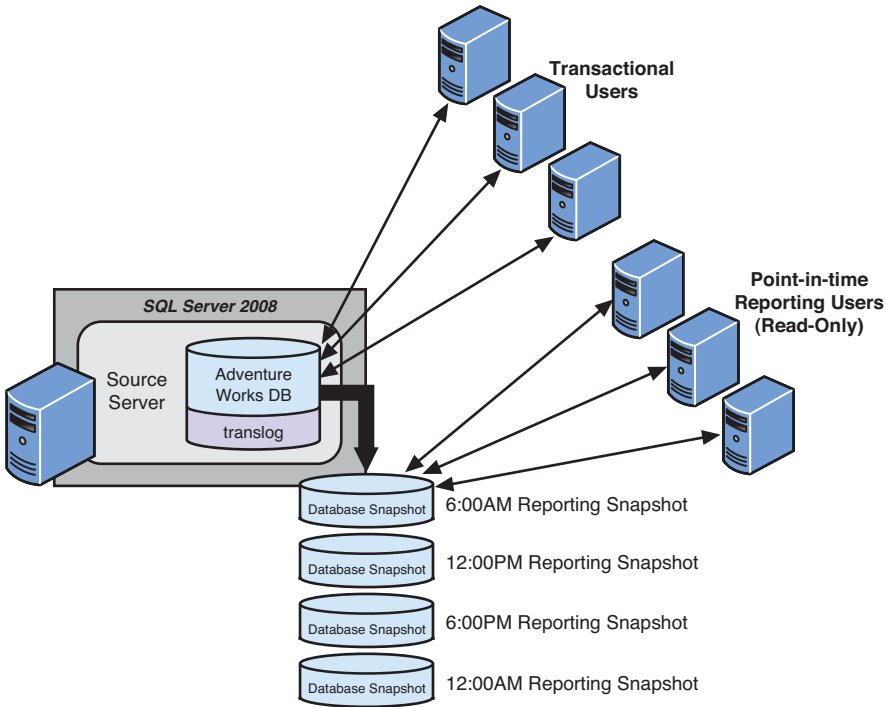

FIGURE 32.9 A point-in-time reporting database via a database snapshot.

Remember, this is a point-in-time snapshot of the source database. How frequently you need to create a new snapshot is dictated by your reporting requirements for data latency (how old the data can be in these reports).

Providing a Highly Available and Offloaded Reporting Database from a Database Mirror

If you are using database mirroring to improve your availability, you can also create a database snapshot against this mirrored database and expose the snapshot to your reporting users. Even though the mirrored database cannot be used for any access whatsoever (it is in constant restore mode), SQL Server allows a snapshot to be created against it (as shown in Figure 32.10). This is a very powerful configuration in that a database snapshot against a mirror does not impact the load of the principal server—guaranteeing high performance against the principal server. Also, when the database snapshot is isolated over to the mirror server, the performance of the reporting users is also more predictable

because they are not competing with the transactional users for resources on the principal server. The only real issues arise when the principal server fails over to the mirror database. You now have both transactional and reporting users using the same database server instance, and the performance of them all is affected.

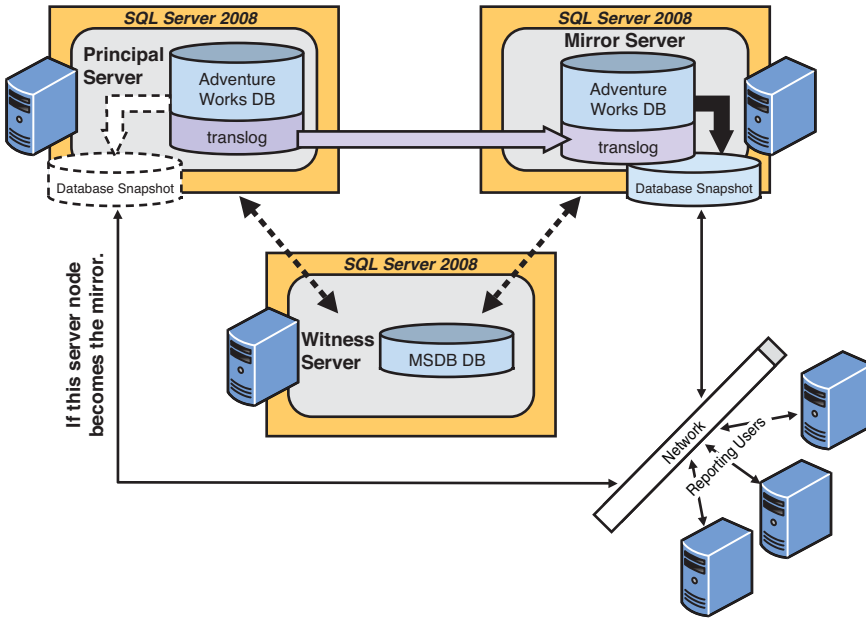

FIGURE 32.10 Creating a database snapshot for reporting against a mirrored database to offload the reporting impact on the principal server.

A possible solution to this situation would be to automatically (or manually) drop the database snapshot on the mirror server if it becomes the principal and create a new snapshot on the old principal server if it is available (it is now the mirror). You then just point all your reporting users to this new database snapshot. This task can be handled fairly easily in an application server layer. This solution is basically a reciprocal principal/mirror reporting configuration approach that always tries to get the database snapshot that is used for reporting to be on the server that is the mirror server. You would never really want to have active database snapshots on both the principal server and mirror server at the same time. This is way too much overhead for both servers. You want just the database snapshots to be on the mirror server. For a full explanation of all the capabilities of a database mirroring configuration, refer to Chapter 20.

Setup and Breakdown of a Database Snapshot

You might actually be surprised to find out how easily you can set up a database snapshot. This simplicity is partly due to the level at which database snapshots are created: at the database level and not at the table level. Setting up a database snapshot only entails

running a `CREATE DATABASE` with the `AS SNAPSHOT OF` statement. You cannot create database snapshots from SQL Server Management Studio or from any other GUI or wizard for that matter. All must be done using SQL scripts. All SQL scripts for this chapter are available to you as a download from the Sams Publishing website for this book title (www.sampublishing.com) and on this book's CD. The script file, named `DBSnapshotSQL2008.sql`, also contains a variety of other useful SQL statements to help you better manage a database snapshot environment.

Creating a Database Snapshot

One of the first things you must figure out before you create a database snapshot is whether your source database data portion has more than one physical file in its allocation. All these file references must be accounted for in the snapshot. You execute the system stored procedure `sp_helpdb` with the source database name as the parameter, as shown here:

```
EXEC SP_HELPDB AdventureWorks
Go
```

The detailed file allocations of this database are as follows:

Name	FileID	File Name
AdventureWorks_Data	1	C:\Server\ MSSQL10.SQL08DE01\MSSQL\DATA\AdventureWorks_Data.mdf
AdventureWorks_Log	2	C:\Server\ MSSQL10.SQL08DE01\MSSQL\DATA\AdventureWorks_Log.ldf

You need to worry about only the data portion of the database for the snapshot:

```
CREATE DATABASE SNAP_AdventureWorks_6AM
ON
  ( NAME = AdventureWorks_Data,
    FILENAME= 'C:\Server\ MSSQL10.SQL08DE01\MSSQL\DATA\SNAP_AW_data_6AM.snap'
  )
AS SNAPSHOT OF AdventureWorks
go
```

Creating the database snapshot is really that easy. Now let's walk through a simple example showing how to create a series of four database snapshots against the AdventureWorks source database that represent snapshots six hours apart (refer to Figure 32.6). Here is the next snapshot to be run at 12:00 p.m.:

```
CREATE DATABASE SNAP_AdventureWorks_12PM
ON
  ( NAME = AdventureWorks_Data,
    FILENAME= 'C:\Server\ MSSQL10.SQL08DE01\MSSQL\DATA\SNAP_AW_data_12PM.snap' )
AS SNAPSHOT OF AdventureWorks
go
```

These represent snapshots at equal time intervals and can be used for reporting or reverting.

NOTE

We use a simple naming convention for the database names for snapshots and for the snapshot files themselves. The database snapshot name is the word `SNAP`, followed by the source database name, followed by a qualifying description of what this snapshot represents, all separated with underscores. For example, a database snapshot that represents a 6:00 a.m. snapshot of the AdventureWorks database would have this name:

```
"SNAP_AdventureWorks_6AM"
```

The snapshot file-naming convention is similar. The name would start with the word `SNAP`, followed by the database name that the snapshot is for (AdventureWorks, in our example), followed by the data portion indication (for example, `data`, `data1`), a short identification of what this snapshot represents (for example, `6AM`), and then the file-name extension `.snap` to distinguish it from `.mdf` and `.ldf` files. For example, the snapshot filename for the preceding database snapshot would look like this:

```
"SNAP_AdventureWorks_data_6AM.snap"
```

We use the AdventureWorks database for this example. AdventureWorks currently uses only a single data file allocation for its data portion. Here's how you create the first snapshot, to reflect a 6:00 a.m. snapshot:

1. Create the snapshot on the source database AdventureWorks:

```
Use [master]
go
CREATE DATABASE SNAP_AdventureWorks_6AM
ON ( NAME = AdventureWorks_Data, FILENAME= 'C:\Program Files\
Microsoft SQL Server\MSSQL10.SQL08DE01\MSSQL\DATA\
SNAP_AdventureWorks_data_6AM.snap')
AS SNAPSHOT OF AdventureWorks
Go
```

2. Look at this newly created snapshot from the SQL Server instance point of view, using a SQL query against the `sys.databases` system catalog, as follows:

```
Use [master]
go
SELECT name,
       database_id,
       source_database_id, — source DB of the snapshot
       create_date,
       snapshot_isolation_state_desc
FROM sys.databases
Go
```

This shows the existing source database and the newly created database snapshot:

name	database_id	source_database_id	create_date	snapshot_isolation_state_desc
AdventureWorks	7	NULL	2009-02-17 23:37:02.763	OFF
SNAP_AdventureWorks_6AM	9	7	2009-12-05 06:18:36.597	ON

Note that `source_database_id` for the newly created database snapshot contains the database ID of the source database. Of course, you can also look at the database snapshot properties by using SQL Server Management Studio, as shown in Figure 32.11.

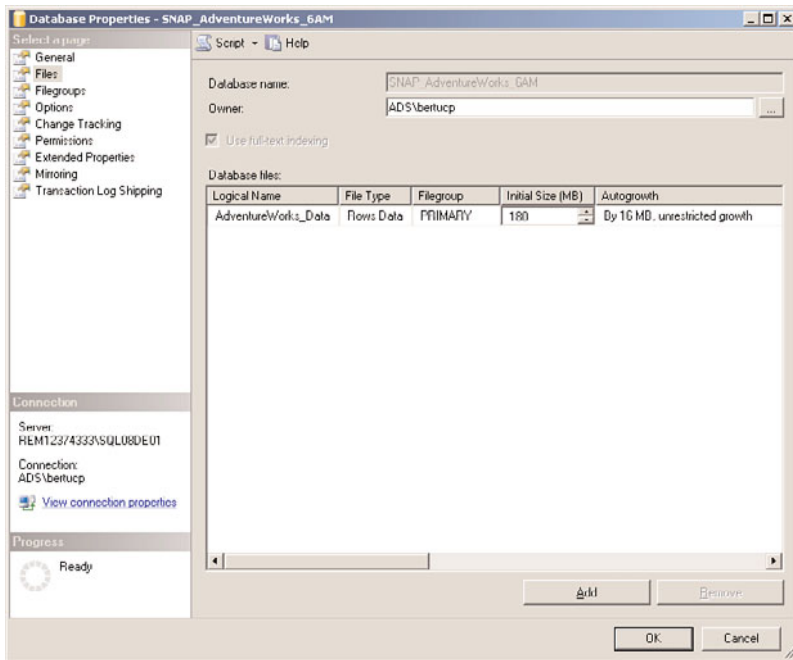

FIGURE 32.11 Using SQL Server Management Studio to view the database snapshot properties.

3. Look at the newly created physical file for the sparse file (for the database snapshot) by querying the `sys.master_files` system catalog:

```
SELECT database_id, file_id, name, physical_name
FROM sys.master_files
WHERE Name = 'AdventureWorks_data'
```

```
and is_sparse = 1
go
```

Note that we are focusing on only the sparse files for the newly created database snapshot (that is, the `is_sparse = 1` qualification). This query results in the following:

```
database_id file_id      name                physical_name
-----
9           1           AdventureWorks_Data C:\Prog...\DATA\
                               SNAP_AdventureWorks_data_6AM.snap
```

- To see the number of bytes that a snapshot sparse file is burning up, you can issue a series of SQL statements against system catalog views/tables by using `fn_virtualfilestats` and `sys.master_files`. However, the following is a quick-and-dirty stored procedure that should make this task much easier. Just create this stored procedure on your SQL Server instance (in the master database), and you can use it to see the sizes of any database snapshot sparse file on your server (also available in the downloadable SQL script file for this chapter):

```
CREATE PROCEDURE SNAP_SIZE_UNLEASHED2008
    @DBDATA varchar(255) = NULL
AS
if @DBDATA is not null
    BEGIN
        SELECT B.name as 'Sparse files for Database Name',
            A.DbId, A.FileId, BytesOnDisk      FROM fn_virtualfilestats
        (NULL, NULL) A,
            sys.master_files B
        WHERE A.DbID = B.database_id
            and A.FileID = B.file_id
            and B.is_sparse = 1
            and B.name = @DBDATA
    END
ELSE
    BEGIN
        SELECT B.name as 'Sparse files for Database Name',
            A.DbId, A.FileId, BytesOnDisk
        FROM fn_virtualfilestats (NULL, NULL) A,
            sys.master_files B
        WHERE A.DbID = B.database_id
            and A.FileID = B.file_id
            and B.is_sparse = 1
    END
Go
```

When the `SNAP_SIZE_UNLEASHED2008` stored procedure is created, you run it with or without the name of the data portion of the database for which you have created a snapshot. If you do not supply the data portion name, you see all sparse files and

their sizes on the SQL Server instance. The following example shows how to execute this stored procedure to see the sparse file current size for the AdventureWorks_data portion:

```
EXEC SNAP_SIZE_UNLEASHED2008 'AdventureWorks_Data'
Go
```

This results in the detail bytes that the sparse file is using on disk:

```
Sparse files for Database Name DbId FileId BytesOnDisk
-----
AdventureWorks_Data          9      1    196608
```

Currently, the sparse file is very small (196KB) because it was recently created. Little to no source data pages have changed, so it is basically empty right now. It will start growing as data is updated in the source database and data pages are copied to the sparse file (by the copy-on-write mechanism). You can use the SNAP_SIZE_UNLEASHED2008 stored procedure to keep an eye on the sparse file size.

5. Believe it or not, the database snapshot is ready for you to use. The following SQL statement selects rows from this newly created database snapshot for a typical point-in-time-based query against the CreditCard table:

```
Use [SNAP_AdventureWorks_6AM]
go
SELECT [CreditCardID]
       ,[CardType]
       ,[CardNumber]
       ,[ExpMonth]
       ,[ExpYear]
       ,[ModifiedDate]
FROM [SNAP_AdventureWorks_6AM].[Sales].[CreditCard]
WHERE CreditCardID = 1
go
```

This statement delivers the correct, point-in-time result rows from the database snapshot:

```
CreditCardID CardType      CardNumber      ExpMonth ExpYear
              ModifiedDate
-----
1            SuperiorCard  33332664695310  1        2010
              2009-12-03 00:00:39.560
```

You can take a look at how this all looks from SQL Server Management Studio. Figure 32.12 shows the database snapshot database SNAP_AdventureWorks_6AM along with the source database AdventureWorks. It also shows the results of the system queries on these database object properties.

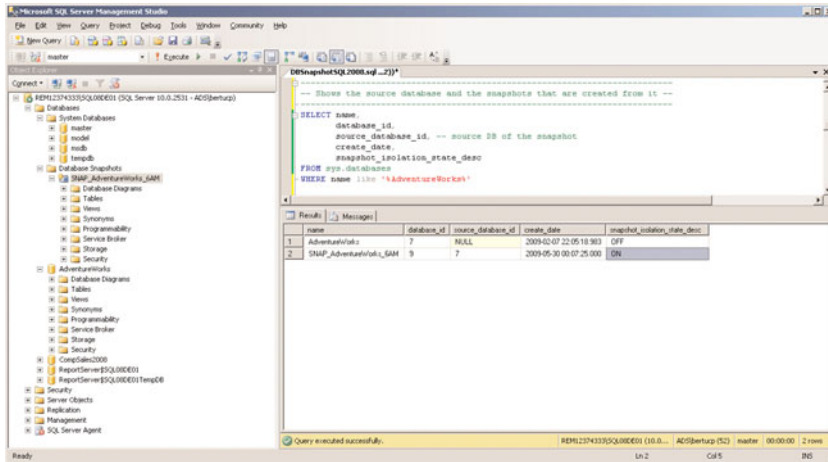

FIGURE 32.12 SSMS snapshot properties, system query results, and snapshot isolation state.

You are now in the database snapshot business!

Breaking Down a Database Snapshot

If you want to get rid of a snapshot or overlay a current snapshot with a more up-to-date snapshot, you simply use the `DROP DATABASE` command and then create it again. The `DROP DATABASE` command immediately removes the database snapshot entry and all sparse file allocations associated with the snapshot. It's very simple indeed. The following example drops the database snapshot just created:

```

Use [master]
go
DROP DATABASE SNAP_AdventureWorks_6AM
go

```

If you'd like, you can also drop (delete) a database snapshot from SQL Server Management Studio by right-clicking the database snapshot entry and choosing the Delete option. However, it's best to do everything with scripts so that you can accurately reproduce the same action over and over.

Reverting to a Database Snapshot for Recovery

If you have a database snapshot defined for a source database, you can use that snapshot to revert the source database to that snapshot's point-in-time milestone. In other words, you consciously overlay a source database with the point-in-time representation of that database (which you got when you created a snapshot). You must remember that you will lose all data changes that occurred from that point-in-time moment and the current state of the source database. However, this may be exactly what you intend.

Reverting a Source Database from a Database Snapshot

Reverting is just a logical term for using the `DATABASE RESTORE` command with the `FROM DATABASE_SNAPSHOT` statement. It effectively causes the point-in-time database snapshot to become the source database. Under the covers, much of this is managed from the system catalog metadata level. However, the results are that the source database will be in exactly the same state as the database snapshot. When you use a database snapshot as the basis of a database restore, all other database snapshots that have the same source database must first be dropped. Again, to see what database snapshots may be defined for a particular database, you can execute the following query:

```
Use [master]
go
SELECT name,
       database_id,
       source_database_id, -- source DB of the snapshot
       create_date,
       snapshot_isolation_state_desc
FROM sys.databases
Go
```

This query shows the existing source database and the newly created database snapshot, as follows:

name	database_id	source_database_id	create_date	snapshot_isolation_state_desc
AdventureWorks	7	NULL	2009-02-17 23:37:02.763	OFF
SNAP_AdventureWorks_6AM	9	7	2009-12-05 06:01:36.597	ON
SNAP_AdventureWorks_12PM	10	7	2009-12-05 12:00:36.227	ON

In this example, there are two snapshots against the AdventureWorks database. The one you don't want to use when reverting must be dropped first. Then you can proceed to restore the source database with the remaining snapshot that you want. These are the steps:

1. Drop the unwanted snapshot(s):

```
Use [master]
go
DROP DATABASE SNAP_AdventureWorks_12PM
go
```

2. Issue the `RESTORE DATABASE` command with the remaining snapshot:

```
USE [master]
```

```

go
RESTORE DATABASE AdventureWorks FROM DATABASE_SNAPSHOT =
'SNAP_AdventureWorks_6AM'
go

```

When this process is complete, the source database and snapshot are essentially the same point-in-time database. But the source database quickly diverges, as updates begin to flow in again.

Using Database Snapshots with Testing and QA

Reverting to a “golden” copy of a database via a database snapshot is going to be popular going forward because of the simplicity that creating and reverting provides. Testing and QA groups will thrive on this feature, and this will directly affect the velocity of testing in your organization. With the increase in the frequency and stability of your testing and QA environments, a direct improvement in the quality of your application should be attainable. Essentially, these are the steps:

1. Create the golden database snapshot *before* you run your testing:

```

Use [master]
go
CREATE DATABASE SNAP_AdventureWorks_GOLDEN
ON ( NAME = AdventureWorks_Data, FILENAME= 'C:\Program Files\
Microsoft SQL Server\ MSSQL10.SQL08DE01\MSSQL\DATA\
SNAP_AdventureWorks_data_GOLDEN.snap')
AS SNAPSHOT OF AdventureWorks
Go

```

2. Run tests or QA to your heart's content.
3. Revert to the golden copy when the testing is completed so that the process can be repeated again, regression testing can be run, stress testing can be done, performance testing can be started, or further application testing can be done:

```

USE [master]
go
RESTORE DATABASE AdventureWorks
FROM DATABASE_SNAPSHOT = 'SNAP_AdventureWorks_GOLDEN'
go

```

Setting Up Snapshots Against a Database Mirror

If you are using database mirroring to improve your availability, you can also create a database snapshot against this mirrored database and expose the snapshot to your reporting users. Doing so further enhances the overall database availability to all end users

(transactional and reporting users). In addition, it serves to isolate the reporting users from the transactional users. The reporting users are connected to the mirror server's version of the database (via a database snapshot of the mirrored database), and their reporting queries do not impact the principal server in any way. Remember that the mirrored database is not usable for any access whatsoever (it is in constant restore mode). SQL Server allows a snapshot to be created against it (refer to Figure 32.10). As mentioned previously, the only real issues arise when the principal server fails over to the mirror database. When the mirror server takes over for the principal, the database snapshot terminates its reporting user connections. The reporting users only need to reconnect to pick up where they left off. However, you now have both transactional and reporting users using the same database server instance, and performance of all is affected.

A possible solution to this situation would be to automatically (or manually) drop the database snapshot on the mirror server if it becomes the principal and create a new snapshot on the old principal server if it is available (it is now the mirror). You then just point all your reporting users to this new database snapshot. This process can be handled fairly easily in an application server layer. This is basically a reciprocal principal/mirror reporting configuration approach that always tries to get the database snapshot that is used for reporting to be on the server that is the mirror server. You would never really want to have active database snapshots on both the principal server and mirror server at the same time.

Reciprocal Principal/Mirror Reporting Configuration

The following steps outline the method to create the snapshot on the mirror, drop it when the mirror becomes the principal, and create a new snapshot against the old principal (now the mirror):

1. Create the database snapshot on a mirrored database server for reporting on the mirror server (REM12374333\SQL08DE02):

```
Use [master]
go
CREATE DATABASE SNAP_AdventureWorks_REPORTING
ON ( NAME = AdventureWorks_Data, FILENAME= 'C:\Program Files\
Microsoft SQL Server\MSSQL10.SQL08DE02\MSSQL\DATA\
SNAP_AdventureWorks_data_REPORTING.snap' )
AS SNAPSHOT OF AdventureWorks
Go
```

As you can see in Figure 32.13, this would be the live configuration of the principal server (REM12374333\SQL08DE01), the mirror server (REM12374333\SQL08DE02), and the reporting database snapshot (SNAP_AdventureWorks_REPORTING), as shown from SQL Server Management Studio.

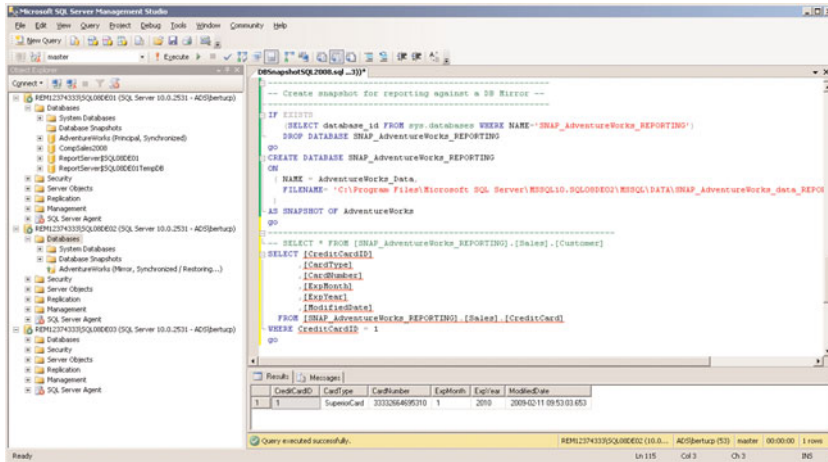

FIGURE 32.13 SQL Server Management Studio, showing database mirroring with a database snapshot for reporting configuration.

If the principal fails over to the mirror, you would drop the database snapshot that is currently created off that database and create a new one on the old principal (now the mirror), as shown in the following steps.

- Drop the reporting database snapshot on the new principal server (the principal is now REM12374333\SQLE08DE02):

```
Use [master]
go
DROP DATABASE SNAP_AdventureWorks_REPORTING
go
```

- Create the new reporting database snapshot on the new mirrored database server (the mirror is now REM12374333\SQLE08DE01):

```
Use [master]
go
CREATE DATABASE SNAP_AdventureWorks_REPORTING
ON ( NAME = AdventureWorks_Data, FILENAME= 'C:\Program Files\
Microsoft SQL Server\MSSQL10.SQLE08DE01\MSSQL\DATA\
SNAP_AdventureWorks_data_REPORTING.snap')
AS SNAPSHOT OF AdventureWorks
Go
```

That's it. You now have your reporting users completely isolated away from your principal server (and the transactional users) again. Life can return to normal very quickly.

Database Snapshots Maintenance and Security Considerations

With regard to database snapshots, several things need to be highly managed: snapshot sparse file size management, data latency management that corresponds to your users' needs, the location of the sparse files within your physical deployment, the sheer number of database snapshots you are willing to support against a single database instance, and the security and access needs of users of database snapshots.

Security for Database Snapshots

By default, you get the security roles and definitions that you have created in the source database available to you within the database snapshot *except* for roles or individual permissions that you have in the source database used for updating data or objects. This is referred to as “inherited from the source database.” These updating rights are not available to you in a database snapshot. A database snapshot is a read-only database! If you have specialized roles or restrictions you want to be present in the database snapshot, you need to define them in the source database, and you get them instantly. You manage from a single place, and everyone is happy.

Snapshot Sparse File Size Management

Sparse file size is probably the most critical aspect to deal with when managing database snapshots. It is imperative that you keep a close watch on the growing size of any (and all) database snapshot sparse files you create. If your snapshot runs out of space because you didn't manage file size well, it becomes suspect and is not available to use. The only path out of this scenario is to drop the snapshot and re-create it. Following are some issues to consider for sparse files:

- ▶ Monitor sparse files regularly. Make use of stored procedures such as the `SNAP_SIZE_UNLEASHED2008` stored procedure to help with this situation.
- ▶ Pay close attention to the volatility of the source database. This rate of change directly translates to the size of the sparse file and how fast it grows. The rule of thumb is to match your drop and re-create of a database snapshot frequency to when the sparse file is at around 30% of the size of the source database. Your data latency user requirements may demand a faster rate of drop/re-create.
- ▶ Isolate sparse files away from the source database data files. You do not want to compete with disk arm movement in any way. Always work to get disk I/O as parallel as possible.

Number of Database Snapshots per Source Database

In general, you shouldn't have too many database snapshots defined on a database because of the copy-on-write overhead each snapshot requires. However, this all depends on the volatility of the source database and a server's capacity. If there is low volatility and

the server is not using much CPU, memory, and disk capacity, this database could more readily support many separate database snapshots at once. If the volatility is high and CPU, memory, and perhaps disk capacity are saturated, you should minimize drastically the number of database snapshots.

Summary

Database snapshots can be thought of as an enabling capability with many purposes. They are great for fulfilling point-in-time reporting requirements easily, reverting a database to a point in time (recoverability and availability), insulating a database from issues that may arise during mass updates, and potentially reducing the processing impact of querying against the primary transactional databases (via database mirroring and database snapshots). You must remember that database snapshots are point in time and read-only. The only way to update a snapshot is to drop it and re-create it. Data latency of this point-in-time snapshot capability must always be made very clear to any of its users.

Database snapshots are snapshots of the entire database, not a subset. This clearly makes data snapshots very different from alternative data access capabilities such as data replication and materialized views. This feature has been made possible via a major breakthrough from Microsoft called copy-on-write technology. This is certainly an exciting extension to SQL Server but is not to be used as a substitute for good old database backups and restores. This is one capability that we recommend you consider using as soon as possible.

Chapter 33, “Database Maintenance,” provides a detailed explanation of the best practices surrounding maintaining a database.

CHAPTER 33

Database Maintenance

Database maintenance is an essential part of database administration needed to keep databases healthy. It includes tasks performed after your database is created to ensure the integrity of the data in the database, provide performance improvements, and help keep your database safe.

This chapter examines some of the key tasks that should be included in your database maintenance plan. It discusses the means for creating these plans, including tools such as the Maintenance Plan Wizard that is part of SQL Server 2008. These tools make the creation of a solid database maintenance plan easier and provide a framework that allows you to create the plan once and let automation do the rest of the work.

What Needs to Be Maintained

The core tasks related to the maintenance of a SQL Server database are backing up the database and log, rebuilding indexes, updating statistics, and running integrity checks against the database. These ongoing, repetitive tasks are best run on a scheduled basis and are the backbone of the maintenance plan. Other tasks related to maintenance involve managing access by the users, maintaining data files, and monitoring performance. These tasks are more apt to be performed on an ad hoc basis when the need arises.

IN THIS CHAPTER

- ▶ What's New in Database Maintenance
- ▶ The Maintenance Plan Wizard
- ▶ Managing Maintenance Plans Without the Wizard
- ▶ Executing a Maintenance Plan
- ▶ Maintenance Without a Maintenance Plan
- ▶ Database Maintenance Policies

What's New in Database Maintenance

The required database maintenance tasks in SQL Server 2008 have remained the same as in earlier versions, and the tools to perform that maintenance are generally the same as they were in SQL Server 2005. Maintenance plans are still the core tool for performing database maintenance. These plans and the tools to create the plans (such as the Maintenance Plan Wizard) look and behave much like they did in SQL Server 2005. Enhancements to the maintenance plans that were introduced in SQL Server 2005 service packs have been carried on to SQL Server 2008.

One new feature related to database maintenance in SQL Server 2008 is the introduction of Database Maintenance Policies (a subset of the Policy-Based Management feature introduced in SQL Server 2008). Policy-Based Management is discussed in detail in Chapter 22, “Administering Policy-Based Management.” In this chapter, we briefly cover the basics of using policies for performing database maintenance.

The Maintenance Plan Wizard

The Maintenance Plan Wizard is a tool that is available in SSMS. It provides an automated means for creating the basic tasks needed to maintain a database. It does not include all the tasks available for use in a maintenance plan but is a great starting point that allows you to quickly generate the basic elements of a good plan.

You launch the Maintenance Plan Wizard by expanding the Management node in SSMS and then right-clicking Maintenance Plans and selecting Maintenance Plan Wizard. The Maintenance Plan Wizard is like most other Microsoft wizards in that it presents sequential dialog boxes that allow you to incrementally provide the information needed to create the wizard's objective.

The Maintenance Plan Wizard first displays an introductory dialog box. When you click Next, it displays a dialog box (like the one shown in Figure 33.1) that allows you to specify the name and a description for your maintenance plan. You should choose a naming convention that will allow you to easily identify a maintenance plan and the type of maintenance it is performing. The name is displayed in the Object Explorer tree, and a good naming convention will make it easier to locate the plan you want.

The Select Plan Properties screen also allows you to specify the schedule for the maintenance plan. This schedule will be tied to the corresponding scheduled job that is created when the Maintenance Plan Wizard completes. You will find that the scheduling dialog that appears when you click on the Change button is very flexible and consistent with other places in SQL Server where a schedule can be defined.

After you name the maintenance plan and specify the schedule, you can click Next. The dialog box that appears next allows you to select the maintenance tasks you would like to perform on the server. Figure 33.2 shows the Select Maintenance Tasks dialog, with the tasks that are available from the wizard. You can select more than one task for a given plan. As mentioned earlier, the tasks listed in the wizard are not all the tasks available in a maintenance plan.

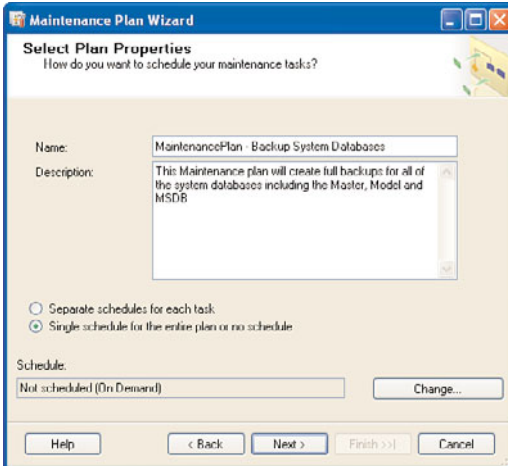

FIGURE 33.1 Setting the Maintenance Plan Properties using the Maintenance Plan Wizard.

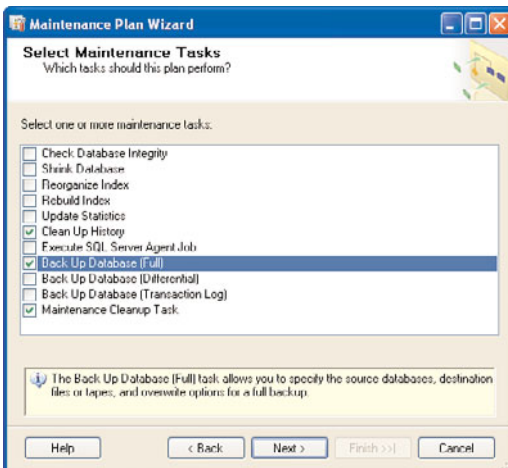

FIGURE 33.2 Selecting maintenance tasks in the Maintenance Plan Wizard.

The dialog box that appears next, as shown in Figure 33.3, allows you to specify the order in which the tasks are executed. Obviously, the order of the tasks can be a critical factor and is dependent on the type of tasks you are running. You can click the Move Up and Move Down buttons to change the order of the tasks.

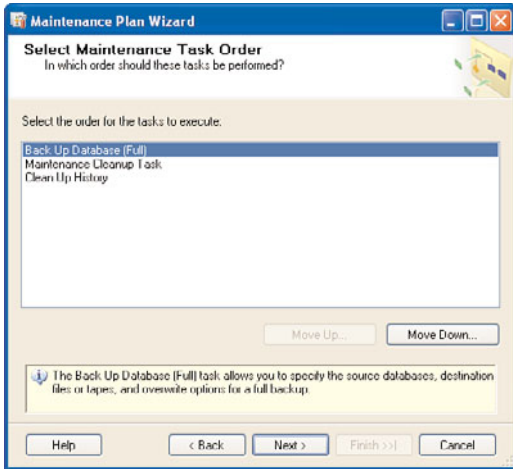

FIGURE 33.3 Selecting the order of the maintenance tasks in the Maintenance Plan Wizard.

The dialog boxes discussed so far are consistent for all the maintenance plans. The dialog boxes that follow are dependent on the tasks selected for the plan. Each task has a relevant set of properties that are displayed for entry in a subsequent dialog box. The following sections cover some of the common maintenance tasks and the wizard screens that relate to them.

Backing Up Databases

Backing up databases is the most basic element of a maintenance plan—and probably the most important part. The importance of backups and the role they play are discussed in detail in Chapter 14, “Database Backup and Restore,” but basically, backups are needed to help limit the amount of data loss. For example, in the event of a disk drive failure, database backups can be used to restore the database data that was located on that drive.

The database backup options available via a maintenance plan include full, differential, and transaction log backups. The type of backup you select for a plan is heavily dependent on the type of environment you are maintaining and the type of database you are backing up. Databases that have very few changes may only need a nightly full backup and do not require transaction log or differential backups.

In most cases, it is a good idea to take a full backup of your system and user databases each night. Figure 33.4 shows the backup options the wizard displays for a full backup.

To set the properties for a full backup, you need to first define the databases you want to back up. You select the databases by using the Databases drop-down at the top of the screen. This drop-down is unique in that it gives you a variety of radio button options

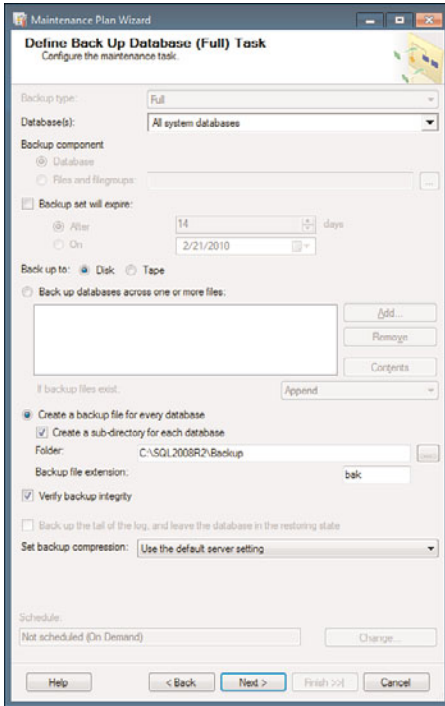

FIGURE 33.4 Full backup options in the Maintenance Plan Wizard.

rather than just a simple list. You can choose to back up all databases, all system databases, or all user databases, or you can select specific databases.

After you select the database(s) you want to back up, you must select a destination for the backup files. The destination includes the type of media (that is, tape or disk) and the file or files on that medium. The option **Back Up Databases Across One or More Files** allows you to specify one or more fixed files that the database backup will always be written to. With this option, you can choose to append each backup to the file(s) or overwrite the contents of the file(s) each time the backup is performed. If you choose to overwrite the backup each time, you have only the latest backup available for restoration. If you choose to append to the file, older backups are retained on this file, and the file continues to grow with each subsequent backup.

The preferred option for creating full backups with the wizard is the option **Create a Backup File for Every Database**. This option creates a separate file for each database in the maintenance plan. The backup file that is created has the database name as the first part of the filename, followed by `_backup_` and then a time stamp that indicates when the backup was created. For example, a backup named `AdventureWorks2008_backup_200608231402.bak` would be a backup file created using this

option for the AdventureWorks2008 database. Multiple versions of backups can be retained with this option, and the identification of the backup is simple because of the naming convention.

CAUTION

You should use the option Back Up Databases Across One or More Files with caution. The pitfall with overwriting the file with this option is that only one backup is available for restoration. When this option is used with the Append option, you can eat up all your disk space if the file is not cleaned up. In addition, if multiple databases are backed up with the plan, all these backups will be spread across the file or files specified for the destination. A separate backup for each database is not created with this option. This can lead to confusion and complicate the restoration process.

Generally speaking, you should steer clear of backing up the database to a single file or set of files. Instead, you should choose the option Create a Backup File for Every Database. This option has fewer pitfalls and requires little attendance.

When you use the Create a Backup File for Every Database option, you need to specify a folder for the database backups to be written to. You can use the default folder, or you can change it to a folder of your choice. It is a good practice to choose a folder on a drive that is different from the drive where your database files reside. Having backups on the same drive as your data could be a big problem if that drive fails and your only backups are on that drive. If you select the option Create a Sub-directory for Each Database, each database has a separate subfolder under the folder specified for the backup.

CAUTION

The main pitfall associated with the option Create a Backup File for Every Database is that many backup files can be created and are not automatically deleted by default. This point has been mentioned already, but it is a critical consideration. The good news is that you can now add the deletion of the older backups to the maintenance plan using the Maintenance Plan Wizard. To accomplish this, you need to select the Maintenance Cleanup task and provide the desired retention information that determines when the older backups are removed.

Another useful option on the Define Back Up Database screen is Verify Backup Integrity. If you select this option, SQL Server checks the integrity of the backup files that were written as part of the backup operation. Selecting this option extends the execution time for the backup plan but is generally a good idea to ensure that you have a viable backup for recovery. It is particularly useful when backups have been written across multiple files. Unfortunately, the backup task does not allow you to utilize the checksum options available with the SQL Server 2008 BACKUP command, but the basic VERIFY option suffices in most instances.

New to SQL Server 2008 is an option to define the compression for the database backup file. The Set Backup Compression drop-down at the bottom of the screen determines whether compression will be used. If the default for the server is set to compress backup or the specific option Compress Backup is selected, the backup file is created in a compressed format that will reduce the size of the backup file and save disk space. The trade-off when using compressed backups is that the creation of these backups takes additional CPU resources during their creation. However, the additional CPU processing time is typically offset by the faster I/O as a result of the reduced size of the backup file.

NOTE

In SQL Server 2008, compressed backups can only be performed in the Enterprise Edition. Beginning in SQL Server 2008 R2, compressed backups can be created in the Standard and all higher editions of SQL Server 2008 R2. Every edition of SQL Server 2008 and later can restore compressed backups, however.

Checking Database Integrity

The Define Database Check Integrity Task screen of the Maintenance Plan Wizard, shown in Figure 33.5, allows you to schedule the database consistency command DBCC CHECKDB, which checks the data pages for inconsistencies and is a good tool for ensuring that a database is healthy. The integrity checks can be made before each backup or on an independent schedule.

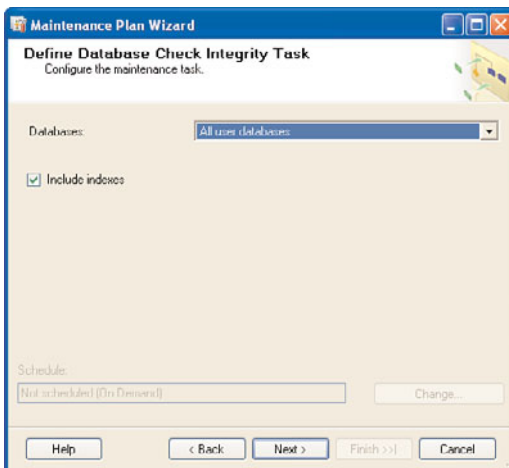

FIGURE 33.5 The Define Database Check Integrity Task screen of the Maintenance Plan Wizard.

The options available for checking database integrity via the wizard are limited.

Checking the Include Indexes check box causes integrity checks to be performed on the index pages as well. Checking the index pages for each table extends the amount of time

the task runs, but it is the most thorough way to perform an integrity check. If problems are found, you can run the `DBCC CHECKDB` command manually with additional options to repair the problems. For more information on resolving DBCC errors, see Chapter 56, “SQL Server Disaster Recovery Planning” (on the CD). In some cases, the problems cannot be fixed without the possibility of data loss. You should consider contacting Microsoft support if you receive consistency errors in a critical database.

Shrinking Databases

The Define Shrink Database Task page of the Maintenance Plan Wizard, shown in Figure 33.6, can be useful for keeping the size of your databases manageable. As its name implies, this task is used to reduce the overall size of a database. This task’s execution is essentially the equivalent to running the `DBCC SHRINKDATABASE` command, and it contains task options that mirror the options available with the DBCC command.

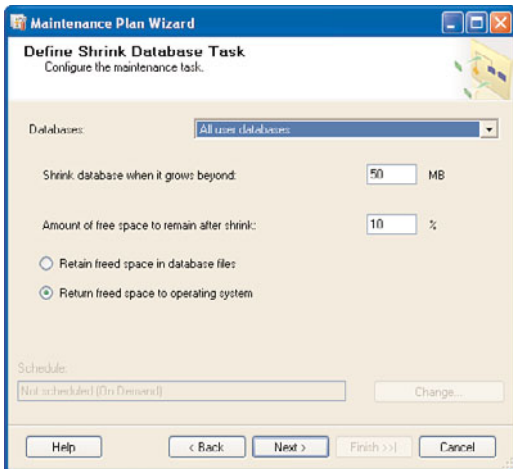

FIGURE 33.6 The Define Shrink Database Task page of the Maintenance Plan Wizard.

The setting *Shrink Database When It Grows Beyond* specifies the overall database size that must be exceeded for the shrink operation to occur. You set the size in megabytes, and it must be a whole number. If the database, including data and log files, is smaller than this size, the shrink operation does not occur.

The remaining options determine how the shrink operation runs when the shrink threshold is exceeded. The *Amount of Free Space to Remain After Shrink* option determines how much space is left in the database files after the shrink operation is finished. This is a target percentage and may not be feasible if the amount of disk space is limited. SQL Server does its best to achieve the target percentage, but it is not guaranteed. Generally, in environments where you have abundant disk space, it is best to leave at least 10% free after the operation so that the database can grow without the need for expanding the size of the database files.

The last settings on the screen determine how free space beyond the target percentage is handled. For example, let's assume that a large number of rows were deleted from a database and the target free space percentage is set to 10%. The shrink operation is run and is able to shrink the database such that 40% is now free. You can choose to retain in the database files the 30% beyond the target that is free by selecting the Retain Freed Space in Database Files option. Choosing this option is the same as running the `DBCC SHRINK DATABASE` command with the `NOTRUNCATE` option. With this option, you do not see any changes to the size of the database files, and the free space on the disk remains unchanged.

The other option, Return Freed Space to Operating System, can reduce the size of the database files and return that space to the operating system. This option utilizes the `TRUNCATEONLY` option that comes with the `DBCC SHRINK DATABASE` command and is the option needed to free up disk space on a server.

TIP

Running the Shrink Database task for every database is not necessarily a good idea. With the Shrink Database task, the database is condensed so that the data is located on contiguous pages in the database data file(s). This involves the movement of pages from one part of the file to another. This movement can cause fragmentation in tables and indexes. The fragmentation can, in turn, cause performance problems and undo work that may have been done with other tasks, such as rebuilding the indexes.

The other problem with shrinking the database relates to the cost of expanding the database at a later time. For example, let's say you have a database that has grown to 1GB. You shrink the database so that it is now only 800MB, but normal use of the database causes it to expand again. The expansion of the database files can be expensive and cause performance problems during the actual expansion, especially on high-volume production systems. The best solution is to purchase the appropriate amount of disk space and size the database so that database files do not need to expand frequently and the shrink operation is not needed. This is easier said than done, but it is the right answer nonetheless.

Maintaining Indexes and Statistics

Maintaining indexes and statistics is essential in most database environments, including those that have frequent changes to the data. These changes can cause tables and their indexes to become fragmented and inefficient. These types of environments can also lead to outdated statistics on indexes. Outdated statistics can cause the query engine to make less-than-optimal choices when determining the best access path to the data.

The maintenance of indexes and statistics is facilitated through the use of three different tasks in the Maintenance Plan Wizard: Reorganize Index, Rebuild Index, and Update Statistics. Using the Reorganize Index task is equivalent to running the `ALTER INDEX REORGANIZE` command. This task defragments and compacts clustered and nonclustered indexes on tables and views. This helps improve index-scanning performance and should improve overall response time. The operation is always done online and is also equivalent to running the `DBCC INDEXDEFRAG` command.

Figure 33.7 shows the screen you use to define the Reorganize Index task. This screen allows you select tables, views, or tables and views. You can also select specific tables or views that you want to reorganize. The Compact Large Objects option is equivalent to `ALTER INDEX LOB_COMPACTION = ON`. It causes data in large object (LOB) data types, such as image or text objects, to be compacted.

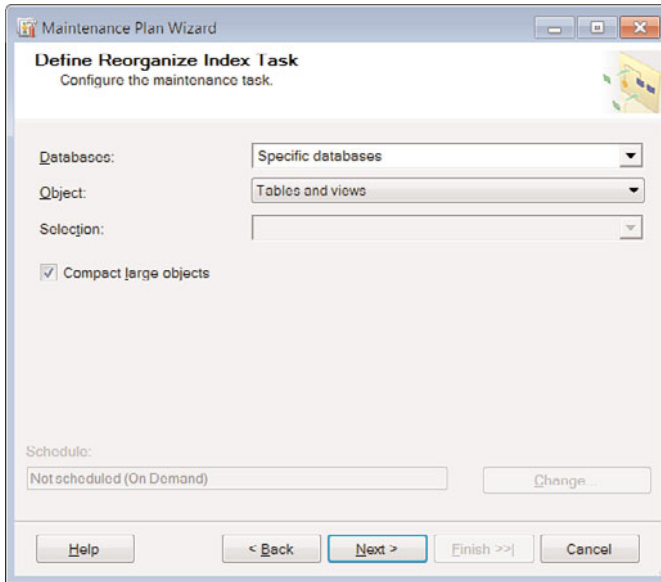

FIGURE 33.7 The Reorganize Index task options in the Maintenance Plan Wizard.

The Reorganize Index task moves the leaf-level pages so that they match the logical ordering of the index. This behavior improves performance, but it is not as extensive as the Rebuild Index task, which is equivalent to the `ALTER INDEX REBUILD` command. It is also equivalent to the `DBCC DBREINDEX` command. When the Rebuild Index task is executed, it rebuilds the indexes from scratch. This rebuilding can achieve the best performance results, but it also has the most impact on users of the database.

Figure 33.8 shows the options available for rebuilding an index with the Maintenance Plan Wizard.

The options for rebuilding are separated into two sections: Free Space Options and Advanced Options. The Free Space Options section pertains to the amount of free space left in the index pages after the rebuild operation completes. This free space is defined by the fill factor for the index. When the Reorganize Pages with the Default Amount of Free Space option is used, the fill factor is reset to the value used when the index was created. The other option, Change Free Space per Page Percentage To, allows you to choose a new fill factor value to be used for all indexes that have been selected for the rebuild operation.

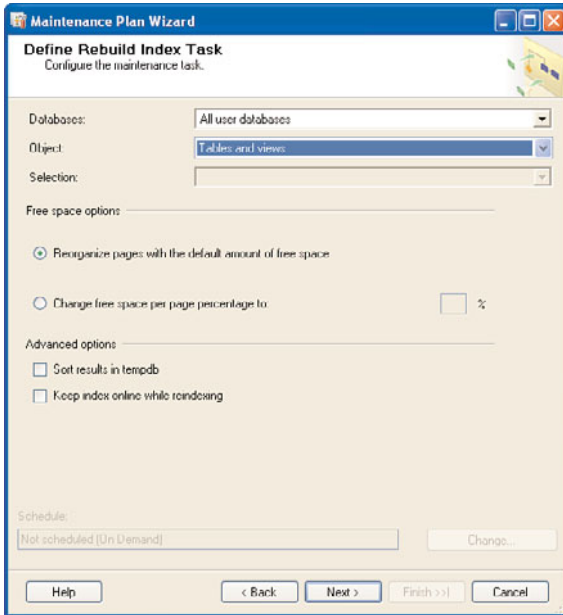

FIGURE 33.8 The Rebuild Index task options in the Maintenance Plan Wizard.

The following advanced Rebuild Index task options are available:

- ▶ **Sort Results in tempdb**—This option is equivalent to the `SORT_IN_TEMPDB` option for the index. It causes `tempdb` to be used to store intermediate results while rebuilding the index. If this option is not used, these intermediate results are stored in the database in which the index resides. Storing the results in `tempdb` can help prevent unnecessary growth of the user database in which the index is being rebuilt.
- ▶ **Keep Index Online While Reindexing**—This option is equivalent to the `ONLINE` option for the index. It allows users to access the underlying table and associated indexes during the index rebuild operation. If this option is not used, the index rebuild is on offline operation, and a table lock is held on the table that is having its indexes rebuilt.

These index options and further information regarding indexes are discussed in Chapter 25, “Creating and Managing Indexes.” Refer to Chapter 34, “Data Structures, Indexes, and Performance,” for details on the performance impact of some of the index options discussed.

The maintenance of statistics can be just as important as the maintenance of indexes on a table. Statistics contain information about the distribution of data in tables and indexes and provide valuable information to the SQL Server query engine. When the statistics are outdated, the query engine may not make the best decisions for getting the data.

Fortunately, there are database options that cause statistics to be automatically updated. The `AUTO UPDATE STATISTICS` and `AUTO UPDATE STATISTICS ASYNCHRONOUSLY` options cause index statistics to be created automatically. However, in some situations the automatic update of statistics does not happen often enough, or the update happens at inopportune times and can cause performance issues. You can address these situations by scheduling the updating of statistics via a maintenance plan, using the Update Statistics task.

Figure 33.9 shows the Maintenance Plan Wizard screen for setting the Update Statistics task options.

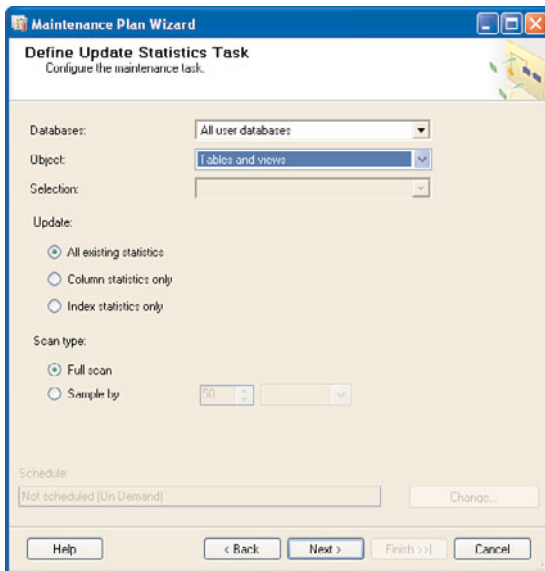

FIGURE 33.9 The Update Statistics task options in the Maintenance Plan Wizard.

The top portion of the Define Update Statistics Task screen is much like the option screens for maintaining indexes. You can choose the type of objects (tables or views) on which you want to update statistics, or you can focus on specific tables or views. The Update options at the bottom of the screen identify the types of statistics to be updated. If the All Existing Statistics option is selected, statistics for both indexes and columns are updated. Statistics on columns exist if the `AUTO CREATE STATISTICS` option has been set to `ON` or the statistics were manually created. The other two update options on the screen allow you to focus the update of statistics on columns only or indexes only.

Scheduling a Maintenance Plan

One of the greatest features of a maintenance plan is that you can schedule it. Scheduling takes manual work off your plate and provides consistency that might be missed if the plan had to be run manually. History is kept for each of the scheduled executions, which provides an audit trail, and notifications can be tied to the scheduled plans to allow a user to respond to failures or other results from the plan.

A schedule can be created for an entire maintenance plan or individual schedules can be created for each task in the plan. The scheduling selection is available on the Select Plan Properties screen, which is one of the first screens displayed while using the Maintenance Plan Wizard (refer to Figure 33.1). Choose the Separate Schedules for Each Task option to create a schedule for each task. The default option is Single Schedule for the Entire Plan or No Schedule. If you choose the option for separate schedules, the Schedule Change button is enabled on the task definition screen and this schedule is tied to that specific task.

Both scheduling options utilize the same scheduling screen. The screen to set scheduling options, the Job Schedule Properties dialog box shown in Figure 33.10, appears when you click on the Schedule Change button. This screen contains the same flexible scheduling features available in the SQL Server Agent.

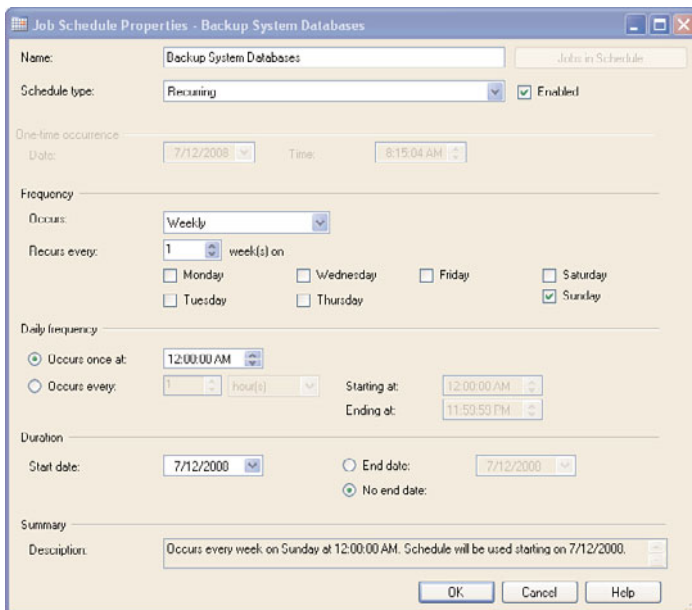

FIGURE 33.10 Scheduling options in the Maintenance Plan Wizard.

When a maintenance plan is saved, a scheduled job with the same name as the maintenance plan is created. The job schedule defined for the maintenance plan is applied to the scheduled job, and the SQL Server Agent manages the execution of the job, based on the schedule. Scheduling changes made to the maintenance plan are automatically reflected in the scheduled job. In addition, if the name of the maintenance plan is changed, the name of the scheduled job is changed as well. If an attempt is made to delete the scheduled job related to the maintenance plan, an error is returned, disallowing the deletion.

TIP

Scheduling in the Maintenance Plan Wizard is limited to one schedule per plan or task depending on which option you choose. You can surpass this limitation by adding additional schedules to the scheduled job associated with the maintenance plan. To do so, you simply open the associated scheduled job located in the SQL Server Agent node in SSMS and create the additional schedules. This capability is handy when you want a varied execution, such as a weekly schedule combined with daily executions of the same plan.

The scheduled job associated with a maintenance plan executes an SSIS package. Figure 33.11 shows an example of the scheduled job step for a SQL Server 2008 maintenance plan.

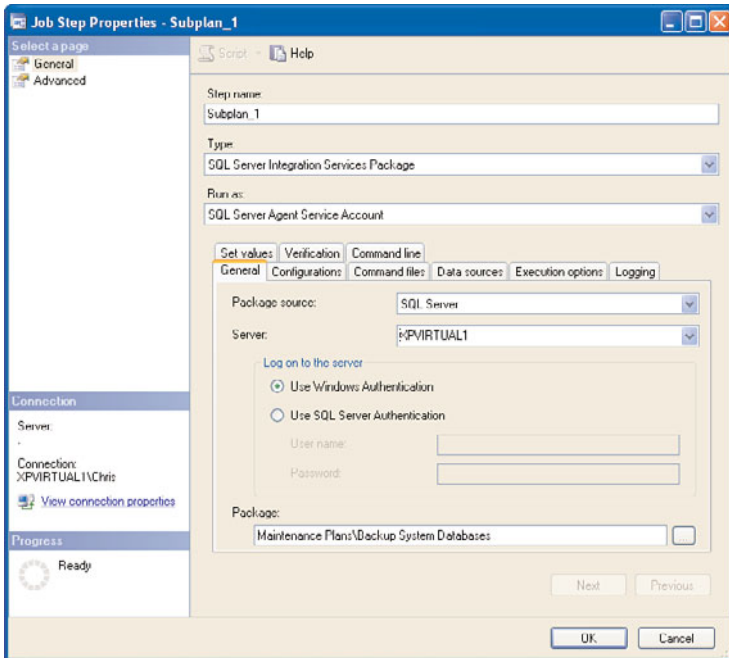

FIGURE 33.11 Scheduling jobs for a maintenance plan.

The utilization of SSIS in the execution of maintenance plans was a significant change in SQL Server 2005. SSIS provides added workflow capabilities and extends the feature set for maintenance plans. The scheduled job step that executes an SSIS package for the maintenance plan shows some of the options and flexibility of SSIS, but the real power is in the maintenance plan editor and the Business Intelligence Design Studio (BIDS) used to manage all SSIS packages. Chapter 52, “SQL Server Integration Services,” provides further details on SSIS. The maintenance plan editor is discussed in the following section.

An integral part of a scheduled maintenance plan is the notification and reporting capabilities. The Select Report Options screen is displayed at the end of the Maintenance Plan Wizard (see Figure 33.12).

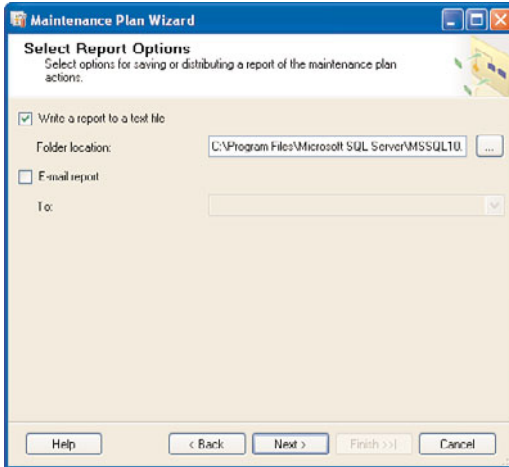

FIGURE 33.12 Reporting options in the Maintenance Plan Wizard.

The option Write a Report to a Text File provides details about the execution of each maintenance plan. This option should be selected for most plans, and it provides excellent information for researching past executions and diagnosing any maintenance plan failures.

The E-mail Report option provides a means for notifying a SQL Server operator when a task fails. You must have Database Mail enabled to be able to use this option, and the operator selected must have a valid email address to receive the notification. You can also edit the job associated with the maintenance plan after it has been created and set up notification there. The notification options on the scheduled job are more extensive than those in the Maintenance Plan Wizard.

CAUTION

If you have a maintenance plan generate a report, you need to make sure you have a means for cleaning up the files. The wizard does not create a plan that deletes the older report files. You can address this situation by modifying the plan after the wizard has created it and adding a Maintenance Cleanup task. This same task can be used to delete old database backup files. The modification of a maintenance plan and addition of the Maintenance Cleanup task are discussed in the following section.

Managing Maintenance Plans Without the Wizard

You can create or modify maintenance plans in SQL Server 2008 without using the Maintenance Plan Wizard. To create a new maintenance plan without the wizard, you right-click the Maintenance Plan node in the Object Explorer and select New Maintenance Plan. You are prompted for a maintenance plan name and then taken to the Design tab for the maintenance plan. The Design tab consists of a properties section at the top of the screen and a plan designer surface that is empty for a new maintenance plan.

Existing maintenance plans are displayed in the Design tab when you right-click the plan and select Modify. Figure 33.13 shows the Design tab for a maintenance plan that was created with the Maintenance Plan Wizard to back up the system databases.

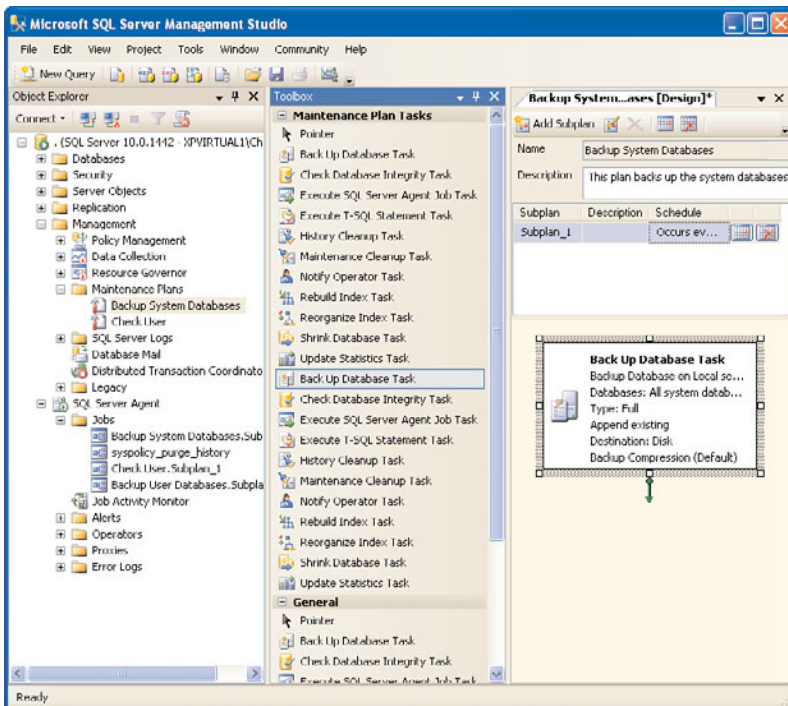

FIGURE 33.13 The maintenance plan Design tab.

The Design tab represents a significant difference from the way maintenance plans were managed in SQL Server 2000. The plan designer surface on the Design tab has drag-and-drop capabilities that allow you to add maintenance tasks to your plan. The available tasks are located in the Toolbox component. The Toolbox and the related tasks are shown in Figure 33.13 in the middle portion of the screen. To add a tool from the Toolbox, you drag the item from the Toolbox to the plan designer surface. Alternatively, you can double-click the task, and the task appears on the plan designer surface.

On the plan designer surface, you can move each of the tasks around, link them to other tasks, and edit them by double-clicking them. You can also right-click a task to edit it, group it with other tasks, autosize it, and gain access to other task options. You can right-click an empty section of the plan designer surface to add annotations or comments that provide additional information about the task or the overall plan.

NOTE

The dialog boxes displayed when you edit a task are unique for each task. The available maintenance plan tasks display an options screen like the one displayed during the execution of the Maintenance Plan Wizard. This provides consistency that is in place regardless of where the task is defined.

33

Adding a task to an existing maintenance plan is a good starting point to become familiar with the workings of the Design tab. Consider, for example, the maintenance plan shown in Figure 33.13. This plan, which was initially created with the Maintenance Plan Wizard, is used to create full database backups of all the system databases. One critical aspect that is missing from this plan is a task to remove older database backups. The task that can help you with this is the Maintenance Cleanup task. If you double-click that task in the Toolbox, the task is added to the plan designer surface, as shown in Figure 33.14.

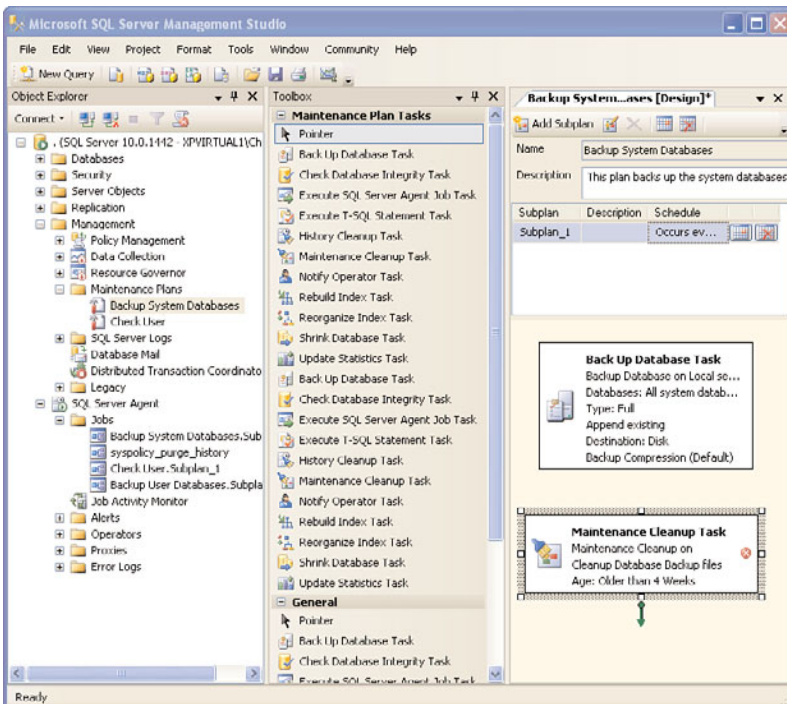

FIGURE 33.14 Adding a task to the plan designer surface.

After you add a task to the plan designer surface, you need to configure it. Note that a small red X icon appears on the right side of the task if the task has not yet been configured. To configure the Maintenance Cleanup task, you double-click it on the plan designer surface. Figure 33.15 shows the screen that appears so you can configure the Maintenance Cleanup task.

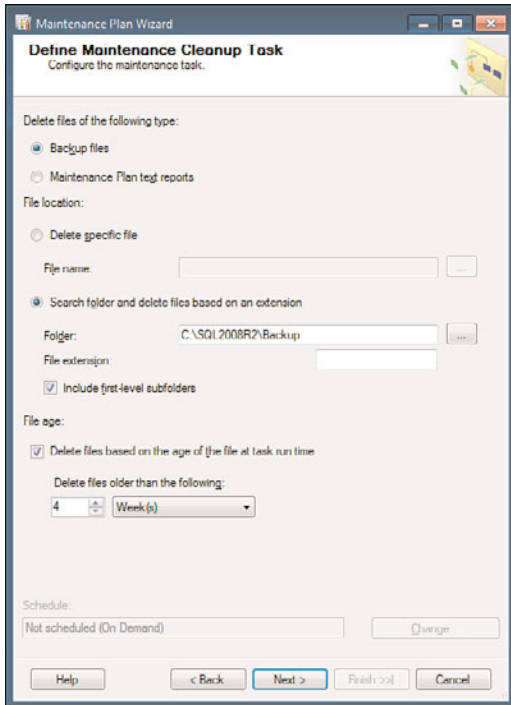

FIGURE 33.15 Configuring the Maintenance Cleanup task.

You can use the Maintenance Cleanup task to clean up old backup files or maintenance plan text reports. The deletion of older backup files is particularly important because database backups tend to be large files and can use up a significant amount of disk space. The File Location section of the screen enables you to delete a specific file, or you can delete files in a folder based on search criteria. In most cases, you want to search the folder to delete older files.

When cleaning up database backup files, you typically specify the file extension `.bak`. If you chose to write each database's backups to a separate folder, you should choose the Include First-Level Subfolders options, which allows you to search all first-level subfolders that exist under the folder specified. This simplifies the cleanup process and eliminates the need to have a separate cleanup task for each subfolder.

In the last section of the configuration screen for the Maintenance Cleanup task, you specify how old a file must be in order to be deleted. The default is four weeks, but you

can adjust this setting to the desired time frame by using the related drop-downs. If you uncheck Delete Files Based on the Age of the File at Task Run Time, all files in the folder or subfolders are deleted, regardless of age.

NOTE

The deletion of database backup files is not based on the file dates or the name of the backup file. The Maintenance Cleanup task uses a procedure named `xp_delete_file` that examines the database backup and time the backup was created. Renaming the database backup file does not affect its inclusion in the deletion process.

After configuring the options for the Maintenance Cleanup task, you can click the View T-SQL button at the bottom of the screen. This feature reveals what is going on behind the scenes when the plan executes. Prior to SQL Server 2005, you had to obtain this kind of information by using the Profiler.

When you click OK, the task is ready to use in the maintenance plan. The task runs in parallel with the other tasks defined in the plan unless a precedence or link is established between the tasks. To establish a link between the tasks, you select the first task that you want to execute. When the task is selected, a green arrow is shown at the bottom of the task's box in the plan designer surface. You click the green arrow and drag it to the task that you want to run next. The green arrow is then connected to the other task. If you double-click the green arrow (or right-click and choose Edit), the Precedence Constraint Editor appears, as shown in Figure 33.16.

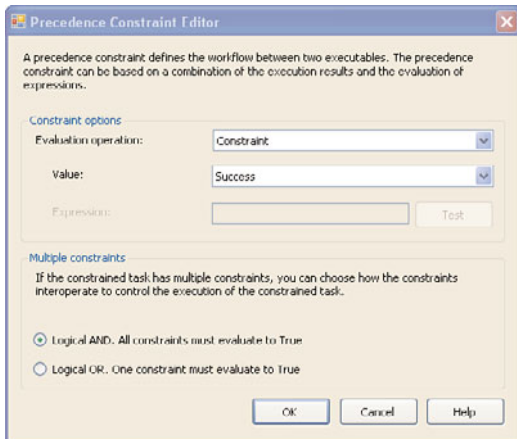

FIGURE 33.16 The Precedence Constraint Editor.

The paragraph at the top of the Precedence Constraint Editor gives a good description of what a precedence constraint is. In short, it can link tasks together based on the results of their execution. For example, if a backup database task succeeds, a Maintenance Cleanup

task can be defined to run next. You can also set the constraint value so that the next task will run only if the first task fails, or you can have the next task run based on the prior task's completion, regardless of whether it succeeds or fails. In addition, you can link multiple tasks together with precedence. You define the logical relationship between tasks in the Multiple Constraints section of the Precedence Constraint Editor.

The workflow and relationships that can be defined between tasks for a maintenance plan are extensive and beyond the scope of this chapter. Many of the workflow concepts are similar to those of the DTS designer in SQL Server 2000 and the SSIS designer in SQL Server 2008.

Executing a Maintenance Plan

Maintenance plans that have been scheduled run automatically according to the schedule defined. You can also run maintenance plans manually by right-clicking a maintenance plan and selecting **Execute** or by selecting the SQL Server Agent job associated with the maintenance plan and starting the job. The execution behavior is different, depending on the means you use. If you choose to run the maintenance plan from the Management node, the SSIS package is launched, and the **Execute Maintenance Plan** window displays the current status of the plan execution.

If you run the SQL Server Agent job to execute the maintenance plan, a dialog box indicating the execution status of the job appears. The dialog does not indicate success for the maintenance plan until the entire maintenance plan has completed. The dialog box for the job can be closed, and the job will still continue to run. The **Execute Maintenance Plan** window, on the other hand, does not have an option to close it, and it must stay open until the plan completes.

There are two other means for monitoring the execution of maintenance plans. The Job Activity Monitor shows a status of executing while a maintenance plan is executing. You can set the refresh settings on the Job Activity Monitor to auto-refresh for the desired increment. You can also monitor the execution by establishing a connection to the SSIS server in SSMS. To establish an SSIS connection in SSMS, you click the **Connect** drop-down in the Object Explorer and choose **Integration Services**. Figure 33.17 shows an example of the Object Explorer with an Integration Services connection.

The Integration Services connection in the Object Explorer shows the packages that are running in addition to the packages that have been created. If you expand the **Stored Packages** node and navigate to the **MSDB** node, you see a node named **Maintenance Plans** that shows all the SSIS packages that have been created. You can also edit the package with **BIDS**, but that topic is beyond the scope of this chapter. See Chapter 52 for more information.

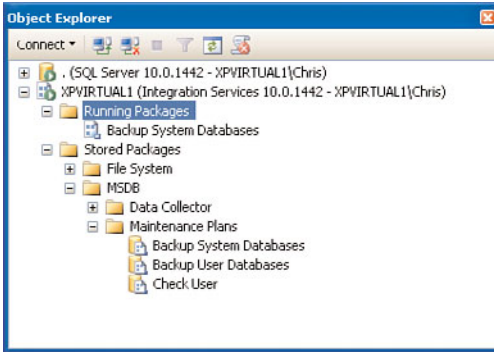

FIGURE 33.17 The Object Explorer with an Integration Services connection.

NOTE

SSIS does not need to be installed on the SQL Server machine to be able to create and execute maintenance plans. In the initial release of SQL Server 2005, this was a requirement but was changed with SQL Server 2005 SP2. This change carried over to SQL Server 2008, and maintenance plans are now fully functional with the SQL Server Database Services installation.

Maintenance Without a Maintenance Plan

You can perform database maintenance without the use of the built-in maintenance plans that come with SQL Server. The additional complexity in SQL Server 2008 may steer some people away from the use of these plans. In addition, these plans cannot be scripted, so deployment to multiple environments is not straightforward.

Database maintenance that is performed without a maintenance plan is often performed using custom scripts or stored procedures that execute the T-SQL commands to perform the maintenance. Other methods include manually executing the `SQLMAINT` utility to perform various maintenance tasks such as database backups and consistency checks. Often these maintenance commands or custom scripts are then scheduled to run on a regular basis by manually setting up jobs within the SQL Server Agent job scheduler in SQL Server Management Studio. (For more information on setting up and scheduling jobs in SQL Server Agent, see Chapter 16, “SQL Server Scheduling and Notification.”)

Setting up maintenance tasks manually is a viable option, especially for the more experienced DBA because it requires additional development work and familiarity with the maintenance commands and options. However, even the experienced DBA should consider using maintenance plans because maintenance tasks set up manually may lack the integration with other SQL Server components that is offered with the SQL Server 2008 maintenance plans.

Database Maintenance Policies

Policy-Based Management, a new management feature introduced in SQL Server 2008, allows you to manage your SQL Server instances through clearly defined policies, reducing the potential for administrative errors or oversight. The policy-based framework implements the policies you defined via a Policy Engine, SQL Server Agent jobs, SQLCLR, DDL triggers, and Service Broker. You can choose to have the policies you defined be applied or evaluated against a single server or a group of servers, thus improving the scalability of monitoring and administration.

Policy-Based Management allows you to prescribe the way you want your databases maintained, and the system will help ensure things stay that way. Essentially, Policy-Based Management allows you to define rules for one or more SQL Servers and evaluate them. The goal of this feature is to make it easier for you to manage one or more servers by notifying you when servers are out of compliance with the database maintenance policies you have defined.

For example, you could define a policy to ensure that transaction log backups are being performed on the appropriate intervals on your OLTP databases. Policy-Based Management allows you to determine when one of your databases is not in compliance with your log backup policy. You can set up this policy to be evaluated on demand or via a schedule.

For more information on defining and using policies, see Chapter 22.

Summary

Establishing a database maintenance plan is important. Just like your car or your home, a database needs maintenance to keep working properly. The powerful features available with the SQL Server 2008 maintenance plans and Maintenance Plan Wizard make the creation of a robust maintenance plan relatively easy. If you establish your maintenance plans early in the life of your databases, you will save yourself time and aggravation in the long run.

Chapter 34 delves further into the importance of indexes and their relationship to performance. It expands on the optimization of indexes mentioned in this chapter and describes the role that indexes play in keeping databases running fast.

CHAPTER 34

Data Structures, Indexes, and Performance

A number of factors affect SQL Server performance. One of the key factors is your table and index design; poor table and index design can result in excessive I/O and poor performance. To aid in developing a good table and index design in an effort to improve SQL Server performance by minimizing I/O, you need to have a good understanding of SQL Server data structures and indexes.

Proper table and index design is a key issue in achieving optimum SQL Server application performance. For example, you can often realize substantial performance gains in your SQL Server applications by creating the proper indexes to support the queries and operations being performed. At the same time, it's important to keep in mind that although many indexes on a table can help improve response time for queries and reports, too many indexes can hurt the performance of inserts, updates, and deletes due to the overhead required to maintain the index and data rows. Additionally, other index design decisions, such as which column(s) to create a clustered index on, might be influenced as much by how the data is inserted and modified and what the possible locking implications might be as they are by the query response time alone.

In this chapter, you learn about the underlying structures of databases, tables, rows, and indexes and how SQL Server maintains index and data structures because this information provides a basis for understanding the performance of your tables and indexes. This chapter discusses the storage structures in SQL Server and how these storage structures are maintained and managed. The chapter also discusses how SQL Server evaluates and uses indexes to improve query response time. Using this information, you should have a better understanding of the issues and factors that influence good table and index design.

IN THIS CHAPTER

- ▶ Choosing Indexes: Query Versus Update Performance
- ▶ Identifying Missing Indexes
- ▶ Identifying Unused Indexes

What's New for Data Structures, Indexes, and Performance

SQL Server 2008 provides a number of new features related to data structures, indexes, and performance.

Among these new features are *filtered indexes* and *statistics*. Filtered indexes utilize a WHERE clause that filters or limits the number of rows included in the index. The smaller filtered index allows queries run against rows containing data values in the index to run faster. These filtered indexes can also save on the disk space used by the index. A well-designed filtered index can improve query performance, reduce index maintenance costs, and reduce index storage costs compared with full-table indexes.

Also new to SQL Server 2008 is the capability to compress data in indexes and tables to reduce the amount of storage space required and, in turn, reduce the I/O needed for these objects. *Page-level data compression* helps to reduce both storage and memory requirements as the data is compressed both on disk and when brought into the SQL Server data cache. *Row-level compression* isn't true data compression but implements a more efficient storage format for fixed-length data.

Other storage features introduced in SQL Server 2008 to reduce storage space requirements are *sparse columns* and *column sets*. Sparse columns are ordinary columns that use an optimized storage format for NULL values.

FILESTREAM storage was also introduced in SQL Server 2008 as a new storage mechanism for binary large object (BLOB) data. FILESTREAM storage is a property that can be applied to varbinary(max) columns and enables SQL Server applications to store unstructured data, such as documents and images, directly in the NTFS file system while still maintaining the behavior of a database column. The advantages of FILESTREAM storage are improved performance and increased size of BLOB data, expanding from the 2GB limit of image columns to the available space in the file system.

Spatial indexes are new to SQL Server 2008 as well. These indexes are used against spatial data defined by coordinates of latitude and longitude. The spatial data is essential for efficient global navigation. The spatial indexes are grid-based and help optimize the performance of searches against the spatial data.

NOTE

This chapter assumes that you already have an understanding of the different types of indexes and how to define them. For more information on index types and how to create indexes, see Chapter 25, "Creating and Managing Indexes."

Understanding Data Structures

SQL Server DBAs and users do not see data and storage the same way SQL Server does. A DBA or end user sees a database more logically as the following:

- ▶ Databases, physically stored in files
- ▶ Tables and indexes, placed in filegroups within databases
- ▶ Rows, stored in tables

SQL Server internally sees these storage structures at a lower, physical level as

- ▶ Databases, physically stored in data and log files
- ▶ Pages within these files, allocated to tables and indexes
- ▶ Data and index rows, stored in slots on pages

Database Files and Filegroups

Databases in SQL Server 2008 span at least two, and optionally several, database files. There must always be at least one file for data and one file for the transaction log. These database files are normal operating system files created in a directory within the operating system. These files are created when the database is created or when a database is expanded.

Each database file has the following set of properties:

- ▶ **A logical filename**—This name is used for internal reference to the file.
- ▶ **A physical filename**—This name is the actual physical pathname of the file.
- ▶ **An initial size**—If no size is specified for primary data file, its initial size, by default, is the minimum size required to hold the contents of the model database.
- ▶ **An optional maximum size**—A maximum file size limit can be specified.
- ▶ **A file growth increment**—This amount is specified in megabytes or as a percentage.

The information and properties about each file for a database are stored in the database visible via the system catalog view called `sys.database_files`. This view exists in every database and contains information about each of the database files. The master database contains a similar view, `sys.master_files`, that contains file information for all databases within the SQL Server instance. Table 34.1 lists the most useful columns in the `sys.database_files` view.

TABLE 34.1 The **sysfiles** Table

Column Name	Description
file_id	A file identification number that is unique within each database
file_guid	GUID for the file
type	File type (0=rows [that is, data files], 1=log, 2=FILESTREAM, 4=Full-text catalogs prior to SQL Server 2008)
type_desc	Description of the file type (ROWS, LOG, FILESTREAM, FULLTEXT)
data_space_id	0 represents a log file; values > 0 represent the ID of the filegroup the data file belongs to
name	The logical name of the file
filename	The physical name of the file, including path
state	File state (0 = OFFLINE, 1 = RESTORING, 2 = RECOVERING, 3 = RECOVERY_PENDING, 4 = SUSPECT, 6 = OFFLINE, 7=DEFUNCT)
state_desc	Description of the file state (OFFLINE, RESTORING, RECOVERING, RECOVERY_PENDING, SUSPECT, OFFLINE, DEFUNCT)
size	Current size of the file in 8KB pages
max_size	Maximum file size in 8KB pages
growth	File growth setting (0=fixed, >0=autogrow in units of 8KB pages or by percentage if is_percent_growth is set to 1)
is_media_read_only	1=file is on read-only media
is_read_only	1= file is marked read-only
is_sparse	1=file is a sparse file
is_percent_growth	1=growth of file value is percentage

SQL Server uses the file location information visible in the `sys.master_files` catalog view most of the time. However, the Database Engine uses the file location information stored in the primary file to initialize the file location entries in the master database when attaching a database using the `CREATE DATABASE` statement with either the `FOR ATTACH` or `FOR ATTACH_REBUILD_LOG` options.

Every database can have three types of files:

- ▶ Primary data file
- ▶ Secondary data files
- ▶ Log files

In addition, in SQL Server 2008, databases can also have FILESTREAM data files and full-text data files.

Primary Data File

Every database has only one primary database file. The location of the primary database file is stored in the master database (visible via the `filename` column in the `sys.master_files` view). When SQL Server opens a database, it looks for this file and then reads from the file information on the other files defined for the database.

The file extension for the primary database file defaults to `.mdf`. The primary database file always belongs to the default filegroup. It is often sufficient to have only one database file for storing your tables and indexes (the primary database file). The file can, of course, be created on a RAID partition to help spread I/O. However, if you need finer control over placement of your tables across disks or disk arrays, or if you want to be able to back up only a portion of your database via filegroups, you can create additional, secondary data files for a database.

Secondary Data Files

A database can have any number of secondary files (in reality, the maximum number of files per database is 32,767, but that should be sufficient for most implementations). You can put a secondary file in the default filegroup or in another filegroup defined for the database. Secondary data files have the file extension `.ndf` by default.

Following are some situations in which the use of secondary database files might be beneficial:

- ▶ You want to perform a partial backup. A backup can be performed for the entire database or a subset of the database. The subset is specified as a set of files or filegroups. The partial backup feature is useful for large databases, where it is impractical to back up the entire database. When recovering with partial backups, a transaction log backup must also be available. For more information about backups, see Chapter 14, “Database Backup and Restore.”
- ▶ You want more control over placement of database objects. When you create a table or index, you can specify the filegroup in which the object is created. This could help you spread I/O by placing your most active tables or indexes on separate filegroups defined on separate disks or disk arrays.
- ▶ Creating multiple files on a single disk provides no real performance benefit but could help in recovery. If you have a 90GB database in a single file and have to restore it, you need to have enough disk space available to create a new 90GB file. If you don't have 90GB of space available on a single disk, you cannot restore the database. On the other hand, if the database was created with three files each 30GB in size, you more likely will be able to find three 30GB chunks of space available on your server.

The Log File

Each database must have at least one log file. The log file contains the transaction log records of all changes made in a database (for more information on what is contained in the transaction log, see Chapter 31, “Transaction Management and the Transaction Log”). By default, log files have the file extension `.ldf`.

A database can have several log files, and each log file can have a maximum size of 32TB. A log file cannot be part of a filegroup. No information other than transaction log records can be written to a log file.

For more information on the log file and log file management, see Chapter 31.

File Management

In SQL Server 2008, you can specify that a database file should grow automatically as space is needed. SQL Server can also shrink the size of the database if the space is not needed. You can control whether to use this feature along with the increment by which the file is to be expanded. The increment can be specified as a fixed number of megabytes or as a percentage of the current size of the file. You can also set a limit on the maximum size of the file or allow it to grow until no more space is available on the disk.

Listing 34.1 provides an example of a database being created with a 10MB growth increment for the first database file, 20MB for the second, and 20% growth increment for the log file.

LISTING 34.1 Creating a Database with Autogrowth

```
CREATE DATABASE Customer
ON ( NAME='Customer_Data',
    FILENAME='D:\SQL_data\Customer_Data1.mdf',
    SIZE=50,
    MAXSIZE=100,
    FILEGROWTH=10),
    ( NAME='Customer_Data2',
    FILENAME='E:\SQL_data\Customer_Data2.ndf',
    SIZE=100,
    FILEGROWTH=20)
LOG ON ( NAME='Customer_Log',
    FILENAME='F:\SQL_data\Customer_Log.ldf',
    SIZE=50,
    FILEGROWTH=20%)
GO
```

The `Customer_Data` file has an initial size of 50MB, a maximum size of 100MB, and a file increment of 10MB.

The `Customer_Data2` file has an initial size of 100MB, has a file growth increment of 20MB, and can grow until the E: disk partition is full.

The transaction log has an initial size of 50MB; the file increases by 20% with each file growth. The increment is based on the *current* file size, not the size originally specified.

When creating or expanding data files in SQL Server 2008, SQL Server uses fast file initialization. This allows for the fast execution of the file creation and growth. With fast file initialization, the space is added to the data file immediately, but without initializing the logical pages in the data file with zeros. The existing disk content in the data file is not overwritten until new data is written to the files. This provides a huge performance advantage when a data file autogrows while an application is attempting to write data to the database. The application does not need to wait until the space is initialized; it can begin writing to the database immediately.

SQL Server also provides an option to autoshrink databases as well as manually shrink databases. However, shrinking a database is a resource-intensive process and should be done only if it is absolutely imperative to reclaim disk space. Also, if a data file is constantly shrinking and growing, it can lead to excessive file fragmentation at the file system level as well as excessive logical fragmentation within the file, both of which can lead to poor I/O performance.

Using Filegroups

All databases have a primary filegroup that contains the primary data file. There can be only one primary filegroup. If you don't create any other filegroups or change the default filegroup to a filegroup other than the primary filegroup, all files will be in the primary file group unless specifically placed in another filegroup.

In addition to the primary filegroup, you can add one or more filegroups to the database, and a filegroup can contain one or more files. The main purpose of using filegroups is to provide more control over the placement of files and data on your server. When you create a table or index, you can map it to a specific filegroup, thus controlling the placement of data. A typical SQL Server database installation generally uses a single RAID array to spread I/O across disks and create all files in the primary filegroup; more advanced installations or installations with very large databases spread across multiple array sets can benefit from the finer level of control of file and data placement afforded by additional filegroups.

For example, for a simple database such as AdventureWorks, you can create just one primary file that contains all data and objects and a log file that contains the transaction log information. For a larger and more complex database, such as a securities trading system where large data volumes and strict performance criteria are the norm, you might create the database with one primary file and four additional secondary files. You can then set up filegroups so you can place the data and objects within the database across all five files. If you have a table that itself needs to be spread across multiple disk arrays for performance reasons, you can place multiple files in a filegroup, each of which resides on a different disk, and create the table on that filegroup. For example, you can create three files (Data1.ndf, Data2.ndf, and Data3.ndf) on three disk arrays, respectively, and then

assign them to the filegroup called `spread_group`. Your table can then be created specifically on the filegroup `spread_group`. Queries for data from the table are spread across the three disk arrays, thereby improving I/O performance.

If a filegroup contains more than one file, when space is allocated to objects stored in that filegroup, the data is stored proportionally across the files. In other words, if you have one file in a filegroup with twice as much free space as another, the first file has two extents allocated from it for each extent allocated from the second file (extents and space allocation are discussed in more detail later in this chapter).

Listing 34.2 provides an example of using filegroups in a database to control the file placement of the `customer_info` table.

LISTING 34.2 Using a Filegroup to Control Placement for a Table

```
CREATE DATABASE Customer
ON ( NAME='Customer_Data',
     FILENAME='C:\SQLData\Customer_Data1.mdf',
     SIZE=50,
     MAXSIZE=100,
     FILEGROWTH=10)
LOG ON ( NAME='Customer_Log',
        FILENAME='C:\SQLData\Customer_Log.ldf',
        SIZE=50,
        FILEGROWTH=20%)
GO

ALTER DATABASE Customer
ADD FILEGROUP Cust_table
GO

ALTER DATABASE Customer
ADD FILE
( NAME='Customer_Data2',
  FILENAME='G:\SQLData\Customer_Data2.ndf',
  SIZE=100,
  FILEGROWTH=20)
TO FILEGROUP Cust_Table
GO

USE Customer
CREATE TABLE customer_info
(cust_no INT, cust_address NCHAR(200), info NVARCHAR(3000))
ON Cust_Table
GO
```

The `CREATE DATABASE` statement in Listing 34.2 creates a database with a primary database file and log file. The first `ALTER DATABASE` statement adds a filegroup. A secondary database file is added with the second `ALTER DATABASE` command. This file is added to the `Cust_Table` filegroup. The `CREATE TABLE` statement creates a table; the `ON Cust_Table` clause places the table in the `Cust_Table` filegroup (the `Customer_Data2` file on the G: disk partition).

The `sys.filegroups` system catalog view contains information about the database filegroups defined within a database, as shown in Table 34.2.

TABLE 34.2 The **sys.filegroups** System Catalog View

Column Name	Description
<code>name</code>	Name of the data space, unique within the database.
<code>data_space_id</code>	Data space ID number, unique within the database.
<code>type</code>	FG = Filegroup.
<code>type_desc</code>	Description of data space type: <code>ROWS_FILEGROUP</code>
<code>is_default</code>	1 = This is the default data space. The default data space is used when a filegroup or partition scheme is not specified in a <code>CREATE TABLE</code> or <code>CREATE INDEX</code> statement. 0 = This is not the default data space.
<code>filegroup_guid</code>	GUID for the filegroup. NULL = PRIMARY filegroup.
<code>log_filegroup_id</code>	Not used; value is NULL.
<code>is_read_only</code>	1 = Filegroup is read-only. 0 = Filegroup is read/write.

The following statement returns the filename, size in megabytes (not including autogrow), and the name of the filegroup to which each file belongs:

```
SELECT
    convert(varchar(30), sf.name) as filename,
    size/128 as size_in_MB,
    convert(varchar(30), sfg.name) as filegroupname
FROM sys.database_files sf
INNER JOIN sys.filegroups sfg
ON sf.data_space_id = sfg.data_space_id
```

```
go
```

filename	size_in_MB	filegroupname
Customer_Data	50	PRIMARY
Customer_Data2	100	Cust_table

FILESTREAM Filegroups

FILESTREAM storage is a new feature in SQL Server 2008 for storing unstructured data, such as documents, images, and videos. FILESTREAM storage helps to solve the issues with using unstructured data by integrating the SQL Server Database Engine with the NTFS file system for storing the unstructured data, such as documents and images, on the file system with the database storing a pointer to the data. Although the actual data resides outside the database in the NTFS file system, you can still use Transact-SQL (T-SQL) statements to insert, update, query, and back up FILESTREAM data, while maintaining transactional consistency between the unstructured data and corresponding structured data with same level of security.

NOTE

To use FILESTREAM storage, you must first enable FILESTREAM storage at the Windows level as well as at the SQL Server instance level. You can enable FILESTREAM at the Windows level during installation of SQL Server 2008 or at any time using SQL Server Configuration Manager. After you enable FILESTREAM at the Windows level, you next need to enable FILESTREAM for the SQL Server instance. You can do this either through SQL Server Management Studio (SSMS) or via T-SQL.

After you enabled FILESTREAM for the SQL Server instance, you can enable it for a database by creating a FILESTREAM filegroup. You can do this when the database is created (or to an existing database) by adding a filegroup and including the `CONTAINS FILESTREAM` clause. Unlike regular filegroups, a FILESTREAM filegroup can contain only a single file reference, which is actually a file system folder rather than an actual file. The actual folder must not exist (although the path up to the folder must exist); SQL Server creates the `filestream` folder. For example, in Listing 34.3, the code adds a FILESTREAM filegroup called `CustFSGroup` and adds the folder `G:\SQLData\custinfo_FS` into the file group. This `custinfo_FS` folder is created by SQL Server in the `G:\SQLData` folder.

LISTING 34.3 Using a Filegroup to Control Placement for a Table

```
ALTER DATABASE Customer
ADD FILEGROUP Cust_FSGroup CONTAINS FILESTREAM
```

```
ALTER DATABASE Customer
```

```
ADD FILE
  ( NAME=custinfo_FS,
    FILENAME = 'G:\SQLData\custinfo_FS')
  to FILEGROUP Cust_FSGroup
GO
```

If you look in the G:\SQLData\custinfo_FS folder, you should see a Filestream.hdr file and an \$FSLOG folder. The Filestream.hdr file is a FILESTREAM container header file that should not be moved or modified.

As you can see in the example in Listing 34.3, for FILESTREAM files or file groups, unlike regular files, you do not specify size or growth information. No space is preallocated. The file and filegroup grow as data is added to tables that have been created with FILESTREAM columns.

As you create tables with FILESTREAM columns, a subfolder is created in the filegroup folder for each table. The filenames are GUIDs. Each FILESTREAM column created in the table results in another subfolder created under the table subfolder. The column subfolder name is also a GUID. At this point, there still are no actual files created. That happens after you start adding rows to the table. A file is created in the column subfolder for each row inserted into the table with a non-NULL value for the FILESTREAM column.

For more information on creating and using tables with FILESTREAM columns, see Chapter 42, “What’s New for Transact-SQL in SQL Server 2008.”

Database Pages

All information in SQL Server is stored at the page level. The *page* is the smallest level of I/O in SQL Server and is the fundamental storage unit. Pages contain the data itself or information about the physical layout of the data. The page size is the same for all page types: 8KB, or 8,192 bytes. The pages are arranged in two basic types of storage structures: linked data pages and index trees.

Databases are divided into logical 8KB pages. Within each file allocated to a database, the pages are numbered contiguously from 0 to n . The actual number of pages in the database file depends on the size of the file. Pages in a database are uniquely referenced by specifying the database ID, the file ID for the file the page resides in, and the page number within the file. When you expand a database with `ALTER DATABASE`, the new space is added at the end of the file, and the page numbers continue incrementing from the previous last page in the file. If you add a completely new file, its first page number is 0. When you shrink a database, pages are removed from the end of the file only, starting at the highest page in the database and moving toward lower-numbered pages until the database reaches the specified size or a used page that cannot be removed. This ensures that page numbers within a file are always contiguous.

Page Types

There are eight page types in SQL Server, as listed in Table 34.3.

TABLE 34.3 Page Types

Page Type	Stores
Data	Data rows for all data except text, ntext, image, nvarchar(max), varchar(max), varbinary(max), and xml data
Row Overflow	Data columns that cause a data row to exceed the 8,060 bytes per page limit
LOB	Large object types (text, ntext, image, nvarchar(max), varchar(max), varbinary(max), xml data, and varchar, nvarchar, varbinary, and sqlvariant when data row size exceeds 8KB)
Index	Index entries and pointers
Global Allocation Map	Information about allocated (used) extents
Page Free Space	Information about page allocation and free space on pages
Index Allocation Map	Information about extents used by a table or an index
Differential Changed Map	Information about which extents have been modified since the last full database backup
Bulk Changed Map	Information about which extents have been used in a minimally logged or bulk-logged operation since the last BACKUP LOG statement

All pages, regardless of type, have a similar layout. They all have a page header, which is 96 bytes, and a body, which consequently is 8,096 bytes. The page layout is shown in Figure 34.1.

FIGURE 34.1 SQL Server page layout.

Data Pages

The actual data rows in tables are stored on data pages. Figure 34.2 shows the basic structure of a data page.

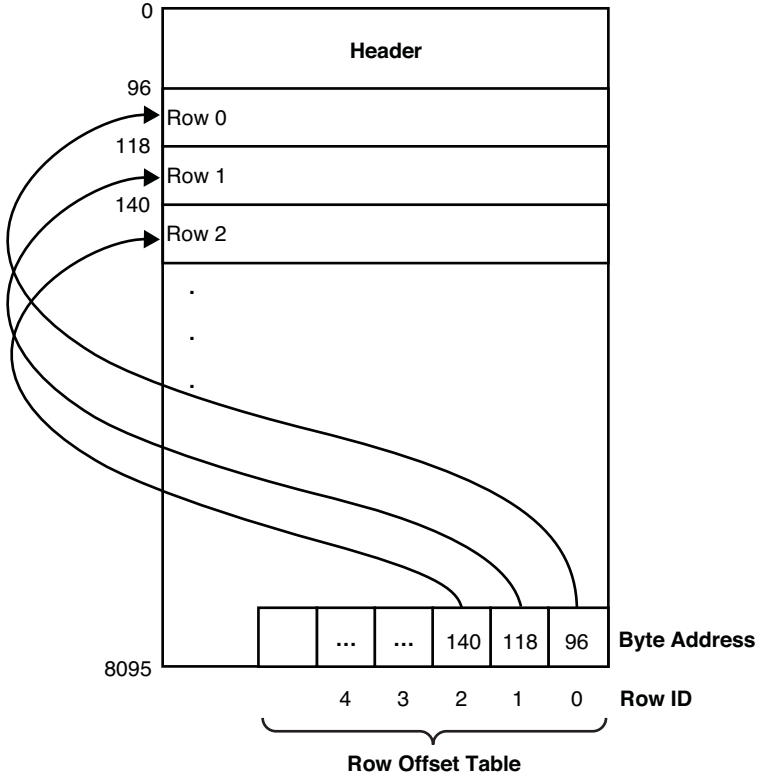

FIGURE 34.2 The structure of a SQL Server data page.

The following sections discuss and examine the contents of the data page.

The Page Header

The *page header* contains control information for the page. Some fields assist when SQL Server checks for consistency among its storage structures, and some fields are used when navigating among the pages that constitute a table. Table 34.4 describes the more useful fields contained in the page header.

TABLE 34.4 Information Contained in the Page Header

Page Header Fields	Description
PageID	Unique identifier for the page. It consists of two parts: the file ID number and page number.
NextPage	File number and page number of the next page in the chain (0 if the page is the last or only page in the chain or if the page belongs to a heap table).
PrevPage	File number and page number of the previous page in the chain (0 if the page is the first or only page in the chain or if the page belongs to a heap table).
ObjectID	ID of the object to which this page belongs.
PartitionID	ID of the partition of which this page is a part.
AllocUnitID	ID of the allocation unit that contains this page.
LSN	Log sequence number (LSN) value used for changes and updates to this page.
SlotCnt	Total number of rows (slots) used on the page.
Level	Level at which this page resides in an index tree (0 indicates a leaf page or data page).
IndexID	ID of the index this page belongs to (0 indicates that it is a data page).
freedata	Byte offset where the available free space starts on the page.
PminLen	Minimum size of a data row. Essentially, this is the number of bytes in the fixed-length portion of the data rows.
FreeCnt	Number of free bytes available on the page.
reservedCnt	Number of bytes reserved by all transactions.
Xactreserved	Number of bytes reserved by the most recently started transaction.
tornBits	Bit string containing 1 bit per sector for detecting torn page writes (or checksum information if <code>torn_page_detection</code> is not on).
flagBits	Two-byte bitmap that contains additional information about the page.

The Data Rows

Following the page header, starting at byte 96 on the page, are the actual data rows. Each data row has a unique row number within the page. Data rows in SQL Server cannot cross page boundaries. The maximum available space in a SQL Server page is 8,060 bytes of in-row data. When a data row is logged in the transaction log (for an insert, for example), additional logging information is stored on the log page along with the data row. Because log pages are 8,192 bytes in size and also have a 96-byte header, a log page has only 8,096 bytes of available space. If you want to store the data row and logging information on a single log page, the in-row data cannot be more than 8,060 bytes in size. This, in effect, limits the maximum in-row data row size for a table in SQL Server 2008 to 8,060 bytes as well.

NOTE

Although 8,060 bytes is the maximum size of in-row data, 8,060 bytes is not the maximum row size limit in SQL Server 2008. Data rows can also have row-overflow and large object (LOB) data stored on separate pages, as you see later in this chapter.

The number of rows stored on a page depends on the size of each row. For a table that has all fixed-length, non-nullable columns, the size of the row and the number of rows that can be stored on a page are always the same. If the table has any variable or nullable fields, the number of rows stored on the page depends on the size of each row. SQL Server attempts to fit as many rows as possible in a page. Smaller row sizes allow SQL Server to fit more rows on a page, which reduces page I/O and allows more data pages to fit in memory. This helps improve system performance by reducing the number of times SQL Server has to read data in from disk.

Because each data row also incurs some overhead bytes in addition to the actual data, the maximum amount of actual *data* that can be stored in a single row on a page is slightly less than 8,060 bytes. The actual amount of overhead required per row depends on whether the table contains any variable-length columns. If you attempt to create a table with a minimum row size including data and row overhead that exceeds 8,060 bytes, you receive an error message as shown in the following example (remember that a multibyte character set data type such as `nchar` or `nvarchar` requires 2 bytes per character, so an `nchar(4000)` column requires 8,000 bytes):

```
CREATE TABLE customer_info2
(cust_no INT, cust_address NCHAR(25), info NCHAR(4000))
go
```

```
Msg 1701, Level 16, State 1, Line 1
Creating or altering table 'customer_info2' failed because the
  minimum row size would be 8061, including 7 bytes of internal
overhead. This exceeds the maximum allowable table row size of 8060
bytes.
```

If the table contains variable-length or nullable columns, you can create a table for which the minimum row size is less than 8,060 bytes, but the data rows could conceivably exceed 8,060 bytes. SQL Server allows the table to be created. If you then try to insert a row that exceeds 8,060 bytes of data and overhead, the data that exceeds the 8,060-byte limit for in-row data is stored in a row-overflow page.

The Structure of Data Rows The data for all fixed-length data fields in a table is stored at the beginning of the row. All variable-length data columns are stored after the fixed-length data. Figure 34.3 shows the structure of the data row in SQL Server.

Status Byte A (1 byte)	Status Byte B (1 byte) <i>not used</i>	Length of Fixed Length Data (2 bytes)	Fixed Length Data Columns (n bytes)	Number of Columns (2 bytes)	Null Bitmap (1 bit for each column)	Number of Variable Length Columns (2 bytes)	Column Offset Array (2 x number of variable columns)	Variable Length Data Columns (n bytes)
------------------------	---	---------------------------------------	-------------------------------------	-----------------------------	-------------------------------------	---	--	--

FIGURE 34.3 The structure of a SQL Server data row.

The total size of each data row is a factor of the sum of the size of the columns plus the row overhead. Seven bytes of overhead is the minimum for any data row:

- ▶ 1 byte for status byte A.
- ▶ 1 byte for status byte B (in SQL Server 2008, only 1 bit is used indicating that the record is a ghost-forwarded row).
- ▶ 2 bytes to store the length of the fixed-length columns.
- ▶ 2 bytes to store the number of columns in the row.
- ▶ 1 byte for every multiple of 8 columns ($\text{ceiling}(\text{numcols} / 8)$) in the table for the NULL bitmap. A 1 in the bitmap indicates that the column allows NULLs.

The values stored in status byte A are as follows:

- ▶ **Bit 0**—This bit provides version information. In SQL Server 2008, it's always 0.
- ▶ **Bits 1 through 3**—This 3-bit value indicates the nature of the row. 0 indicates that the row is a primary record, 1 indicates that the row has been forwarded, 2 indicates a forwarded stub, 3 indicates an index record, 4 indicates a blob fragment, 5 indicates a ghost index record, 6 indicates a ghost data record, and 7 indicates a ghost version record. (Many of these topics, such as forwarded and ghost records, are discussed in further detail later in this chapter.)
- ▶ **Bit 4**—This bit indicates that a NULL bitmap exists. This is somewhat unnecessary in SQL Server 2008 because a NULL bitmap is always present, even if no NULLs are allowed in the table.
- ▶ **Bit 5**—This bit indicates that one or more variable-length columns exists in the row.
- ▶ **Bit 6**—This bit indicates the row contains versioning information.
- ▶ **Bit 7**—This bit is not currently used in SQL Server 2008.

If the table contains any variable-length columns, the following additional overhead bytes are included in each data row:

- ▶ 2 bytes to store the number of variable-length columns in the row.
- ▶ 2 bytes times the number of variable-length columns for the offset array. This is essentially a table in the row identifying where each variable-length column can be found within the variable-length column block.

Within each block of fixed-length or variable-length data, the data columns are stored in the column order in which they were defined when the table was created. In other words,

all fixed-length fields are stored in column ID order in the fixed-length block, and all nullable or variable-length fields are stored in column ID order in the variable-length block.

Storage of the `sql_variant` Data Type The `sql_variant` data type can contain a value of any column data type in SQL Server except for `text`, `ntext`, `image`, variable-length columns with the `MAX` qualifier, and `timestamp`. For example, a `sql_variant` in one row could contain character data; in another row, an integer value; and in yet another row, a `float` value. Because they can contain any type of value, `sql_variant` columns are always considered variable length. The format of a `sql_variant` column is as follows:

- ▶ Byte 1 indicates the actual data type being stored in the `sql_variant`.
- ▶ Byte 2 indicates the `sql_variant` version, which is always 1 in SQL Server 2008.
- ▶ The remainder of the `sql_variant` column contains the data value and, for some data types, information about the data value.

The data type value in byte 1 corresponds to the values in the `xtype` column in the `systypes` database system table. For example, if the first byte contains a hex 38, that corresponds to the `xtype` value of 56, which is the `int` data type.

Some data types stored in a `sql_variant` column require additional information bytes stored at the beginning of the data value (after the `sql_variant` version byte). The data types requiring additional information bytes and the values in these information bytes are as follows:

- ▶ Numeric and decimal data types require 1 byte for the precision and 1 byte for the scale.
- ▶ Character strings require 2 bytes to store the maximum length and 4 bytes for the collation ID.
- ▶ Binary and varbinary data values require 2 bytes to store the maximum length.

Storage of Sparse Columns A new storage feature introduced in SQL Server 2008 is sparse columns. Sparse columns are ordinary columns that use an optimized storage format for `NULL` values. Sparse columns reduce the space requirements for `NULL` values at the cost of more overhead to retrieve non-`NULL` values. A rule of thumb is to consider using sparse columns when you expect at least 90% of the rows to contain `NULL` values. Prime candidates are tables that have many columns where most of the attributes are `NULL` for most rows—for example, when different attributes apply to different subsets of rows and, for each row, only a subset of columns are populated with values.

The sparse columns feature significantly increases the number of possible columns in a table from 1,024 to 30,000. However, not all 30,000 can contain values. The number of actual populated columns you can have depends on the number of bytes of data in the rows. With sparse columns, storage of `NULL` values is optimized, requiring no space at all for storing `NULL` values. This is unlike nonsparse columns, which, as you saw earlier, do need space even for `NULL` values (a fixed-length `NULL` value requires the full column width, and a variable-length `NULL` requires at least 2 bytes of storage in the column offset array).

Although sparse columns themselves require no space for NULL values, there is some fixed overhead space required to allow rows to contain sparse columns. This space is needed to add the sparse vector to the end of the data row. A sparse vector is added to the end of a data row only if at least one sparse column is defined on the table.

The sparse vector is used to keep track of the physical storage of sparse columns in the row. It is stored as the last variable-length column in the row. No bit is stored in the NULL bitmap for the sparse vector column but it is included in the count of the variable columns (refer to Figure 34.3 for the general structure of a data row). The bytes stored in the sparse vector are shown in Table 34.5.

TABLE 34.5 Bytes Stored in the Sparse Vector

Name	Number of Bytes	Description
Complex column header	2	A value of 05 indicates the column is a sparse vector
Sparse column count	2	Number of sparse columns
Column ID set	$2 \times \#$ of sparse columns	The column IDs of each column with a value stored in the sparse vector
Column offset table	$2 \times \#$ of sparse columns	The offset of the ending position of each sparse column
Sparse data	Depends on actual values	The actual data values for each sparse column stored in column ID order

With the required overhead space for the sparse vector, the maximum size of all fixed-length non-NULL sparse columns is reduced to 8,019 bytes per row.

As you can see, the contents of a sparse vector are like a data row structure within a data row. If you refer to Figure 34.3, you can see that the structure of the sparse vector is similar to the shaded structure of a data row. One of the main differences is that the sparse vector stores no information for any sparse columns that contain NULL values. Also, fixed-length and variable-length columns are stored the same within the sparse vector. However, if you have any variable-length columns in the sparse vector that are too large to fit in the 8,019-byte limit of the data row, they are stored on row-overflow pages.

The Row Offset Table

The location of a row within a page is identified by the *row offset table*, which is located at the end of the page. To find a specific row within a page, SQL Server looks up the starting byte address for a given row ID in the row offset table, which contains the offset of the row from the beginning of the page (refer to Figure 34.2). Each entry in the row offset table is 2 bytes in size, so for each row in a table, an additional 2 bytes of space is added in from the end of the page for the row offset entry.

The row offset table keeps track of the logical order of rows on a data page. If a table has a clustered index defined on it, the data rows are stored in clustered index order. However, they may not be physically stored in clustered key order on the page itself. Instead, the row offset array indicates the logical clustered key order of the data rows. For example, row offset slot 0 refers to the first row in the clustered index key order, slot 1 refers to the second row, slot 2 refers to the third row, and so on. The physical location of the rows on the page may be in any order, depending on when rows on the page were inserted or deleted.

Row-Overflow Pages

While the maximum in-row size is 8,060 bytes per row, SQL Server 2008 allows actual rows to exceed this size for tables that contain `varchar`, `nvarchar`, `varbinary`, `sql_variant`, or common language runtime (CLR) user-defined type columns. Although the length of each one of these columns must still fall within the limit of 8,000 bytes, the combined width of the row can exceed the 8,060-byte limit.

When a combination of `varchar`, `nvarchar`, `varbinary`, `sql_variant`, or CLR user-defined type columns exceeds the 8,060-byte limit, SQL Server moves the record column with the largest width to another page in the `ROW_OVERFLOW_DATA` allocation unit, while maintaining a 24-byte pointer to the row-overflow page on the original page. Moving large records to another page occurs dynamically as records are lengthened based on update operations. Update operations that shorten records may cause records to be moved back to the original page in the `IN_ROW_DATA` allocation unit.

Row-overflow pages are used only under certain circumstances. For one, the row itself has to exceed 8,060 bytes; it does not matter how full the data page itself is. If a row is less than 8,060 bytes and there's not enough space in the data page, normal page splitting occurs to store the row. Also, each column in a table must be completely on the row or completely off it. A variable-length column cannot have some of its data on the regular data page and some of its data on the row-overflow page. One row can span multiple row-overflow pages depending on how many large variable-length columns there are.

Be aware that having data rows that require a row-overflow page increases the I/O cost of retrieving the data row. Querying and performing other select operations, such as sorts or joins on large records that contain row-overflow data, also slow processing time because these records are processed synchronously instead of asynchronously.

Therefore, when you design a table with multiple `varchar`, `nvarchar`, `varbinary`, `sql_variant`, or CLR user-defined type columns, you might want to consider the percentage of rows that are likely to require row overflow and the frequency with which this overflow data is likely to be queried. If there are likely to be frequent queries on many rows of row-overflow data, you should consider normalizing the table so that some columns are moved to another table, reducing the overall row size so that the rows fit within 8,060 bytes. The data can then be recombined in a query using an asynchronous JOIN operation.

TIP

Because of the performance implications, row-overflow pages are intended to be a solution for situations in which most of your data rows fit completely on your data pages and you only occasionally have rows that require a row-overflow page. Row-overflow pages allow SQL Server to handle the large data rows effectively without requiring a redesign of your table. However, if you find more than a few of your rows exceed the in-row size, you probably should look into using the LOB data types or redesigning your table.

LOB Data Pages

If you want to store large amounts of text or binary data, you can use the `text`, `ntext`, and `image` data types, as well as the `varchar(max)`, `nvarchar(max)`, and `varbinary(max)` data types. (For information about how to use these data types, see Chapter 24, “Creating and Managing Tables,” and Chapter 38, “Database Design and Performance.”) Each column for a row of these data types can store up to 2GB (minus 2 bytes) of data. By default, the LOB values are not stored as part of the data row, but as a collection of pages on their own. For each LOB column, the data page contains a 16-byte pointer, which points to the location of the initial page of the LOB data. A row with several LOB columns has one pointer for each column.

The pages that hold LOB data are 8KB in size, just like any other page in SQL Server. An individual LOB page can hold LOB data for multiple columns and also from multiple rows. A LOB data page can even contain a mix of LOB data. This helps reduce the storage requirements for the LOB data, especially when smaller amounts of data are stored in these columns. For example, if SQL Server could store data for only a single column for a single row on a single LOB data page and the data value consisted of only a single character, it would still use an entire 8KB data page to store that data! Definitely not an efficient use of space.

A LOB data page can hold LOB data for only a single table, however. A table with a LOB column has a single set of pages to hold all its LOB data.

LOB information is presented externally (to the user) as a long string of bytes. Internally, however, the information is stored within a set of pages. The pages are not necessarily organized sequentially but are logically organized as a B-tree structure. (B-tree structures are covered in more detail later in this chapter.) If an operation addresses some information in the middle of the data, SQL Server can navigate through the B-tree to find the data. In previous versions, SQL Server had to follow the entire page chain from the beginning to find the desired information.

If the amount of the data in the LOB field is less than 32KB, the 16-byte pointer in the data row points to an 84-byte root structure in the LOB B-tree. This root structure points to the pages and location where the actual LOB data is stored (see Figure 34.4). The data itself can be placed anywhere within the LOB pages for the table. The root structure keeps

track of the location of the information in a logical manner. If the data is less than 64 bytes, it is stored in the root structure itself.

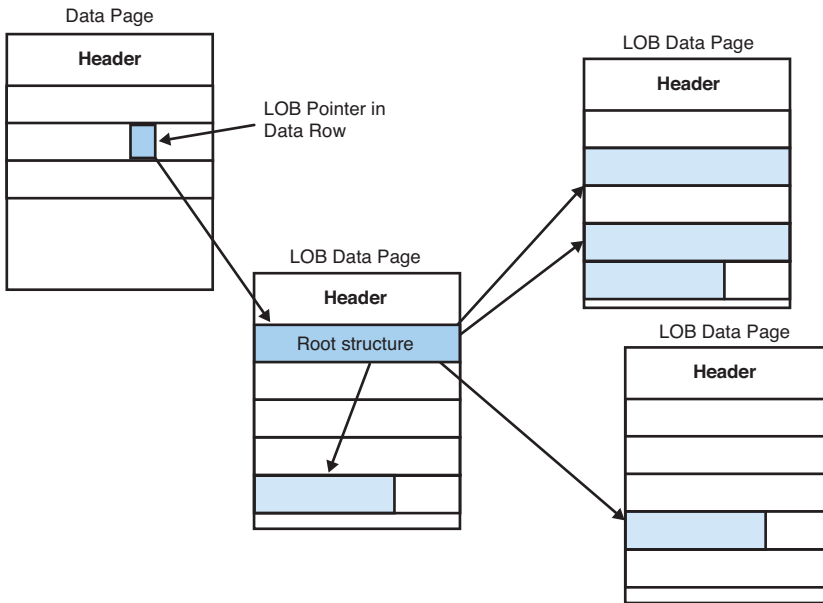

FIGURE 34.4 LOB data root structure pointing at the location of LOB data in the LOB B-tree.

If the amount of LOB data exceeds 32KB, SQL Server allocates intermediate B-tree index nodes that point to the LOB pages. In this situation, the intermediate node pages are stored on pages not shared between different occurrences of LOB columns; the intermediate node pages store nodes for only one LOB column in a single data row.

Storing LOB Data in the Data Row

To further conserve space and help minimize I/O, SQL Server 2008 supports storing LOB data in the actual data row. When the LOB data is stored outside the data row pages, at a minimum, SQL Server needs to perform one additional page read per row to get the LOB data.

Why would you want to store LOB data in the row? Why not just store the data in a `varchar(8000)`? Well, primarily because there is an upper limit of 8KB if the data is stored within the data row (not counting the other columns). Using a LOB data type, you can store more than 2 billion bytes of text. If you know most of your records will be small, but on occasion, some very large values will be stored, the `text in row` option provides optimum performance and better space efficiency for the majority of your LOB values, while providing the flexibility you need for the occasional large values. This option also provides the benefit of keeping the data all in a single column instead of having to split it across multiple columns or rows when the data exceeds the size limit of a single row.

If you want to enable the `text in row` option for a table with a LOB column, use the `sp_tableoption` stored procedure:

```
exec sp_tableoption pub_info, 'text in row', 512
```

This example enables up to 512 bytes of LOB data in the `pub_info` table to be stored in the data row. The maximum amount of LOB data that can be stored in a data row is 7,000 bytes. When a LOB value exceeds the specified size, rather than store the 16-byte pointer in the data row as it would normally, SQL Server stores the 24-byte root structure that contains the pointers to the separate chunks of LOB data for the row in the LOB column.

The second parameter to `sp_tableoption` can be just the option `ON`. If no size is specified, the option is enabled with a default size of 256 bytes. To disable the `text in row` option, you can set its value to `0` or `OFF` with `sp_tableoption`. When the option is turned off, all LOB data stored in the row is moved off to LOB pages and replaced with the standard 16-byte pointer. This can be a time-consuming process for a large table.

Also, you should keep in mind that just because this option is enabled it doesn't always mean that the LOB data will be stored in the row. All other data columns that are not LOB take priority over LOB data for storage in the data row. If a variable-length column grows and there is not enough space left in the row or page for the LOB data, the LOB data is moved off the page.

Storage of MAX Data

An alternative to the `text` and `image` data types in SQL Server 2008 is the option of defining variable-length data using the `MAX` specifier. When you use the `MAX` specifier with `varchar`, `nvarchar`, and `varbinary` columns, SQL Server determines automatically whether to store the data as a regular `varchar`, `nvarchar`, or `varbinary` value or as a LOB. Essentially, if the actual length is less than 8,000 bytes, SQL Server treats it as if it were one of the regular variable-length data types, including using row-overflow pages if necessary. If the `MAX` column exceeds 8,000 bytes, it is stored like LOB data.

Index Pages

Index information is stored on index pages. An *index page* has the same layout as a data page. The difference is the type of information stored on the page. Generally, a row in an index page contains the index key and a pointer to the page or row at the next (lower) level.

The actual information stored in an index page depends on the index type and whether it is a leaf-level page. A leaf-level clustered index page is the data page itself; you've already seen its structure. The information stored on other index pages is as follows:

- ▶ **Clustered indexes, nonleaf pages**—Each index row contains the index key and a pointer (the `fileId` and a page address) to a page in the index tree at the next lower level.
- ▶ **Nonclustered index, nonleaf pages**—Each index row contains the index key and a page-down pointer (the `file ID` and a page address) to a page in the index tree at

the next lower level. For nonunique indexes, the nonleaf row also contains the row locator information for the corresponding data row.

- **Nonclustered index, leaf pages**—Rows on this level contain an index key and a reference to a data row. For heap tables, this is the Row ID; for clustered tables, this is the clustered key for the corresponding data row.

The actual structure and content of index rows, as well as the structure of the index tree, are discussed in more detail later in this chapter.

Space Allocation Structures

When a table or index needs more space in a database, SQL Server needs a way to determine where space is available in the database to be allocated. If the table or index is still fewer than eight pages in size, SQL Server must find a mixed extent with one or more pages available that can be allocated. If the table or index is eight pages or larger in size, SQL Server must find a free uniform extent that can be allocated to the table or index.

Extents

If SQL Server allocated space one page at a time as pages were needed for a table (or an index), SQL Server would be spending a good portion of its time just allocating pages, and the data would likely be scattered noncontiguously throughout the database. Scanning such a table would not be very efficient. For these reasons, pages for each object are grouped together and allocated in *extents*; an extent consists of eight logically contiguous pages.

When a table or index is created, it is initially allocated a page on a mixed extent. If no mixed extents are available in the database, a new mixed extent is allocated. A mixed extent can be shared by up to eight objects (each page in the extent can be assigned to a different table or index).

As the table grows to at least eight pages in size, all future allocations to the table are done as *uniform extents*.

Figure 34.5 shows the use of mixed and uniform extents.

FIGURE 34.5 Mixed and uniform extents.

If SQL Server had to search throughout an entire database file to find free extents, it wouldn't be efficient. Instead, SQL Server uses two special types of pages to record which extents have been allocated to tables or indexes and whether it is a mixed or uniform extent:

- ▶ Global allocation map pages (GAMs)
- ▶ Shared global allocation map pages (SGAMs)

Global and Shared Global Allocation Map Pages

The allocation map pages track whether extents have been allocated to objects and indexes and whether the allocation is for mixed extents or uniform extents. As mentioned in the preceding section, there are two types of GAMs:

- ▶ **Global allocation map (GAM)**—The GAM keeps track of all allocated extents in a database, regardless of what it's allocated to. The structure of the GAM is straightforward: each bit in the page outside the page header represents one extent in the file, where 1 means that the extent is not allocated, and 0 means that the extent is allocated. Nearly 8,000 bytes (64,000 bits) are available in a GAM page after the header and other overhead bytes are taken into account. Therefore, a single GAM covers approximately 64,000 extents, or 4GB (64,000 * 64KB) of data.
- ▶ **Shared global allocation map (SGAM)**—The SGAM keeps track of mixed extents that have free space available. An SGAM has a structure similar to a GAM, with each bit representing an extent. A value of 1 means that the extent is a mixed extent and there is free space (at least one unused page) available on the extent. A value of 0 means that the extent is not currently allocated, that the extent is a uniform extent, or that the extent is a mixed extent with no free pages.

Table 34.6 summarizes the meaning of the bit in GAMs and SGAMs.

TABLE 34.6 Meaning of the GAM and SGAM Bits

Extent Usage	GAM Bit	SGAM Bit
Free, not used	1	0
Uniform or mixed with no free pages	0	0
Mixed, with free pages available	0	1

When SQL Server needs to allocate a uniform extent, it simply searches the GAM for a bit with a value of 1 and sets it to 0 to indicate it has been allocated. To find a mixed extent with free pages, it searches the SGAM for a bit set to 1. When all pages in a mixed extent are used, its corresponding bit is set to 0. When a mixed extent needs to be allocated, SQL Server searches the GAM for an extent whose bit set to 1 and sets the bit to 0, and the corresponding SGAM bit is set to 1. There is some more processing involved as well, such as spreading the data evenly across database files, but the allocation algorithms are still relatively simple.

SQL Server is able to easily locate GAM pages in a database because the first GAM page is located at the third page in the file (page number 2). There is another GAM every 511,230 pages after the first GAM. The fourth page (page number 3) in each database file is the SGAM page, and there is another SGAM each 511,230 pages after the first SGAM.

Page Free Space Pages

A *page free space (PFS)* page records whether each page is allocated and the amount of free space available on the page. Each PFS covers 8,088 contiguous pages in the file. For each of the 8,088 pages, the PFS has a 1-byte record that contains a bitmap for each page indicating whether the page is empty, 1 to 50% full, 51 to 80% full, 81 to 95% full, or more than 95% full. The first PFS page in a file is located at page number 1, the second PFS page is located at page 8088, and each additional PFS page is located every 8,088 pages after that. SQL Server uses PFS pages to find free pages on extents and to find pages with space available on extents when a new row needs to be added to a table or index.

Figure 34.6 shows the layout of GAM, SGAM, and PFS pages in a database file. Note that every file has a single file header located at page 0.

FIGURE 34.6 The layout of GAM, SGAM, and PFS pages in a database file.

Index Allocation Map Pages

Index allocation map (IAM) pages keep track of the extents used by a heap or index. Each heap table and index has at least one IAM page for each file where it has extents. An IAM cannot reference pages in other database files; if the heap or index spreads to a new database file, a new IAM for the heap or index is created in that file. IAM pages are allocated as needed and are spread randomly throughout the database files.

An IAM page contains a small header that has the address of the first extent in the range of pages being mapped by the IAM. It also contains eight page pointers that keep track of index or heap pages that are in mixed extents. These pointers might or might not contain any information, depending on whether any data has been deleted from the tables and the page(s) released. Remember, an index or heap will have no more than eight pages in mixed extents (after eight pages, it begins using uniform extents), so only the first IAM page stores this information. The remainder of the IAM page is for the allocation bitmap. The IAM bitmap works similarly to the GAM, indicating which extents over the range of extents covered by the IAM are used by the heap or index the IAM belongs to. If a bit is on, the corresponding extent is allocated to the table.

Each IAM covers a possible range of 63,903 extents (511,224 pages), covering a 4GB section of a file. Each bit represents an extent within that range, whether or not the

extent is allocated to the object that the IAM belongs to. If the bit is set to 1, the relative extent in the range is allocated to the index or heap. If the bit is set to 0, the extent is either not allocated or might be allocated to another heap or index.

For example, assume that an IAM page resides at page 649 in the file. If the bit pattern in the first byte of the IAM is 1010 0100, the first, third, and sixth extents within the range of the IAM are allocated to the heap or index. The second, fourth, fifth, seventh, and eighth extents are not.

NOTE

For a heap table, the data pages and rows within them are not stored in any specific order. Unlike versions of SQL Server prior to 7.0, the pages in a heap structure are not linked together in a page chain. The only logical connection between data pages is the information recorded in the IAM pages, which are linked together. The structure of heap tables is examined in more detail later in this chapter.

Differential Changed Map Pages

The seventh page (page number 6), and every 511,232nd page thereafter, in the database file is the *differential changed map (DCM)* page. This page keeps track of which extents in a file have been modified since the last full database backup. When an extent has been modified, its corresponding bit in the DCM is turned on. This information is used when a differential backup is performed on the database. A differential backup copies only the extents changed since the last full backup was made. Using the DCM, SQL Server can quickly tell which extents need to be backed up by examining the bits on the DCM pages for each data file in the database. When a full backup is performed for the database, all the bits are set back to 0.

Bulk Changed Map Pages

The eighth page (page number 7), and every 511,232nd page thereafter, in the database file is the *bulk changed map (BCM)*. When you perform a minimally or bulk-logged operation in SQL Server 2008 in BULK_LOGGED recovery mode, SQL Server logs only the fact that the operation occurred and doesn't log the actual data changes. The operation is still fully recoverable because SQL Server keeps track of what extents were actually modified by the bulk operation in the BCM page. Similar to the DCM page, each bit on a BCM page represents an extent within its range, and if the bit is set to 1, that indicates that the corresponding extent has been changed by a minimally logged bulk operation since the last full database backup. All the bits on the BCM page are reset to 0 whenever a full database backup or log backup occurs.

When you initiate a log backup for a database using the BULK_LOGGED recovery model, SQL Server scans the BCM pages and backs up all the modified extents along with the contents of the transaction log itself. You should be aware that the log file itself might be small, but the backup of the log can be many times larger if a large bulk operation has been performed since the last log backup.

Data Compression

SQL Server 2008 introduced a new data compression feature that is available in Enterprise and Datacenter Editions. Data compression helps to reduce both storage and memory requirements as the data is compressed both on disk and when brought into the SQL Server data cache.

When compression is enabled and data is written to disk, it is compressed and stored in the designated compressed format. When the data is read from disk into the buffer cache, it remains in its compressed format. This helps reduce both storage requirements and memory requirements. It also reduces I/O because more data can be stored on a data page when it's compressed. When the data is passed to another component of SQL Server, however, the Database Engine then has to uncompress the data on the fly. In other words, every time data has to be passed to or from the buffered cache, it has to be compressed or uncompressed. This requires extra CPU overhead to accomplish. However, in most cases, the amount of I/O and buffer cache saved by compression more than makes up for the CPU costs, boosting the overall performance of SQL Server.

Data compression can be applied on the following database objects:

- ▶ Tables (clustered or heap)
- ▶ Nonclustered indexes
- ▶ Indexed views

As the DBA, you need to evaluate which of the preceding objects in your database could benefit from compression and then decide whether you want to compress it using either row-level or page-level compression. Compression is enabled or disabled at the object level. There is no single option you can enable that turns compression on or off for all objects in the database. Fortunately, other than turning compression on or off for the preceding objects, you don't have to do anything else to use data compression. SQL Server handles data compression transparently without your having to re-architect your database or your applications.

Row-Level Compression

Row-level compression isn't true data compression. Instead, space savings are achieved by using a more efficient storage format for fixed-length data to use the minimum amount of space required. For example, the `int` data type uses 4 bytes of storage regardless of the value stored, even `NULL`. However, only a single byte is required to store a value of `100`. Row-level compression allows fixed-length values to use only the amount of storage space required.

Row-level compression saves space and reduces I/O by

- ▶ Reducing the amount of metadata required to store data rows
- ▶ Storing fixed-length numeric data types as if they were variable-length data types, using only as many bytes as necessary to store the actual value
- ▶ Storing `CHAR` data types as variable-length data types
- ▶ Not storing `NULL` or `0` values

Row-level data compression provides less compression than page-level data compression, but it also incurs less overhead, reducing the amount of CPU resources required to implement it.

Row-level compression can be enabled when creating a table or index or using the ALTER TABLE or ALTER INDEX commands by specifying the WITH (DATA_COMPRESSION = ROW) option. The following example enables row compression on the titles table in the bigpubs2008 database:

```
ALTER TABLE titles REBUILD WITH (DATA_COMPRESSION=ROW)
```

Additionally, if a table or index is partitioned, you can apply compression at the partition level.

When row-level compression is applied to a table, a new row format is used that is unlike the standard data row format discussed previously, which has a fixed-length data section separate from a variable-length data section (see Figure 34.3). This new row format is referred to as column descriptor, or CD, format. The name of this row format refers to the fact that every column has description information contained in the row itself. Figure 34.7 illustrates a representative view of the CD format (a definitive view is difficult because, except for the header, the number of bytes in each region is completely dependent on the values in the data row).

FIGURE 34.7 A representative structure of a CD format row.

The row header is always 1 byte in length and contains information similar to Status Bits A in a normal data row:

- ▶ **Bit 0**—This bit indicates the type of record (*1* = CD record format).
- ▶ **Bit 1**—This bit indicates whether the row contains versioning information.
- ▶ **Bits 2–4**—This three-bit value indicates what kind of information is stored in the row (such as primary record, ghost record, forwarding record, index record).
- ▶ **Bit 5**—This bit indicates whether the row contains a Long data region (with values greater than 8 bytes in length).
- ▶ **Bits 6 and 7**—These bits are not used.

The CD region consists of two parts. The first is either a 1- or 2-byte value indicating the number of short columns (8 bytes or less). If the most significant bit of the first byte is set to 0, it's a 1-byte field representing up to 127 columns; if it's 1, it's a 2-byte field representing up to 32,767 columns. Following the first 1 or 2 bytes is the CD array. The CD array uses 4 bits for each column in the table to represent information about the length of the

column. A bit representation of 0 indicates the column is NULL. A bit representation of the values 1 to 9 indicates the column is 0 to 8 bytes in length, respectively. A bit representation of 10 (0xa) indicates that the corresponding column value is a long data value and uses no space in the short data region. A bit representation of 11 (0xb) represents a bit column with a value of 1, and a bit representation of 12 (0xc) indicates that the corresponding value is a 1-byte symbol representing a value in the page compression dictionary (the page compression dictionary is discussed next in the page-level compression section).

The short data region contains each of the short data values. However, because accessing the last columns can be expensive if there are hundreds of columns in the table, columns are grouped into clusters of 30 columns. At the beginning of the short data region, there is an area called the *short data cluster array*. Each entry in the array is a single byte, which indicates the sum of the sizes of all the data in the previous cluster in the short data region; the value is essentially a pointer to the first column of the cluster (no row offset is needed for the first cluster because it starts immediately after the CD region).

Any data value in the row longer than 8 bytes is stored in the long data region. This can include LOB and row-overflow pointers. Long data needs an actual offset value to allow SQL Server to locate each value. This offset array looks similar to the offset array used in the standard data row structure. The long data region consists of three parts: an offset array, a long data cluster array, and the long data. The long data cluster array is similar to the short data cluster array; it has one entry for each 30-column cluster (except for the last one) and serves to limit the cost of locating columns near the end of a long list of columns.

The special information section at the end of the row contains three optional pieces of information. The existence of any or all of this information is indicated by bits in the first 1-byte header at the beginning of the row. The three special pieces of information are

- ▶ **Forwarding pointer**—This pointer is used in a heap when a row is forwarded due to an update (forward pointers are discussed later in this chapter).
- ▶ **Back pointer**—If the row is a forwarded row, it contains a pointer back to the original row location.
- ▶ **Versioning information**—If snapshot isolation is being used, 14 bytes of versioning information are appended to the row.

Page-Level Compression

Page-level compression is an implementation of true data compression, using both column prefix and dictionary-based compression. Data is compressed by storing repeating values or common prefixes only once and then referencing those values from other columns and rows. When you implement page compression for a table, row compression is applied as well. Page-level compression offers increased data compression over row-level compression alone but at the expense of greater CPU utilization. It works using these techniques:

- ▶ First, row-level data compression is applied to fit as many rows as it can on a single page.

- ▶ Next, column prefix compression is run. Essentially, repeating patterns of data at the beginning of the values of a given column are removed and substituted with an abbreviated reference, which is stored in the compression information (CI) structure stored after the page header.
- ▶ Finally, dictionary compression is applied on the page. Dictionary compression searches for repeated values anywhere on a page and stores them in the CI.

Page compression is applied only after a page is full and if SQL Server determines that compressing a page will save a meaningful amount of space.

The amount of compression provided by page-level data compression is highly dependent on the data stored in a table or index. If a lot of the data repeats itself, compression is more efficient. If the data is more randomly discrete values, fewer benefits are gained from using page-level compression.

Column prefix compression looks at the column values on a single page and chooses a common prefix that can be used to reduce the storage space required for values in that column. The longest value in the column that contains the prefix is chosen as the anchor value. A row that represents the prefix values for each column is created and stored in the CI structure that immediately follows the page header. Each column is then stored as a delta from the anchor value, where repeated prefix values in the column are replaced by a reference to the corresponding prefix. If the value in a row does not exactly match the selected prefix value, a partial match can still be indicated.

For example, consider a page that contains the following data rows before prefix compression as shown in Figure 34.8.

Page Header			
aaabb	aaaab	abcd	abc
aaabccc	bbbbbb	abcd	mno
aaacc	aaaacc	bbbb	xyz

} Data Rows

FIGURE 34.8 Sample page of a table before prefix compression.

After you apply column prefix compression on the page, the CI structure is stored after the page header holding the prefix values for each column. The columns then are stored as the difference between the prefix and column value, as shown in Figure 34.9.

In the first column in the first data row, the value 4b represents that the first four characters of the prefix (aaab) are present at the beginning of the column for that row and also the character b. If you append the character b to the first four values of the prefix, it rebuilds the original value of aaabb. For any columns values that are [empty], the column matches the prefix value exactly. Any column value that starts with 0 means that none of the first characters of the column match the prefix. For the fourth column, there is no common prefix value in the columns, so no prefix value is stored in the CI structure.

Page Header			
aaabccc	aaabccc	aaabccc	aaabccc
4b	4b	[empty]	abcd
[empty]	0bbbb	[empty]	mno
3ccc	[empty]	0bbbb	xyz

} **Data Rows**

FIGURE 34.9 Sample page of a table after prefix compression.

After column prefix compression is applied to every column individually on the page, SQL Server then looks to apply dictionary compression. Dictionary compression looks for repeated values anywhere on the page and also stores them in the CI structure after the column prefix values. Dictionary compression values replace repeated values anywhere on a page. The following illustrates the same page shown previously after dictionary compression has been applied:

Page Header			
aaabccc	aaaacc	abcd	[NULL]
4b	0bbbb		
0	0	[empty]	abcd
[empty]	1	[empty]	mno
3ccc	[empty]	1	xyz

} **Data Rows**

FIGURE 34.10 Sample page of a table after dictionary compression.

The dictionary is stored as a set of these duplicate values and a symbol to represent these values in the columns on the page. As you can see in this example, 4b is repeated in multiple columns in multiple rows, and the value is replaced by the symbol 0 throughout the page. The value 0bbbb is replaced by the symbol 1. SQL Server recognizes that the value stored in the column is a symbol and not a data value by examining the coding in the CD array, as discussed earlier.

Not all pages contain both the prefix record and a dictionary. Having them both depends on whether the data has enough repeating values or patterns to warrant either a prefix record or a dictionary.

The CI Record

The CI record is the only main structural change to a page when it is page compressed versus a page that uses row compression only. As shown in the previous examples, the CI record is located immediately after the page header. There is no entry for the CI record in the row offset table because its location is always the same. A bit is set in the page header to indicate whether the page is page compressed. When this bit is present, SQL Server knows to look for the CI record. The CI record contains the data elements shown in Table 34.7.

TABLE 34.7 Data Elements Within the CI Record

Name	Description
Header	This structure contains 1 byte to keep track of information about the CI. Bit 0 is the version (currently always 0), Bit 1 indicates the presence of a column prefix anchor record, and Bit 2 indicates the presence of a compression dictionary.
PageModCount	This value keeps track of the number of changes to the page to determine whether the compression on the page should be reevaluated and the CI record rebuilt.
Offsets	This element contains values to help SQL Server find the dictionary. It contains the offset of the end of the Column prefix anchor record and offset of the end of the CI record itself.
Anchor Record	This record looks exactly like a regular CD record (see Figure 34.7). Values stored are the common prefix values for each column, some of which might be NULL.
Dictionary	The first 2 bytes represent the number of entries in the dictionary, followed by an offset array of 2-byte entries, which indicate the end offset of each dictionary entry, and then the actual dictionary values.

Implementing Page Compression

Page compression can be implemented for a table at the time it is created or by using the ALTER TABLE command, as in the following example:

```
ALTER TABLE sales_big REBUILD WITH (DATA_COMPRESSION=PAGE)
```

Unlike row compression, which is applied immediately on the rows, page compression isn't applied until the page is full. The rows cannot be compressed until SQL Server can determine what encodings for prefix and dictionary substitution are going to be used to replace the actual data. When you enable page compression for a table or a partition, SQL Server examines every full page to determine the possible space savings. Any pages that are not full are not considered for compression. During the compression analysis, the prefix and dictionary values are created, and the column values are modified to reflect the prefix and dictionary values. Then row compression is applied. If the new compressed page can hold at least five additional rows, or 25% more rows than the page currently

holds, the page is compressed. If neither one of these criteria is met, the compressed version of the page is discarded.

New rows inserted into a compressed page are compressed as they are inserted. However, new entries are not added to the prefix list or dictionary based on a single new row. The prefix values and dictionary symbols are rebuilt only on an all-or-nothing basis. After the page is changed a sufficient number of times, SQL Server evaluates whether to rebuild the CI record. The `PageModCount` field in the CI record is used to keep track of the number of changes to the page since the CI record was last built or rebuilt. This value is updated every time a row is updated, deleted, or inserted. If SQL Server encounters a full page during a data modification and the `PageModCount` is greater than 25 or the `PageModCount` divided by the number of rows on the page is greater than 25%, SQL Server reapplies the compression analysis on the page. Again, only if recompressing the page creates room for five additional rows, or 25% more rows than the page currently holds, the new compressed page replaces the existing page.

In B-tree structures (nonclustered indexes or a clustered table), only the leaf-level and data pages are considered for compression. When you insert a new row into a leaf or data page, if the compressed row fits, it is inserted and nothing more is done. If it doesn't fit, SQL Server attempts to recompress the page and then recompress the row based on the new CI record. If the row fits after recompression, it is inserted and nothing more is done. If the row still doesn't fit, the page needs to be split. When a compressed page is split, the CI record is copied to the new page exactly as it was, along with the rows moved to the new page. However, the `PageModCount` value is set to 25, so that when the new page gets full, it will be immediately analyzed for recompression. Leaf and data pages are also checked for recompression whenever you run an index rebuild or shrink operation.

If you enable compression on a heap table, pages are evaluated for compression only during rebuild and shrink operations. Also, if you drop a clustered index on a table, turning it into a heap, SQL Server runs compression analysis on any full pages. Compression is avoided during normal data modification operations on a heap to avoid changes to the Row IDs, which are used as the row locators for any indexes on the heap. (See the "Understanding Index Structures" section later in this chapter for a discussion of row locators.) Although the `RowModCounter` is still maintained, SQL Server essentially ignores it and never tries to recompress a page based on the `RowModCounter` value.

Evaluating Page Compression

Before choosing to implement page compression, you should determine if the overhead of page compression will provide sufficient benefit in space savings. To determine how changing the compression state will affect a table or an index, you can use the SQL Server 2008 `sp_estimate_data_compression_savings` stored procedure, which is available only in the editions of SQL Server that support data compression. This stored procedure evaluates the effects of compression by sampling up to 5,000 pages in the table and creating a copy of these 5,000 pages of the table in `tempdb`, performing the compression, and then using the sample to estimate the overall size for the table after compression. The syntax for `sp_estimate_data_compression_savings` is as follows:

```

sp_estimate_data_compression_savings
    [ @schema_name = ] 'schema_name'
    , [ @object_name = ] 'object_name'
    , [ @index_id = ] index_id
    , [ @partition_number = ] partition_number
    , [ @data_compression = ] 'data_compression'

```

You can estimate the data compression savings for a table for either row or page compression by specifying either 'ROW' or 'PAGE' as the value for the @data_compression parameter. You can also estimate the average size of the compressed table if compression is disabled by specifying NONE as the value for @data_compression. You can also use the sp_estimate_data_compression_savings procedure to estimate the space savings for compression on a specific index or partition. The following example estimates the space savings if page compression were applied to the big_sales table in the bigpubs2008 table versus row compression:

```

use bigpubs2008
go
exec sp_estimate_data_compression_savings 'dbo', 'sales_big', null, null, 'PAGE'
go

```

```

You can see in this example that the space savings from page compression would be significant, with an estimated reduction in the size of the table itself (`index_id = 1`) from 113MB (116,512 KB) to 38MB (39,128 KB), a savings of more than 66%. Row compression would not provide nearly as significant a savings, with an estimated reduction in size from 113MB to only 95MB (97,936 KB), only a 16% savings.

If you compress the table, you can compare the estimated space savings to the actual size. For example, let's look at the initial size of the `sales_big` table:

```

use bigpubs2008
go

select sum(page_count) as pages, sum(compressed_page_count) as compressed_pages
from sys.dm_db_index_physical_stats (DB_ID(),
OBJECT_ID('sales_big'), 1, null, 'DETAILED')
where index_level = 0

SELECT SUM(used_page_count/ 128.0) AS size_in_MB
FROM sys.dm_db_partition_stats
WHERE object_id=OBJECT_ID('dbo.sales_big') AND index_id=1
GO

pages                compressed_pages
-----
14519                0

```

```
size_in_MB
-----
```

```
113.742187
```

Now, implement page compression on the `sales_big` table:

```
ALTER TABLE sales_big REBUILD WITH (DATA_COMPRESSION=PAGE)
```

Now, re-examine the size of the `sales_big` table:

```
select sum(page_count) as pages, sum(compressed_page_count) as compressed_pages
from sys.dm_db_index_physical_stats (DB_ID(),
OBJECT_ID('sales_big'), 1, null, 'DETAILED')
where index_level = 0
```

```
SELECT SUM(used_page_count/ 128.0) AS size_in_MB
FROM sys.dm_db_partition_stats
WHERE object_id=OBJECT_ID('dbo.sales_big') AND index_id=1
GO
```

```
pages                compressed_pages
-----
4452                  4451
```

```
size_in_MB
-----
```

```
34.906250
```

In this example, you can see that the table was reduced in size significantly, from 14,519 pages to 4,452 pages (113.7MB to 34.9MB), pretty much right in line with the estimated space savings. You can also see that compression was reasonably effective, compressing 4,451 of 4,452 pages.

Be aware that you may not always receive the space savings predicted due to the effects of fill factor and the actual size of the rows. For example, if you have a row that is 8,000 bytes long and compression reduces its size by 40%, only one row can still be fit on the data page, so there is no space savings for that page. If the results of running `sp_estimate_data_compression_savings` indicate that the table will grow, this indicates that many of the rows in the table are using nearly the full precision of the data types, and the addition of the small overhead needed for the compressed format is more than the savings from compression. In this, it is obvious that there is no advantage to enabling compression.

Managing Data Compression with SSMS

The preceding examples show the T-SQL commands you can use to evaluate and manage row and page compression in SQL Server 2008. SSMS provides a Data Compression Wizard for evaluating and performing data compression activities. To invoke the Data

Compression Wizard, right-click on the table in the Object Explorer and select Storage and then select Manage Compression. Click Next to move past the Welcome page to bring up the Select Compression Type page, as shown in Figure 34.11.

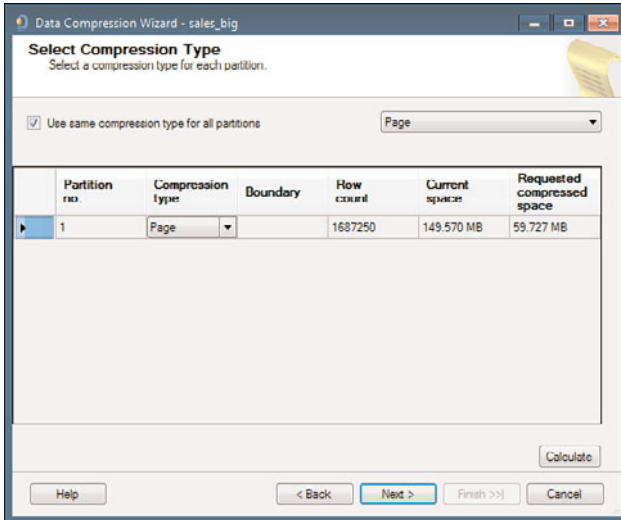

FIGURE 34.11 The Data Compression Wizard's Select Compression Type page.

On the Compression Type Page, you can choose the compression type to use at the partition level or to use the same compression type for all partitions. You can also see the estimated savings for selected compression type by clicking on the Calculate button. After you click on Calculate, the wizard displays the current partition size and requested compression size in the corresponding columns (note that it might take a few moments to do the calculation).

After making your selections, click on Next to display the Select and Output Option page. Here, you have the opportunity to have the wizard generate a script of commands you can run manually to implement the selected compression type. If you choose to generate a script, you have the option to save the script to a file, the Clipboard, or to a new query window in SSMS. You also have the option to run the compression changes immediately or schedule a SQL Agent job to run the changes at a specified time.

Understanding Table Structures

A table is logically defined as a set of columns with certain properties, such as the data type, nullability, constraints, and so on. Information about data types, column properties, constraints, and other information related to defining and creating tables can be found in Chapters 24, “Creating and Managing Tables,” and 27, “Creating and Managing Views.”

Internally, a table is contained in one or more partitions. A *partition* is a user-defined unit of data organization. By default, a table has at least one partition that contains all the table pages. This partition resides in a single filegroup, as described earlier. When a table has multiple partitions, the data is partitioned horizontally so that groups of rows are mapped into individual partitions, based on a specified column. The partitions can be placed in one or more filegroups in the database. The table is treated as a single logical entity when queries or updates are performed on the data. Figure 34.12 shows the organization of a table in SQL Server 2008.

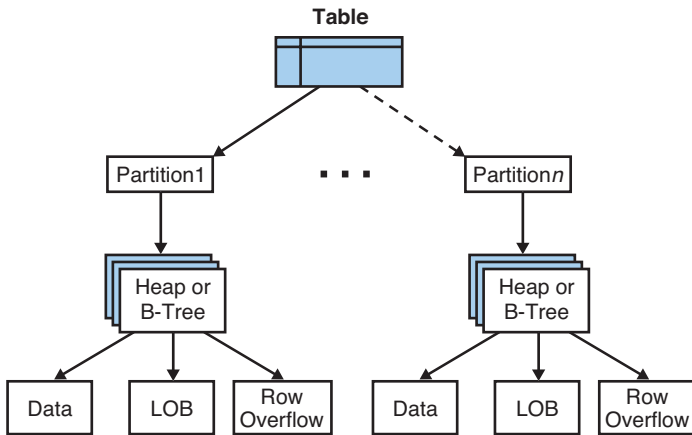

FIGURE 34.12 Table organization in SQL Server 2008.

Each table has one row in the `sys.objects` catalog view, and each table and index in a database is represented by a single row in the `sys.indexes` catalog view. Each partition of a table or index is represented by one or more rows in the `sys.partitions` catalog view. Each partition can have three types of data, each stored on its own set of pages: in-row data pages, row-overflow pages, and LOB data pages. Each of these types of pages has an allocation unit, which is contained in the `sys.allocation_units` view. There is always at least one allocation unit for the in-row data. The following sample query shows how to view the partition and allocation information for the `database1log` and `currency` tables in the `AdventureWorks2008R2` database:

```

use AdventureWorks2008R2
go
SELECT convert(varchar(15), o.name) AS table_name,
       p.index_id as indid,
       convert(varchar(30), i.name) AS index_name ,
       convert(varchar(18), au.type_desc) AS allocation_type,
       au.data_pages as d_pgs,
       partition_number as ptn
FROM sys.allocation_units AS au
     JOIN sys.partitions AS p ON au.container_id = p.partition_id
     JOIN sys.objects AS o ON p.object_id = o.object_id
     JOIN sys.indexes AS i ON p.index_id = i.index_id AND i.object_id = p.object_id
  
```

```
WHERE o.name = N'databaseLog' OR o.name = N'currency'
ORDER BY o.name, p.index_id;
```

table_name	indid	index_name	allocation_type	d_pgs	ptn
Currency	1	PK_Currency_CurrencyCode	IN_ROW_DATA	1	1
Currency	2	AK_Currency_Name	IN_ROW_DATA	1	1
DatabaseLog	0	NULL	IN_ROW_DATA	753	1
DatabaseLog	0	NULL	LOB_DATA	0	1
DatabaseLog	0	NULL	ROW_OVERFLOW_DATA	0	1
DatabaseLog	2	PK_DatabaseLog_DatabaseLogID	IN_ROW_DATA	3	1

In this example, you can see that the DatabaseLog table (which is a heap table) has three allocation units associated with the table—LOB, row-overflow, and in-row data—and one allocation unit for the nonclustered index PK_DatabaseLog_DatabaseLogID. The currency table (which is a clustered table) has a single in-row allocation unit for both the table (index_id = 1) and the nonclustered index (AK_Currency_Name).

In SQL Server 2008, there are two types of tables: heap tables and clustered tables. Let's look at how they are stored.

Heap Tables

A table without a clustered index is a *heap table*. There is no imposed ordering of the data rows for a heap table. Additionally, there is no direct linkage between the pages in a heap table.

By default, a heap has a single partition. Heaps have one row in sys.partitions, with an index ID of 0 for each partition used by the heap. When a heap has multiple partitions, each partition has a heap structure that contains the data for that specific partition. For example, if a heap has four partitions, there are four heap structures (one in each partition) and four rows in sys.partitions.

Depending on the data types in the heap, each heap structure has one or more allocation units to store and manage the data for each partition. At a minimum, each heap has one IN_ROW_DATA allocation unit per partition. The heap also has one LOB_DATA allocation unit per partition, if it contains large object columns. It also has one ROW_OVERFLOW_DATA allocation unit per partition if it contains variable-length columns that exceed the 8,060-byte row size limit.

To access the contents of a heap, SQL Server uses the IAM pages. In SQL Server 2008, each heap table has at least one IAM page. The address of the first IAM page is available in the undocumented sys.system_internals_allocation_units system view. The column first_iam_page points to the first IAM page in the chain of IAM pages that manage the space allocated to the heap in a specific partition. The following query returns the first IAM pages for each of the allocation units for the heap table DatabaseLog in AdventureWorks2008R2:

```

use AdventureWorks2008R2
go
select p.partition_number as ptn,
       type_desc,
       filegroup_id,
       first_iam_page
from sys.system_internals_allocation_units i
inner join
sys.partitions p
on p.hobt_id = i.container_id
where p.object_id = OBJECT_ID('DatabaseLog')
and index_id = 0
go

```

ptn	type_desc	filegroup_id	first_iam_page
1	IN_ROW_DATA	1	0xAA0000000100
1	LOB_DATA	1	0xB90000000100
1	ROW_OVERFLOW_DATA	1	0x000000000000

Note that the value `0x000000000000` for the `first_iam_page` for `ROW_OVERFLOW_DATA` indicates that no extents have yet been allocated for storing row-overflow data.

NOTE

The `sys.system_internals_allocation_units` system view is reserved for Microsoft SQL Server internal use only. Future compatibility and availability of this view is not guaranteed.

The data pages and rows in the heap are not sorted in any specific order and are not linked. The IAM page registers which extents are used by the table. SQL Server can then simply scan the allocated extents referenced by the IAM page, in physical order. This essentially avoids the problem of page chain fragmentation during reads because SQL Server always reads full extents in sequential order. Using the IAM pages to set the scan sequence also means that rows from the heap often are not returned in the order in which they were inserted.

As discussed earlier, each IAM can map a maximum of 63,903 extents for a table. As a table uses extents beyond the range of those 63,903 extents, more IAM pages are created for the heap table as needed. A heap table also has at least one IAM page for each file on which the heap table has extents allocated. Figure 34.13 illustrates the structure of a heap and how its contents are traversed using the IAM pages.

Clustered Tables

A *clustered table* is a table that has a clustered index defined on it. When you create a clustered index, the data rows in the table are physically sorted in the order of the columns in the index key. The data pages are chained together in a doubly linked list (each page points

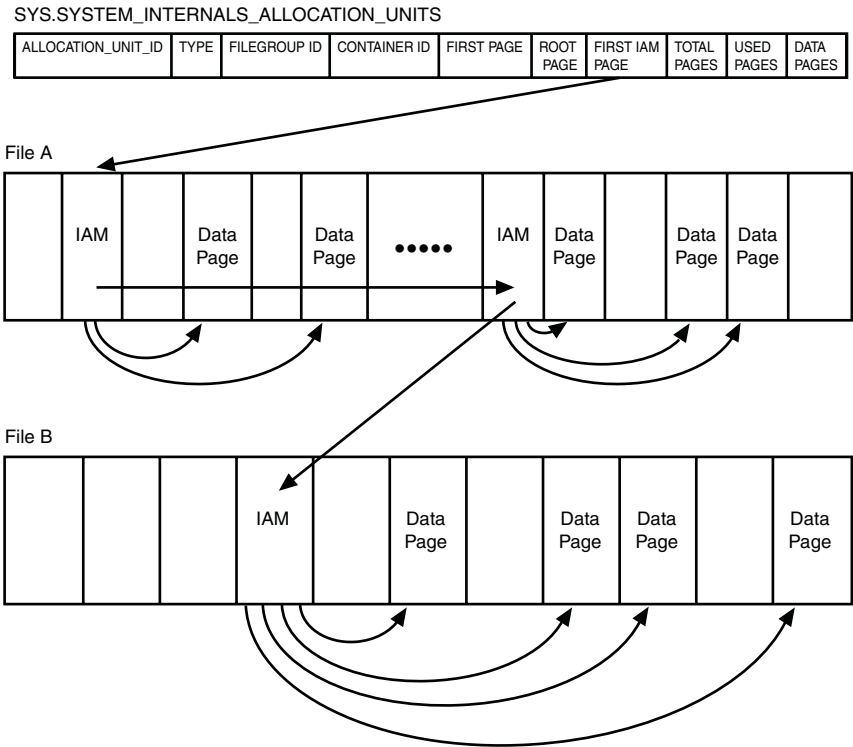

FIGURE 34.13 The structure of a heap table.

to the next page and to the previous page). Normally, data pages are not linked. Only index pages within a level are linked in this manner to allow for ordered scans of the data in an index level. Because the data pages of a clustered table constitute the leaf level of the clustered index, they are chained as well. This allows for an ordered table scan. The page pointers are stored in the page header. Figure 34.14 shows a simplified example of the data pages of a clustered table. (Note that the figure shows only the data pages.)

FIGURE 34.14 The data page structure of a clustered table.

TIP

More details on the structure and maintenance of clustered tables are provided in the remainder of this chapter.

Understanding Index Structures

When you run a query against a table that has no indexes, SQL Server has to read every page of the table, looking at every row on each page to find out whether each row satisfies the search arguments. SQL Server has to scan all the pages because there's no way of knowing whether any rows found are the only rows that satisfy the search arguments. This search method is referred to as a *table scan*.

A table scan is *not* an efficient way to retrieve data unless you really need to retrieve all rows. The Query Optimizer in SQL Server always calculates the cost of performing a table scan and uses that as a baseline when evaluating other access methods. The various access methods and query plan cost analysis are discussed in more detail in Chapter 35, "Understanding Query Optimization."

Suppose that a table is stored on 10,000 pages; even if only one row is to be returned or modified, all the pages must be searched, resulting in a scan of approximately 80MB of data (that is, $10,000 \text{ pages} \times 8\text{KB per page} = 80,000\text{KB}$).

Indexes are structures stored separately from the actual data pages; they contain pointers to data pages or data rows. Indexes are used to speed up access to the data; they are also the mechanism used to enforce the uniqueness of key values.

Indexes in SQL Server are balanced trees (B-trees; see Figure 34.12). There is a single root page at the top of the tree, which branches out into N pages at each intermediate level until it reaches the bottom (leaf level) of the index. The leaf level has one row stored for each row in the table. The index tree is traversed by following pointers from the upper-

FIGURE 34.15 The basic structure of a B-tree index.

level pages down through the lower-level pages. Each level of the index is linked as a doubly linked list.

An index can have many intermediate levels, depending on the number of rows in the table, index type, and index key width. The maximum number of columns in an index is 16; the maximum width of an index row is 900 bytes.

To provide a more efficient mechanism to identify and locate specific rows within a table quickly and easily, SQL Server supports two types of indexes: clustered and nonclustered.

Clustered Indexes

When you create a clustered index, all rows in the table are sorted and stored in the clustered index key order. Because the rows are physically sorted by the index key, you can have only one clustered index per table. You can think of the structure of a clustered index as being similar to a filing cabinet: the data pages are like folders in a file drawer in alphabetical order, and the data rows are like the records in the file folder, also in sorted order.

You can think of the intermediate levels of the index tree as the file drawers, also in alphabetical order, that assist you in finding the appropriate file folder. Figure 34.16 shows an example of a clustered index tree structure.

In Figure 34.16, note that the data page chain is in clustered index order. However, the rows on each page might not be physically sorted in clustered index order, depending on when rows were inserted or deleted in the page. SQL Server still keeps the proper sort order of the rows via the row IDs and the row offset table. A clustered index is useful for range-retrieval queries or searches against columns with duplicate values because the rows within the range are physically located in the same page or on adjacent pages.

The data pages of the table are also the leaf level of a clustered index. To find all clustered index key values, SQL Server must eventually scan all the data pages.

SQL Server performs the following steps when searching for a value using a clustered index:

1. Queries the system catalogs for the page address for the root page of the index. (For a clustered index, the `root_page` column in `sys.system_internals_allocation_units` points to the top of the clustered index for a specific partition.)
2. Compares the search value against the key values stored on the root page.
3. Finds the highest key value on the page where the key value is less than or equal to the search value.
4. Follows the page pointer stored with the key to the appropriate page at the next level down in the index.
5. Continues following page pointers (that is, repeats steps 3 and 4) until the data page is reached.
6. Searches the rows on the data page to locate any matches for the search value. If no matching row is found on that data page, the table contains no matching values.

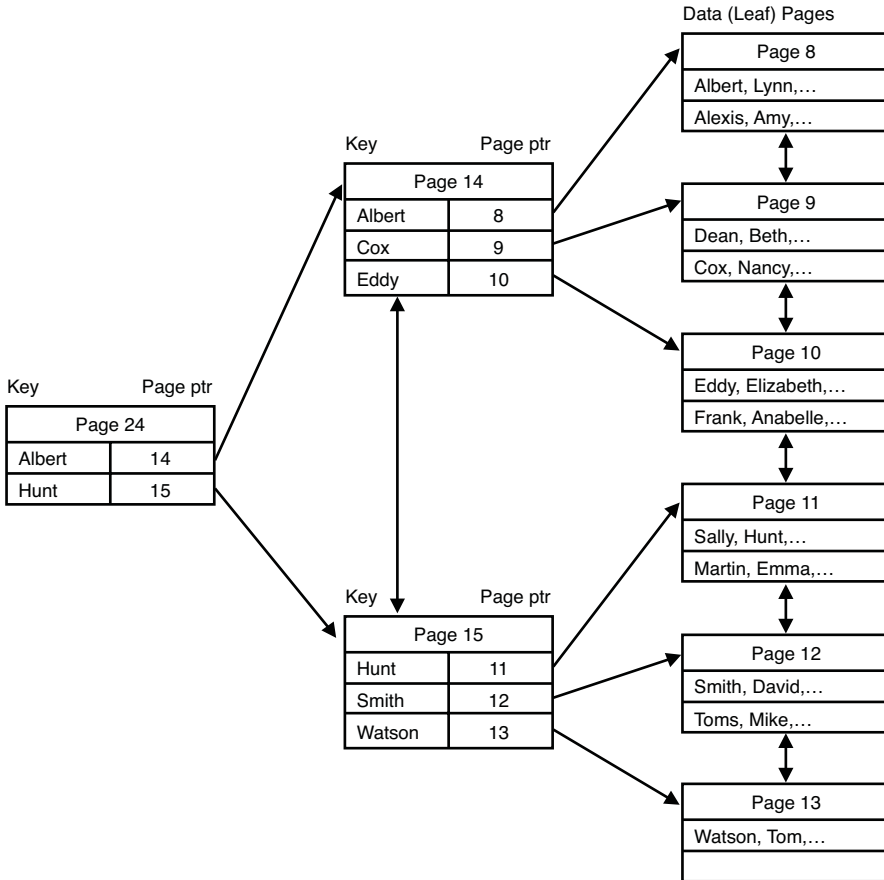

FIGURE 34.16 The structure of a clustered index.

By default, a clustered index has a single partition and thus has at least one row in `sys.partitions` with `index_id = 1`. When a clustered index has multiple partitions, a separate B-tree structure contains the data for that specific partition.

Depending on the data types in the clustered index, each clustered index structure has one or more allocation units in which to store and manage the data for a specific partition. At a minimum, each clustered index has one `IN_ROW_DATA` allocation unit per partition. If the table contains any LOB data, the clustered index also has one `LOB_DATA` allocation unit per partition and one `ROW_OVERFLOW_DATA` allocation unit per partition if the table contains any variable-length columns that exceed the 8,060-byte row size limit.

Clustered Index Row Structure

The structure of a clustered index row is similar to the structure of a data row except that it contains only key columns; this structure is detailed in Figure 34.17.

(Shaded Areas represent data present only when index contains nullable or variable length columns)

FIGURE 34.17 Clustered index row structure.

Notice that unlike a data row, index rows do not contain the status byte B or the 2 bytes to hold the length of fixed-length data fields. Instead of storing the length of the fixed-length data, which also indicates where the fixed-length portion of a row ends and the variable-length portion begins, the page header `pmnlen` value is used to help describe an index row. The `pmnlen` value is the minimum length of the index row, which is essentially the sum of the size of all fixed-width fields and overhead. Therefore, if no variable-length or nullable fields are in the index key, `pmnlen` also indicates the width of each index row.

The null bitmap field and field for the number of columns in the index row are present only when an index key contains nullable columns. The number of columns value is only needed to determine how many bits are needed in the null bitmap and therefore how many bytes are required to store the null bitmap (1 byte per eight columns). The data contents of a clustered index row include the key values along with a 6-byte down-page pointer (the first 2 bytes are the file ID, and the last 4 bytes are the page number). The down-page pointer is the last value in the fixed-data portion of the row.

Nonunique Clustered Indexes

When a clustered index is defined on a table, the clustered index keys are used as row locators to identify the data rows being referenced by nonclustered indexes (more on this topic in the following section on nonclustered indexes). Because the clustered keys are used as unique row pointers, there needs to be a way to uniquely refer to each row in the table. If the clustered index is defined as a unique index, the key itself uniquely identifies every row. If the clustered index was not created as a unique index, SQL Server adds a 4-byte integer field, called a *uniqueifier*, to the data row to make each key unique when necessary. When is the uniqueifier necessary? SQL Server adds the uniqueifier to a row when the row is added to a table and that new row contains a key that is a duplicate of the key for an already-existing row.

The uniqueifier is added to the variable-length data area of the data row, which also results in the addition of the variable-length overhead bytes. Therefore, each duplicate row in a clustered index has a minimum of 4 bytes of overhead added for the additional

uniqueifier. If the row had no variable-length keys previously, an additional 8 bytes of overhead are added to the row to store the uniqueifier (4 bytes) plus the overhead bytes required for the variable data (storing the number of variable columns requires 2 bytes, and the column offset array requires 2 bytes).

Nonclustered Indexes

A nonclustered index is a separate index structure, independent of the physical sort order of the data rows in the table. You can have up to 999 nonclustered indexes per table.

A nonclustered index is similar to the index in the back of a book. To find the pages on which a specific subject is discussed, you look up the subject in the index and then go to the pages referenced in the index. This method is efficient as long as the subject is discussed on only a few pages. If the subject is discussed on many pages, or if you want to read about many subjects, it can be more efficient to read the entire book.

A nonclustered index works similarly to the book index. From the index's perspective, the data rows are randomly spread throughout the table. The nonclustered index tree contains the index key values, in sorted order. There is a row at the leaf level of the index for each

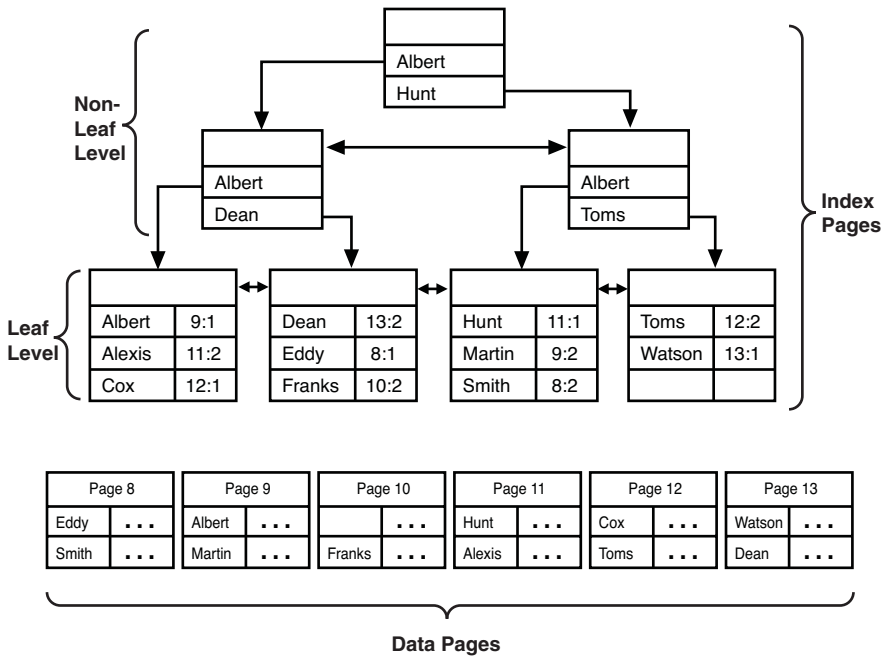

FIGURE 34.18 A nonclustered index on a heap table.

data row in the table. Each leaf-level row contains a data row locator to locate the actual data row in the table.

If no clustered index is created for the table, the data row locator for the leaf level of the index is an actual pointer to the data page and the row number within the page where the row is located (see Figure 34.18).

Nonclustered indexes on clustered tables use the associated clustered index key value for the record as the data row locator. When SQL Server reaches the leaf level of a nonclus-

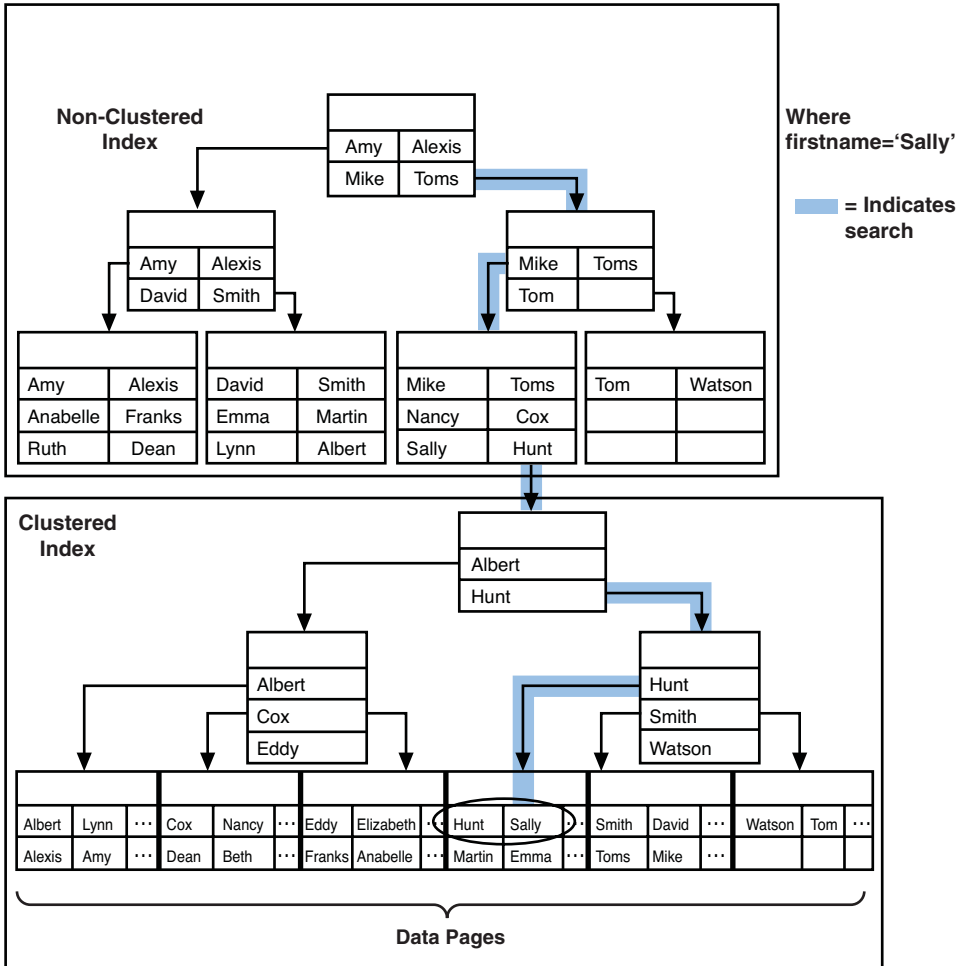

FIGURE 34.19 A nonclustered index on a clustered table.

tered index, it uses the clustered index key to start searching through the clustered index to find the actual data row (see Figure 34.19). This adds some I/O to the search itself, but the benefit is that if a page split occurs in a clustered table, or if a data row is moved (for example, as a result of an update), the nonclustered index row locator stays the same. As

long as the clustered index key value itself is not modified, no data row locators in the nonclustered index have to be updated.

SQL Server performs the following steps when searching for a value by using a nonclustered index:

1. Queries the system catalog to determine the page address for the root page of the index.
2. Compares the search value against the index key values on the root page.
3. Finds the highest key value on the page where the key value is less than or equal to the search value.
4. Follows the down-page pointer to the next level down in the nonclustered index tree.
5. Continues following page pointers (that is, repeats steps 3 and 4) until the nonclustered index leaf page is reached.
6. Searches the index key rows on the leaf page to locate any matches for the search value. If no matching row is found on the leaf page, the table contains no matching values.
7. If a match is found on the leaf page, SQL Server follows the data row locator to the data row on the data page.

Nonclustered Index Leaf Row Structures

In nonclustered indexes, if the row locator is a row ID, it is stored at the end of the fixed-length data portion of the row. The rest of the structure of a nonclustered index leaf row is similar to a clustered index row. Figure 34.20 shows the structure of a nonclustered leaf row for a heap table.

(Shaded Areas represent data present only when index contains nullable or variable length columns)

FIGURE 34.20 The structure of a nonclustered index leaf row for a heap table.

If the row locator is a clustered index key value, the row locator resides in either the fixed or variable portion of the row, depending on whether the clustered key columns were defined as fixed or variable length. Figure 34.21 shows the structure of a nonclustered leaf row for a clustered table.

When the row locator is a clustered key value and the clustered and nonclustered indexes share columns, the data value for the key is stored only once in the nonclustered index row. For example, if your clustered index key is on lastname and you have a nonclustered

(Shaded Areas represent data present only when index contains nullable or variable length columns)

FIGURE 34.21 The structure of a nonclustered index leaf row for a clustered table.

index defined on both `firstname` and `lastname`, the index rows do not store the value of `lastname` twice, but only once for both keys.

Nonclustered Index Nonleaf Row Structures

The nonclustered index nonleaf rows are similar in structure to clustered index nonleaf rows in that they contain a page-down pointer to a page at the next level down in the index tree. The nonleaf rows don't need to point to data rows; they only need to provide the path to traverse the index tree to a leaf row. If the nonclustered index is defined as unique, the nonleaf index key row contains only the index key value and page-down pointer. Figure 34.22 shows the structure of a nonleaf index row for a unique nonclustered index.

(Shaded Areas represent data present only when index contains nullable or variable length columns)

FIGURE 34.22 The structure of a nonclustered nonleaf index row for a unique index.

If the nonclustered index is not defined as a unique index, the nonleaf rows also contain the row locator information for the corresponding data row. Storing the row locator in the nonleaf index row ensures each index key row is unique (because the row locator, by its

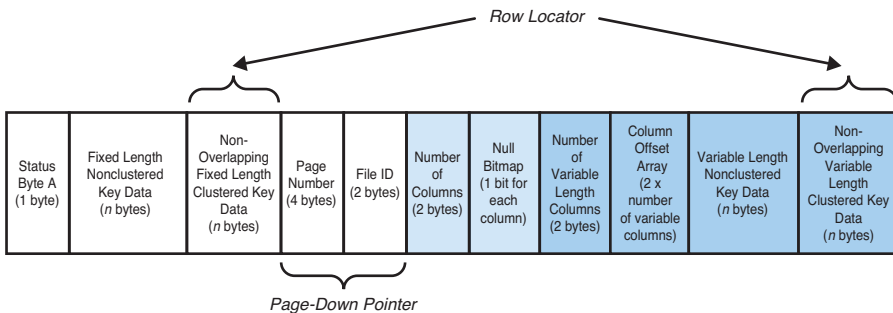

nature, must be unique). Ensuring each index key row is unique allows any corresponding nonleaf index rows to be located and deleted more easily when the data row is deleted. For a heap table, the row locator is the corresponding data row's page and row pointer, as shown in Figure 34.23.

(Shaded Areas represent data present only when index contains nullable or variable length columns)

FIGURE 34.23 The structure of a nonclustered nonleaf index row for a nonunique index on a heap table.

If the table is clustered, the clustered key values are stored in the nonleaf index rows of the nonunique nonclustered index just as they are in the leaf rows, as shown in Figure 34.24.

(Shaded Areas represent data present only when index contains nullable or variable length columns)

FIGURE 34.24 The structure of a nonclustered nonleaf index row for a nonunique index on a clustered table.

As you can see, it's possible for the index pointers and row overhead to exceed the size of the index key itself. This is why, for I/O and storage reasons, it is always recommended that you keep your index keys as small as possible.

Data Modification and Performance

Now that you have a better understanding of the storage structures in SQL Server, it's time to look at how SQL Server maintains and manages those structures when data modifications are taking place in the database.

Inserting Data

When you add a data row to a heap table, SQL Server adds the row to the heap wherever space is available. SQL Server uses the IAM and PFS pages to identify whether any pages with free space are available in the extents already allocated to the table. If no free pages are found, SQL Server uses the information from the GAM and SGAM pages to locate a free extent and allocate it to the table.

For clustered tables, the new data row is inserted to the appropriate location on the appropriate data page relative to the clustered index key order. If no more room is available on the destination page, SQL Server needs to link a new page in the page chain to make room available and add the row. This is called a *page split*.

In addition to modifying the affected data pages when adding rows, SQL Server needs to update all nonclustered indexes to add a pointer to the new record. If a page split occurs, this incurs even more overhead because the clustered index needs to be updated to store the pointer for the new page added to the table. Fortunately, because the clustered key is used as the row locator in nonclustered indexes when a table is clustered, even though the page and row IDs have changed, the nonclustered index row locators for rows moved by a page split do not have to be updated as long as the clustered key column values remain the same.

Page Splits

When a page split occurs, SQL Server looks for an available page to link into the page chain. It first tries to find an available page in the same extent as the pages it will be linked to. If no free pages exist in the same extent, it looks at the IAM to determine whether there are any free pages in any other extents already allocated to the table or index. If no free pages are found, a new extent is allocated to the table.

When a new page is found or allocated to the table and linked into the page chain, the original page is "split." Approximately half the rows are moved to the new page, and the rest remain on the original page (see Figure 34.25). Whether the new page goes before or after the original page when the split is made depends on the amount of data to be moved. In an effort to minimize logging, SQL Server moves the smaller rows to the new page. If the smaller rows are at the beginning of the page, SQL Server places the new page before the original page and moves the smaller rows to it. If the larger rows are at the beginning of the page, SQL Server keeps them on the original page and moves the smaller rows to the new page after the original page.

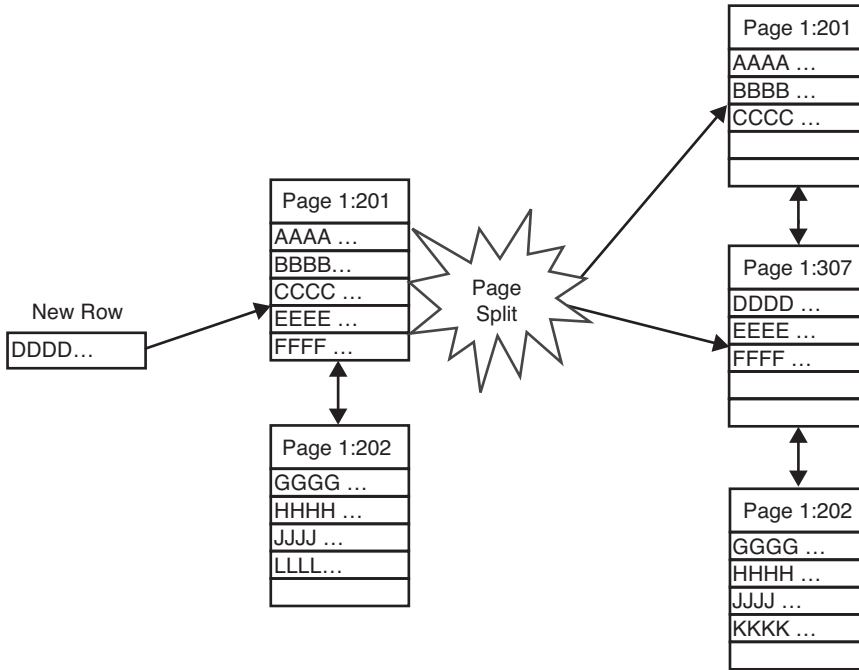

FIGURE 34.25 Page splitting due to inserts.

After determining where the new row goes between the existing rows and whether the new page is to be added before or after the original page, SQL Server has to move rows to the new page. The simplified algorithm for determining the split point is as follows:

1. Place first row (with the lowest clustered key value) at the beginning of first page.
2. Place the last row (with the highest clustered key value) on the second page.
3. Place the row with the next lowest clustered key value on the first page after the existing row(s).
4. Place the next-to-last row (with the second highest clustered key value) on the second page.
5. Continue alternating back and forth until the space between the two pages is balanced or one of the pages is full.

In some situations a double split can occur. If the new row has to go between two existing rows on a page, but the new row is too large to fit on either page with any of the existing rows, a new page is added after the original. The new row is added to the new page, a second new page is added after that, and the remaining original rows are inserted into the second new page. An example of a double split is shown in Figure 34.26.

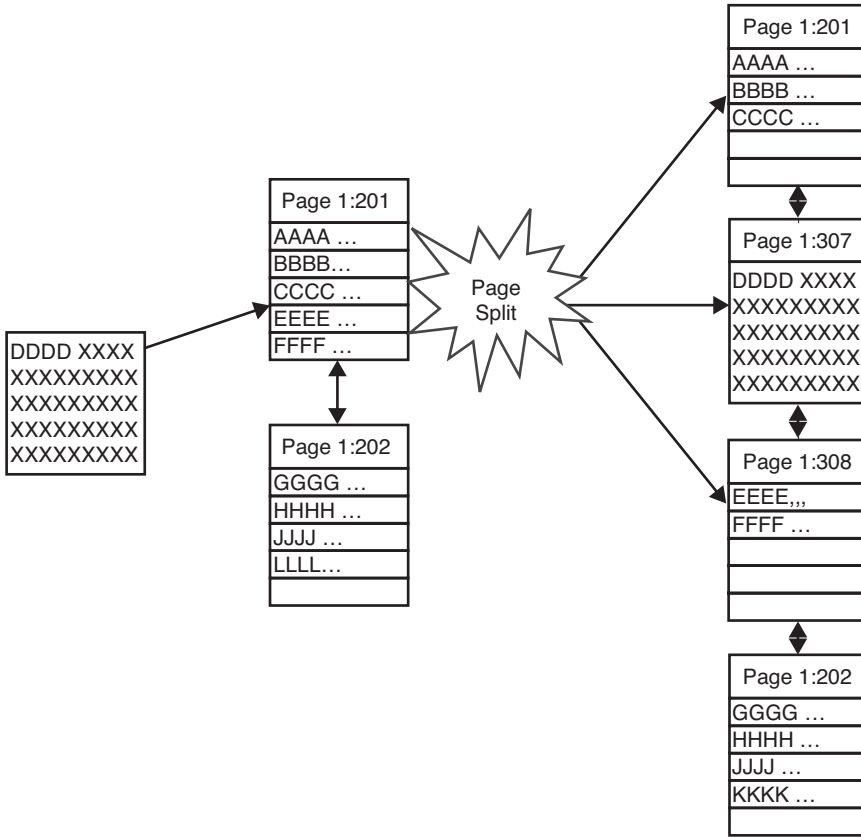

FIGURE 34.26 Double page split due to large row insert.

NOTE

Although page splits are expensive when they occur, they do generate free space in the split pages for future inserts into those pages. Page splits also help keep the index tree balanced as rows are added to the table. However, if you monitor the system with Performance Monitor and are seeing hundreds of page splits per second, you might want to consider rebuilding the clustered index on the table and applying a lower fill factor to provide more free space in the existing pages. This can help improve system performance until eventually the pages fill up and start splitting again. For this reason, some shops supporting high-volume online transaction processing (OLTP) environments with a lot of insert activity rebuild the indexes with a lower fill factor on a daily basis.

Deleting Rows

What happens when rows are deleted from a table? How, and when, does SQL Server reclaim the space when data is removed from a table?

Deleting Rows from a Heap

In a heap table, SQL Server does not automatically compress the space on a page when a row is removed; that is, the rows are not all moved up to the beginning of the page to keep all free space at the end, as SQL Server did in versions prior to 7.0. To optimize performance, SQL Server holds off on compacting the rows until the page needs contiguous space for storing a new row.

Deleting Rows from an Index

Because the data pages of a clustered table are actually the leaf pages of the clustered index, the behavior of data row deletes on a clustered table is the same as row deletions from an index page.

When rows are deleted from the leaf level of an index, they are not actually deleted but are marked as ghost records. Keeping the row as a ghost record makes it easier for SQL Server to perform key-range locking (key-range locking is discussed in Chapter 37, “Locking and Performance”). If ghost records were not used, SQL Server would have to lock the entire range surrounding the deleted record. With the ghost record still present and visible internally to SQL Server (it is not visible in query result sets), SQL Server can use the ghost record as an endpoint for the key-range lock to prevent “phantom” records with the same key value from being inserted, while allowing inserts of other values to proceed.

Ghost records do not stay around forever, though. SQL Server has a special internal house-keeping process that periodically examines the leaf level of B-trees for ghost records and removes them. This is the same thread that performs the autoshrink process for databases.

Whenever you delete a row, all nonclustered indexes need to be updated to remove the pointers to the deleted row. Nonleaf index rows are not ghosted when deleted. As with heap tables, however, the space is not compressed on the nonleaf index page until space is needed for a new row.

Reclaiming Space

Only when the last row is deleted from a data page is the page deallocated from the table. The only exception is if it is the last page remaining; all tables must have at least one page allocated, even if it's empty. When a deletion of an index row leaves only one row remaining on the page, the remaining row is moved to a neighboring page, and the now-empty index page is deallocated.

If the page to be deallocated is the last remaining used page in a uniform extent allocated to the table, the extent is deallocated from the table as well.

Updating Rows

SQL Server 2008 performs row updates by evaluating the number of rows affected, whether the rows are being accessed via a scan or index retrieval and whether any index keys are being modified, and automatically chooses the appropriate and most efficient update strategy for the rows affected. SQL Server can perform two types of update strategies:

- ▶ In-place updates
- ▶ Not-in-place updates

In-Place Updates

In SQL Server 2008, in-place updates are performed as often as possible to minimize the overhead of an update. An *in-place update* means that the row is modified where it is on the page, and only the affected bytes are changed.

When an in-place update is performed, in addition to the reduced overhead in the table itself, only a single modify record is written to the log. However, if the table has a trigger on it or is marked for replication, the update is still done in place but is recorded in the log as a delete followed by an insert (this provides the before-and-after image for the trigger that is referenced in the inserted and deleted tables).

In-place updates are performed whenever a heap is being updated and the row still fits on the same page, or when a clustered table is updated and the clustered key itself is not changed. You can get an in-place update if the clustered key changes but the row does not have to move; that is, the sorting of the rows wouldn't change.

Not-In-Place Updates

If the change to a clustered key prevents an in-place update from being performed, or if the modification to a row increases its size such that it can no longer fit on its current page, the update is performed as a delete followed by an insert; this is referred to as a *not-in-place update*.

When performing an update that affects multiple index keys, SQL Server keeps a list of the rows that need to be updated in memory, if it's small enough; otherwise, it is stored in tempdb. SQL Server then sorts the list by index key and type of operation (delete or insert). This list of operations, called the *input stream*, consists of both the old and new values for every column in the affected rows as well as the unique row identifier for each row.

SQL Server then examines the input stream to determine whether any of the updates conflict or would generate duplicate key values while processing (if they were to generate a duplicate key after processing, the update cannot proceed). It then rearranges the operations in the input stream in a manner to prevent any intermediate violations of the unique key.

For example, consider the following update to a table with a unique key on a sequential primary key:

```
update table1 set pkey = pkey + 1
```

Even though all values would still be unique when the update finished, if the update were performed internally one row at a time in sequential order, it would generate duplicates during the intermediate processing as the pkey value was incremented and matched the next pkey value. SQL Server would rearrange and rework the updates in the input stream to process them in a manner that would avoid the duplicates and then process them a row at a time. If possible, deletes and inserts on the same key value in the input stream are collapsed into a single update. In some cases, you might still get some rows that can be updated in place.

Forward Pointers

As mentioned earlier, when page splits on a clustered table occur, the nonclustered indexes do not need to be updated to reflect the new location of the rows because the row locator for the row is the clustered index key rather than the page and row ID. When an update operation on a heap table causes rows to move, the row locators in the nonclustered index would need to be updated to reflect the new location of the rows. This could be expensive if there were a larger number of nonclustered indexes on the heap.

SQL Server 2008 addresses this performance issue through the use of forward pointers. When a row in a heap moves, it leaves a forward pointer in the original location of the row. The forward pointer avoids having to update the nonclustered index row locator. When SQL Server is searching for the row via the nonclustered index, the index pointer directs it to the original location, where the forward pointer redirects it to the new row location.

A row never has more than one forward pointer. If the row moves again from its forwarded location, the forward pointer stored at the original row location is updated to the row's new location. There is never a forward pointer that points to another forward pointer. If the row ever shrinks enough to fit back into its original location, the forward pointer is removed, and the row is put back where it originated.

When a forward pointer is created, it remains unless the row moves back to its original location. The only other circumstance that results in forward pointers being deleted occurs when the entire database is shrunk. When a database file is shrunk and the data reorganized, all row locators are reassigned because the rows are moved to new pages.

Index Utilization

Now that you have an understanding of table and index structures and the overhead required to maintain your data and indexes, you might want to put things into practice to actually come up with an index design for your database, defining the appropriate indexes to support your queries. To effectively determine the appropriate indexes that should be created, you need to determine whether they'll actually be used by the SQL Server Query Optimizer. If an index is not being used effectively, it's just wasting space and creating unnecessary overhead during updates.

The main criterion to remember is that SQL Server does not use an index for the more efficient row locator lookup if at least the first column of the index is not included in a valid search argument (SARG) or join clause. You should keep this point in mind when choosing the column order for composite indexes. For example, consider the following index on the stores table in the bigpubs2008 database:

```
create index nc1_stores on stores (city, state, zip)
```

NOTE

Unless stated otherwise, all sample queries from this point on in this chapter are run in the bigpubs2008 database, which is available on the included CD or via download from this book's website at www.sampublishing.com. Instructions on installing this database is provided in the Introduction.

Each of the following queries could use the index because they include the first column, city, of the index as part of the SARG:

```
select stor_name from stores
  where city = 'Frederick'
     and state = 'MD'
     and zip = '21702'
```

```
select stor_name from stores
  where city = 'Frederick'
     and state = 'MD'
```

```
select stor_name from stores
  where city = 'Frederick'
     and zip = '21702'
```

However, the following queries do not use the index for a row locator lookup because they don't specify the city column as a SARG:

```
select stor_name from stores
  where state = 'MD'
     and zip = '21702'
```

```
select stor_name from stores
  where zip = '21702'
```

For the index nc1_stores to be used for a row locator lookup in the last query, you would have to reorder the columns so that zip is first—but then the index wouldn't be useful for

any queries specifying only *city* and/or *state*. Satisfying all the preceding queries in this case would require additional indexes on the *stores* table.

NOTE

For the two preceding queries, if you were to display the execution plan information (as described in Chapter 36, “Query Analysis”), you might see that the queries actually use the *nc1_stores* index to retrieve the result set. However, if you look closely, you can see the queries are not using the index in the most efficient manner; the index is being used to perform an index scan rather than an index seek. An index seek is what we are really after. (Alternative query access methods are discussed in more detail in Chapter 35). In an index *seek*, SQL Server searches for the specific SARG by walking the index tree from the root level down to the specific row(s) with matching index key values and then uses the row locator value stored in the index key to directly retrieve the matching row(s) from the data page(s); the row locator is either a specific row identifier or the clustered key value for the row.

For an index *scan*, SQL Server searches all the rows in the leaf level of the index, looking for possible matches. If any are found, it then uses the row locator to retrieve the data row.

Although both seeks and scans use an index, the index scan is still more expensive in terms of I/O than an index seek but slightly less expensive than a table scan, which is why it is used. However, in this chapter you learn to design indexes that result in index seeks, and when this chapter talks about queries using an index, index seeks are what it refers to (except for the section on index covering, but that’s a horse of a slightly different color).

You might think that the easy solution to get row locator lookups on all possible columns is to index all the columns on a table so that any type of search criteria specified for a query can be helped by an index. This strategy might be somewhat appropriate in a read-only decision support system (DSS) environment that supports ad hoc queries, but it is not likely because many of the indexes probably still wouldn’t even be used. As you see in the section “Index Selection,” later in this chapter, just because an index is defined on a column doesn’t mean that the Query Optimizer is necessarily always going to use it if the search criteria are not selective enough. Also, creating that many indexes on a large table could take up a significant amount of space in the database, increasing the time required to back up and run DBCC checks on the database. As mentioned earlier, too many indexes on a table in an OLTP environment can generate a significant amount of overhead during inserts, updates, and deletes and have a detrimental impact on performance.

TIP

A common design mistake often made is too many indexes defined on tables in OLTP environments. In many cases, some of the indexes are redundant or are never even considered by the SQL Server Query Optimizer to process the queries used by the applications. These indexes end up simply wasting space and adding unnecessary overhead to data updates.

A case in point was one client who had eight indexes defined on a table, four of which had the same column, which was a unique key, as the first column in the index. That column was included in the WHERE clauses for all queries and updates performed on the table. Only one of those four indexes was ever used.

It is hoped that, by the end of this chapter, you understand why all these indexes were unnecessary and are able to recognize and determine which columns benefit from having indexes defined on them and which indexes to avoid.

Index Selection

To determine which indexes to define on a table, you need to perform a detailed query analysis. This process involves examining the search clauses to see what columns are referenced, knowing the bias of the data to determine the usefulness of the index, and ranking the queries in order of importance and frequency of execution. You have to be careful not to examine individual queries and develop indexes to support one query, without considering the other queries that are executed on the table as well. You need to come up with a set of indexes that work for the best cross-section of your queries.

TIP

A useful tool to help you identify your frequently executed and critical queries is SQL Server Profiler. I've found SQL Server Profiler to be invaluable when going into a new client site and having to identify the problem queries that need tuning. SQL Server Profiler allows you to trace the procedures and queries being executed in SQL Server and capture the runtime, reads and writes, execution plans, and other processing information. This information can help you identify which queries are providing substandard performance, which ones are being executed most often, which indexes are being used by the queries, and so on.

You can analyze this information yourself manually or save a trace to analyze with the Database Engine Tuning Advisor. The features of SQL Server Profiler are covered in more detail in Chapter 6, "SQL Server Profiler." The Database Engine Tuning Advisor is discussed in more detail in Chapter 55, "Configuring, Tuning, and Optimizing SQL Server Options."

Because it's usually not possible to index for everything, you should index first for the queries most critical to your applications or those run frequently by many users. If you have a query that's run only once a month, is it worth creating an index to support only that query and having to maintain it throughout the rest of the month? The sum of the additional processing time throughout the month could conceivably exceed the time required to perform a table scan to satisfy that one query.

TIP

If, due to query response time requirements, you must have an index in place when a query is run, consider creating the index only when you run the query and then dropping the index for the remainder of the month. This approach is feasible as long as the time it takes to create the index and run the query that uses the index doesn't exceed the time it takes to simply run the query without the index in place.

Evaluating Index Usefulness

SQL Server provides indexes for two primary reasons: as a method to enforce the uniqueness of the data in the database tables and to provide faster access to data in the tables. Creating the appropriate indexes for a database is one of the most important aspects of physical database design. Because you can't have an unlimited number of indexes on a table, and it wouldn't be feasible anyway, you should create indexes on columns that have high selectivity so that your queries will use the indexes. The selectivity of an index can be defined as follows:

$$\text{Selectivity ratio} = \text{Number of unique index values} / \text{Number of rows in table}$$

If the selectivity ratio is high—that is, if a large number of rows can be uniquely identified by the key—the index is highly selective and useful to the Query Optimizer. The optimum selectivity would be 1, meaning that there is a unique value for each row. A low selectivity means that there are many duplicate values and the index would be less useful. The SQL Server Query Optimizer decides whether to use any indexes for a query based on the selectivity of the index. The higher the selectivity, the faster and more efficiently SQL Server can retrieve the result set.

For example, say that you are evaluating useful indexes on the authors table in the `bigpubs2008` database. Assume that most of the queries access the table either by author's last name or by state. Because a large number of concurrent users modify data in this table, you are allowed to choose only one index—author's last name or state. Which one should you choose? Let's perform some analysis to see which one is a more useful, or selective, index.

First, you need to determine the selectivity based on the author's last name with a query on the authors table in the `bigpubs2008` database:

```
select count(distinct au_lname) as '# unique',
       count(*) as '# rows',
       str(count(distinct au_lname) / cast (count(*) as real),4,2) as 'selectivity'
from authors
go
```

# unique	# rows	selectivity
160	172	0.93

The selectivity ratio calculated for the `au_lname` column on the `authors` table, 0.93, indicates that an index on `au_lname` would be highly selective and a good candidate for an index. All but 12 rows in the table contain a unique value for last name.

Now, look at the selectivity of the `state` column:

```
select count(distinct state) as '# unique',
       count(*) '# rows',
       str(count(distinct state) / cast (count(*) as real),4,2) as 'selectivity'
from authors
go
```

```
# unique    # rows      selectivity
-----
38          172         0.22
```

As you can see, an index on the `state` column would be much less selective (0.22) than an index on the `au_lname` column and possibly not as useful.

One of the questions to ask at this point is whether a few values in the `state` column that have a high number of duplicates are skewing the selectivity or whether there are just a few unique values in the table. You can determine this with a query similar to the following:

```
select state,
       count(*) as numrows,
       count(*)/b.totalrows * 100 as percentage
from authors a,
     (select convert(numeric(6,2), count(*)) as totalrows from authors) as b
group by state, b.totalrows
having count(*) > 1
order by 2 desc
go
```

```
state numrows    percentage
-----
CA    37             21.5116200
NY    18             10.4651100
TX    15             8.7209300
OH    9              5.2325500
FL    8              4.6511600

PA    6              3.4883700
CO    5              2.9069700
LA    5              2.9069700
MI    5              2.9069700
```

MN	3	1.7441800
MO	3	1.7441800
OK	3	1.7441800
AZ	3	1.7441800
AK	2	1.1627900
IN	2	1.1627900
GA	2	1.1627900
MA	2	1.1627900
NC	2	1.1627900
NE	2	1.1627900
SD	2	1.1627900
VA	2	1.1627900
WI	2	1.1627900
WV	2	1.1627900

As you can see, most of the state values are relatively unique, except for one value, 'CA', which accounts for more than 20% of the values in the table. Therefore, state is probably not a good candidate for an indexed column, especially if most of the time you are searching for authors from the state of California. SQL Server would generally find it more efficient to scan the whole table rather than search via the index.

NOTE

When a single value skews the selectivity of an index, as in this example with the state column, this type of column might be a candidate for a filtered index, a new feature in SQL Server 2008. See the section “Filtered Indexes and Statistics,” later in this chapter.

As a general rule of thumb, if the selectivity ratio for a nonclustered index key is less than 0.85 (in other words, if the Query Optimizer cannot discard at least 85% of the rows based on the key value), the Query Optimizer generally chooses a table scan to process the query rather than a nonclustered index. In such cases, performing a table scan to find all the qualifying rows is more efficient than seeking through the B-tree to locate a large number of data rows.

NOTE

You can relate the concept of selectivity to a hypothetical example. Say that you need to find every instance of the word *SQL* in this book. Would it be easier to do it by using the index and going back and forth from the index to all the pages that contain the word, or would it be easier just to scan each page from beginning to end to locate every occurrence? What if you had to find all references to the word *squonk*, if any? *Squonk* would definitely be easier to find via the index (actually, the index would help you determine that it doesn't even exist). Therefore, the selectivity for *Squonk* would be high, and the selectivity for *SQL* would be much lower.

How does SQL Server determine whether an index is selective and which index, if it has more than one to choose from, would be the most efficient to use? For example, how would SQL Server know how many rows the following query might return?

```
select * from table
    where key between 1000000 and 2000000
```

If the table contains 10,000,000 rows with values ranging between 0 and 20,000,000, how does the Query Optimizer know whether to use an index or a table scan? There could be 10 rows in the range, or 900,000. How does SQL Server estimate how many rows are between 1,000,000 and 2,000,000? The Query Optimizer gets this information from the index statistics, as described in the next section.

Index Statistics

As mentioned earlier, the selectivity of a key is an important factor that determines whether an index will be used to retrieve the data rows that satisfy a query. SQL Server stores the selectivity and a histogram of sample values of the key; based on the statistics stored for the key columns for the index and the SARGs specified for the query, the Query Optimizer decides which index to use.

To see the statistical information stored for an index, use the DBCC SHOW_STATISTICS command, which returns the following pieces of information:

- ▶ A histogram that contains an even sampling of the values for the first column in the index key. SQL Server stores up to 200 sample values in the histogram.
- ▶ Index densities for the combination of columns in the index. Index density indicates the uniqueness of the index key(s) and is discussed later in this section.
- ▶ The number of rows in the table at the time the statistics were computed.
- ▶ The number of rows sampled to generate the statistics.
- ▶ The number of sample values (steps) stored in the histogram.
- ▶ The average key length.
- ▶ Whether the index is defined on a string column.
- ▶ The date and time the statistics were generated.

The syntax for DBCC SHOW_STATISTICS is as follows:

```
DBCC SHOW_STATISTICS (tablename, index)
```

Listing 34.4 displays the abbreviated output from DBCC SHOW_STATISTICS, showing the statistical information for the `au_nmind` nonclustered index on the `au_lname` and `au_fname` columns of the `authors` table.

LISTING 34.4 **DBCC SHOW_STATISTICS** Output for the **aunmind** Index on the **authors** Table

```
dbcc show_statistics (authors, aunmind )
go
```

Name	Updated	Rows	Rows	Steps	Density

Wilson	0	1	0	1
Yates	0	1	0	1
Yokomoto	0	1	0	1
Young	0	1	0	1

Looking at the output, you can determine that the statistics were last updated on March 14, 2010. At the time the statistics were generated, the table had 172 rows, and all 172 rows were sampled to generate the statistics (no filtering was applied). The average key length is 24.06977 bytes. From the `All density` information, you can see that this index is highly selective. (A low density means high selectivity; index densities are covered shortly.)

After the general information and the index densities, the index histogram is displayed.

The Statistics Histogram

Up to 200 sample values can be stored in the statistics histogram. Each sample value is called a *step*. The sample value stored in each step is the endpoint of a range of values. Three values are stored for each step:

- ▶ **RANGE_ROWS**—This indicates how many other rows are inside the range between the current step and the step prior, not including the step values themselves.
- ▶ **EQ_ROWS**—This is the number of rows that have the same value as the sample value. In other words, it is the number of duplicate values for the step.
- ▶ **Range density**—This indicates the number of distinct values within the range. The range density information is actually displayed in two separate columns, `DISTINCT_RANGE_ROWS` and `AVG_RANGE_ROWS`:
 - ▶ `DISTINCT_RANGE_ROWS` is the number of distinct values between the current step and the step prior, not including the step values itself.
 - ▶ `AVG_RANGE_ROWS` is the average number of rows per distinct value within the range of the step.

In the output in Listing 34.4, distinct key values in the first column of the index are stored as the sample values in the histogram. Because most of the values for au_lname are unique, most of the range values are 0. You can see that there is a duplicate in the index key for the last name of Hutchins (EQ_ROWS is 2). For comparison purposes, Listing 34.5 shows a snippet of the DBCC SHOW_STATISTICS output for the titleidind index on the sales table in bigpubs2008.

LISTING 34.5 DBCC SHOW_STATISTICS Output for the titleidind Index on the sales Table in the bigpubs2008 Database

```

dbcc show_statistics (sales, 'titleidind')
go

As you can see in this example, there are a greater number of rows per range and a greater number of duplicates for each step value. Also, 188 steps in the histogram are used, and the sample values for the 168,725 rows in the table are distributed across those 188 step values. Also, in this example, 152,432 rows, rather than the whole table, were sampled to generate the statistics.

How the Statistics Histogram Is Used

The histogram steps are used for SARGs only when a constant expression is compared against an indexed column and the value of the constant expression is known at query compile time. The following SARG examples show where histogram steps can be used:

- ▶ where col_a = getdate()
- ▶ where cust_id = 12345
- ▶ where monthly_sales < 10000 / 12
- ▶ where l_name like "Smith" + "%"

Some constant expressions cannot be evaluated until query runtime. They include search arguments that contain local variables or subqueries and also join clauses, such as the following:

- ▶ where price = @avg_price
- ▶ where total_sales > (select sum(qty) from sales)
- ▶ where titles.pub_id = publishers.pub_id

For these types of statements, you need some other way of estimating the number of matching rows. In addition, because histogram steps are kept only on the first column of the index, SQL Server must use a different method for determining the number of matching rows for SARGs that specify multiple column values for a composite index, such as the following:

```
select * from sales
  where title_id = 'BI3976'
     and stor_id = 'P648'
```

When the histogram is not used or cannot be used, SQL Server uses the index density values to estimate the number of matching rows.

Index Densities

SQL Server stores the density values of each column in the index for use in queries where the SARG value is not known until runtime or when the SARG is on multiple columns of the index. For composite keys, SQL Server stores the density for the first column of the composite key; for the first and second columns; for the first, second, and third columns; and so on. This information is shown in the `ALL` density section of the `DBCC SHOW_STATISTICS` output in Listings 34.4 and 34.5.

Index density essentially represents the inverse of all unique key values of the key. The density of each key is calculated by using the following formula:

$$\text{Key density} = 1.00 / \text{Count of distinct key values in the table}$$

Therefore, the density for the `au_lname` column in the `authors` table in the `bigpubs2008` database is calculated as follows:

```
Select Density = 1.00/ (select count(distinct au_lname) from authors)
go
Density
-----
0.0062500000000
```

The density for the combination of the columns `au_lname` and `au_fname` is as follows:

```
Select Density = 1.00/ (select count(distinct au_lname + au_fname) from authors)
go
Density
-----
0.0058139534883
```

Notice that, unlike with the selectivity ratio, a *smaller* index density indicates a more selective index. As the density value approaches 1, the index becomes less selective and essentially useless. When the index selectivity is poor, the Query Optimizer might choose to do a table scan or a leaf-level index scan rather than perform an index seek because it is more cost-effective.

TIP

Watch out for database indexes that have poor selectivity. Such indexes are often more of a detriment to the performance of the system than they are a help. Not only are they usually not used for data retrieval, but they also slow down your data modification statements because of the additional index overhead. You should identify such indexes and consider dropping them.

Typically, the density value should become smaller (that is, more selective) as you add more columns to the key. For example, in Listing 34.5, the densities get progressively smaller (and thus, more selective) as additional columns are factored in, as shown in Table 34.8.

TABLE 34.8 Index Densities for the **titleidind** Index on the **sales** Table

Key Column	Index Density
title_id	0.001858736
title_id, stor_id	5.99844E-06 (.00000599844)
title_id, stor_id, ord_num	5.926804E-06 (.000005926804)

Estimating Rows Using Index Statistics

How does the Query Optimizer use the index statistics to estimate the number of rows that match the SARGs in a query?

SQL Server uses the histogram information when searching for a known value being compared to the leading column of the index key column, especially when the search spans a range or when there are duplicate values in the key. Consider this query on the sales table in the bigpubs2008 database:

```
select * from sales
  where title_id = 'BI3976'
```

Because there are duplicates of `title_id` in the table, SQL Server uses the histogram on `title_id` (refer to Listing 34.5) to estimate the number of matching rows. For the value of `BI3976`, it would look at the `EQ_ROWS` value, which is `260.778`. This indicates that there are approximately 261 rows in the table that have a `title_id` value of `BI3976`.

When an exact match for the search argument is not found as a step in the histogram, SQL Server uses the `AVG_RANGE_ROWS` value for the next step greater than the search value. For example, SQL Server would estimate that for a search value of `'BI4184'`, on average, it would >match approximately `300.0652` rows because that is the `AVG_RANGE_ROWS` value for the step value of `'BI8448'`, which is the next step greater than `'BI3976'`.

When the query is a range retrieval that spans multiple steps, SQL Server sums the `RANGE_ROWS` and `EQ_ROWS` values between the endpoints of the range retrieval. For example, when we use the histogram in Listing 34.5, if the search argument were `where title_id <= 'BI3976'`, the row estimate would be $274.8199+639.6047+312.9337+893.1208+271.811+637.2789+260.778$, or 3290.3470 rows.

As mentioned previously, when the histogram cannot be used, SQL Server uses just the index density to estimate the number of matching rows. The formula is straightforward for an equality search; it looks like this:

$$\text{Row Estimate} = \text{Number of Rows in Table} \times \text{Index Density}$$

For example, to estimate the number of matching rows for any given `title_id` in the `sales` table, multiply the number of rows in the `sales` table by the index density for the `title_id` key (0.001862197), as follows:

```
select count(*) * 0.001862197 as 'Row Estimate'
from sales
go
```

```
Row Estimate
-----
314.199188825
```

If a query specifies both the `title_id` and `stor_id` as SARGs, and if the SARG for `title_id` is a constant expression that can be evaluated at optimization time, SQL Server uses both the index density on `title_id` and `stor_id` as well as the histogram on `title_id` to estimate the number of matching rows. For some data values, the estimated number of matching rows for `title_id` and `stor_id` calculated using the index density could be greater than the estimated number of rows that match the specific `title_id`, as determined by the histogram. SQL Server uses whichever is the smaller of the two to calculate the row estimate.

Multiplying the number of rows in the `sales` table by the index density for `title_id`, `stor_id` (5.997505E-06), you can see that it is nearly unique, essentially matching only a single row:

```
select count(*) * 5.997505E-06 as 'Row Estimate'
from sales

Row Estimate
-----
1.011929031125
```

In this example, SQL Server would use the index density on `title_id` and `stor_id` to estimate the number of matching rows. In this case, it is estimated that the query will return, on average, one matching row.

Generating and Maintaining Index and Column Statistics

At this point, you might ask, “How do the index statistics get created?” and “How are they maintained?” The index statistics are first created when you create the index on a table that already contains data rows or when you run the `UPDATE STATISTICS` command. Index statistics can also be automatically updated by SQL Server. SQL Server can be configured to constantly monitor the update activity on the indexed key values in a database and update the statistics through an internal process, when appropriate.

Auto-Update Statistics

To automatically update statistics, an internal SQL Server process monitors the updates to a table's columns to determine when statistics should be updated. SQL Server internally keeps track of the number of modifications made to a column via column modification counters (`colmodctr`s). SQL Server uses information about the table and the `colmodctr`s to determine whether statistics are out of date and need to be updated. Statistics are considered out of date in the following situations:

- ▶ When the table size has gone from 0 to >0 rows
- ▶ When the number of rows in the table at the time the statistics were gathered was 500 or fewer and the `colmodctr` of the leading column of the statistics object has changed by more than 500
- ▶ When the table had more than 500 rows at the time the statistics were gathered and the `colmodctr` of the leading column of the statistics object has changed by more than $500 + 20\%$ of the number of rows in the table

If the statistics are defined on a temporary table, there is an additional threshold for updating statistics every six column modifications if the table contains fewer than 500 rows.

The `colmodctr`s are incremented in the following situations:

- ▶ When a row is inserted into the table
- ▶ When a row is deleted from the table
- ▶ When an indexed column is updated

Whenever the index statistics have been updated for a column, the `colmodctr` for that column is reset to 0.

When SQL Server generates an update of the column statistics, it generates the new statistics based on a sampling of the data values in the table. Sampling helps minimize the overhead of the AutoStats process. The sampling is random across the data pages, and the values are taken from the table or the smallest nonclustered index on the columns needed to generate the statistics. After a data page containing a sampled row has been read from disk, all the rows on the data page are used to update the statistical information.

CAUTION

Having up-to-date statistics on tables helps ensure that optimum execution plans are being generated for queries at all times. In most cases, you would want SQL Server to automatically keep the statistics updated. However, it is possible that Auto-Update Statistics can cause an update of the index statistics to run at inappropriate times in a production environment or in a high-volume environment to run too often. If this problem is occurring, you might want to turn off the AutoStats feature and set up a scheduled job to update statistics during off-peak periods. Do not forget to update statistics periodically; otherwise, the resulting performance problems might end up being much worse than the momentary ones caused by the AutoStats process.

To determine how often the AutoStats process is being run, you can use SQL Server Profiler to determine when an automatic update of index statistics is occurring by monitoring the Auto Stats event in the Performance event class. (For more information on using SQL Server Profiler, see Chapter 6.)

If necessary, it is possible to turn off the AutoStats behavior by using the `sp_autostats` system stored procedure. This stored procedure allows you to turn the automatic updating of statistics on or off for a specific index or all the indexes of a table. The following command turns off the automatic update of statistics for an index named `anmind` on the `authors` table:

```
Exec sp_autostats 'authors', 'OFF', 'anmind'
```

When you run `sp_autostats` and simply supply the table name, it displays the current setting for the table as well as the database. Following are the settings for the `authors` table:

```
Exec sp_autostats 'authors'
go
```

Global statistics settings for [bigpubs2008]:

```
Automatic update statistics: ON
Automatic create statistics: ON
```

settings for table [authors]

There are three other ways to disable auto-updating of statistics for an index:

- ▶ Specify the `STATISTICS_NORECOMPUTE` clause when creating the index.
- ▶ Specify the `NORECOMPUTE` option when running the `UPDATE STATISTICS` command.
- ▶ Specify the `NORECOMPUTE` option when creating statistics with the `CREATE STATISTICS` command. (You learn more about this command in the “Creating Statistics” section, later in the chapter.)

You can also turn AutoStats on or off for the entire database by setting the database option in SQL Server Management Studio; to do this, right-click the database in Object Explorer to bring up the Database Properties dialog, select the Options page, and set the Auto Update Statistics option to False. You can also disable or enable the AutoStats option for a database by using the `ALTER DATABASE` command:

```
ALTER DATABASE dbname SET AUTO_UPDATE_STATISTICS { ON | OFF }
```

NOTE

What actually happens when you execute `sp_autostats` or use the `NORECOMPUTE` option in the `UPDATE STATISTICS` command to turn off auto-update statistics for a specific index or table? SQL Server internally sets a flag in the system catalog to inform the internal SQL Server process not to update the index statistics for the table or index that has had the option turned off using any of these commands. To re-enable Auto Update Statistics, you either run `UPDATE STATISTICS` without the `NORECOMPUTE` option or execute the `sp_autostats` system stored procedure and specify the value 'ON' for the second parameter.

Asynchronous Statistics Updating

In versions prior to SQL Server 2005, when SQL Server determined that the statistics being examined to optimize a query were out of date, the query would wait for the statistics update to complete before compilation of the query plan would continue. This is still the default behavior in SQL Server 2008. However, the database option, `AUTO_UPDATE_STATISTICS_ASYNC`, can be enabled to support asynchronous statistics updating.

When the `AUTO_UPDATE_STATISTICS_ASYNC` option is enabled, queries do not have to wait for the statistics to be updated before compiling. Instead, SQL Server puts the out-of-date statistics on a queue to be updated by a worker thread, which runs as a background process. The query and any other concurrent queries compile immediately by using the existing out-of-date statistics. Because there is no delay for updated statistics, query response times are more predictable, even if the out-of-date statistics may cause the Query Optimizer to choose a less-efficient query plan. Queries that start after the updated statistics are ready use the updated statistics.

Manually Updating Statistics

Whether or not you've disabled AutoStats, you can still manually update index statistics by using the `UPDATE STATISTICS` T-SQL command, whose syntax is as follows:

```
UPDATE STATISTICS table | view
    [ { { index | statistics_name }
      | ( { index | statistics_name } [ , ...n ] ) } ]
    [ WITH [ [ FULLSCAN ]
            | SAMPLE number { PERCENT | ROWS } ]
          | RESAMPLE
          [ [ , ] [ ALL | COLUMNS | INDEX ]
          [ [ , ] NORECOMPUTE ] ]
```

If neither the `FULLSCAN` nor `SAMPLE` option is specified, the default behavior is to perform a sample scan to calculate the statistics, and SQL Server automatically computes the appropriate sample size.

The `FULLSCAN` option forces SQL Server to perform a full scan of the data in the table or index to calculate the statistics. This generates more accurate statistics than using sampling but is also the most time-consuming and I/O-intensive method. When you use the `SAMPLE` option, you can specify a fixed number of rows or a percentage of rows to sample to build or update the index statistics. If the sampling ratio specified ever results in too few rows being sampled, SQL Server automatically corrects the sampling, based on the number of existing rows in the table or view. At a minimum, approximately 1,000 data pages are sampled.

The `RESAMPLE` option specifies that the statistics be generated using the previously defined sampling ratio. This `RESAMPLE` option is useful for indexes or column statistics created with different sampling values. For example, if the index statistics were created using `FULLSCAN`, and the column statistics were created using a 50% sample, specifying the `RESAMPLE` option would update the statistics using `FULLSCAN` on the indexes and using the 50% sample for the others.

Specifying `ALL`, `COLUMNS`, or `INDEX` specifies whether the `UPDATE STATISTICS` command affects all existing statistics or only column or index statistics. By default, if no option is specified, the `UPDATE STATISTICS` statement affects all statistics.

As previously discussed, SQL Server automatically updates the index statistics by default. If you specify the `NORECOMPUTE` option with `UPDATE STATISTICS`, it disables AutoStats for the table or index.

When the automatic update statistics option is turned off, you should run the `UPDATE STATISTICS` command periodically, when appropriate. To determine the last time statistics were updated, you run the following command:

```
select STATS_DATE(tableid, indexid)
```

Following is an example:

```
select STATS_DATE(object_id('authors'), 1)
go
```

```
-----
2010-03-15 00:04:51.407
```

TIP

You can get the index ID from `sys.indexes` for each index on a table by using the following query:

```
select name, index_id from sys.indexes
       Where object_id = object_id('table_name') and index_id > 0
```

Column-Level Statistics

In addition to statistics on indexes, SQL Server can also store statistics on individual columns that are not part of any indexes. Knowing the likelihood of a particular value being found in a nonindexed column can help the Query Optimizer better estimate the number of matching rows for SARGs on the nonindexed columns. This helps it determine the optimal execution plan, whether or not SQL Server is using an index to actually locate the rows.

For example, consider the following query:

```
select stor_name
       from stores st
       join sales s on (st.stor_id = s.stor_id)
       where s.qty <= 100
```

SQL Server knows the density of the `stor_id` column in both the `sales` and `stores` tables because of indexes on the column in those tables. There is no index on `qty`. However, if the Query Optimizer were to know how many rows in the `sales` table had a `qty` less than 100, it would be better able to choose the most efficient query plan for joining between `sales` and `stores`. For example, assume that, on average, there are approximately 500 sales per store. However, there are only approximately 5 sales per store where the `qty` is less than 100. With the statistics on `qty`, SQL Server has the opportunity to determine this, and knowing there might be only 5 matching rows per store in `sales` versus 500, it might choose a different, more efficient, join strategy between the two tables.

Being able to keep statistics on the `qty` column without having to add it to an existing index with `stor_id` or create a separate index on `qty` provides SQL Server with the selectivity information it needs for optimization. By not having to create an index on `qty` to

generate statistics on the column, you avoid incurring the overhead of having to maintain the index key rows for each insert, update, and delete that occurs on the table. Only the index statistics on qty need to be maintained, which is required only after many modifications to the data have occurred.

By default, SQL Server generates column statistics automatically when queries are optimized and the column is specified in a SARG or join clause. If no column statistics exist and the Query Optimizer needs to estimate the approximate density or distribution of column values, SQL Server automatically generates statistics for that column. This rule has two exceptions:

- ▶ Statistics are not automatically created for columns when the cost of creating the statistics exceeds the cost of the query plan itself.
- ▶ Statistics are not automatically created when SQL Server is too busy (that is, when there are too many outstanding query compilations in progress).

If you want to disable or re-enable the database option to autocreate statistics in the database, you use the ALTER DATABASE command:

```
ALTER DATABASE dbname SET AUTO_CREATE_STATISTICS { ON | OFF }
```

You can also turn the Auto Create Statistics option on or off for the entire database by setting the database option in SSMS. In Object Explorer, right-click the database to bring up the Database Properties dialog, select the Options page, and set the Auto Create Statistics option to True or False.

Column statistics are stored in the system catalogs. General information about them can be viewed in the sys.stats catalog view. Autogenerated statistics have a name in the format `_WA_Sys_colName_systemgeneratednumber`. You can retrieve a list of autogenerated column statistics with a query similar to the following:

```
SELECT cast(object_name(object_id) as varchar(30)) as 'table',
       cast (name as varchar(30)) as autostats
FROM sys.stats
WHERE auto_created = 1
      AND objectproperty (object_id, 'IsUserTable') = 1
go
table                autostats
-----
table                autostats
-----
authors              _WA_Sys_state_4AB81AF0
sales                _WA_Sys_ord_num_628FA481
sales                _WA_Sys_qty_628FA481
stores               _WA_Sys_state_6477ECF3
stores               _WA_Sys_zip_6477ECF3
titles               _WA_Sys_type_6A30C649
```

Creating Statistics

If you want finer control over how the column statistics are generated, you can use the `CREATE STATISTICS` command. Its syntax is similar to that of `UPDATE STATISTICS`, with the exception that you specify a column or list of columns instead of an index on which to create statistics:

```
CREATE STATISTICS statistics_name ON table (column [,...n])
    [ WITH [ [ FULLSCAN | SAMPLE number { PERCENT | ROWS } ] [, ] ]
    [ NORECOMPUTE ] ]
```

Any column that can be specified as an index key can also be specified for statistics, except for XML columns or when the maximum allowable size of the combined column values exceeds the 900-byte limit on an index key. Statistics can also be created on computed columns if the `ARITHABORT` and `QUOTED_IDENTIFIER` database options are set to `ON`. In addition, statistics can be created on CLR user-defined type columns if the CLR type supports binary ordering.

If you want to create single-column statistics on all eligible columns in a database, you can use the `sp_createstats` system procedure:

```
sp_createstats [[@indexonly =] 'indexonly']
               [,[@fullscan =] 'fullscan']
               [,[@norecompute =] 'norecompute']
```

The created statistics have the same name as the column on which they are created. Statistics are not created on columns that already have statistics on them (for example, the first column of an index or a column that already has explicitly created statistics).

To display a list of all column statistics, whether autogenerated or manually created, you use a query similar to the previous one, but you include user-created statistics as well:

```
SELECT cast(object_name(object_id) as varchar(30)) as 'table',
       cast (name as varchar(30)) as name,
       stats_id
FROM sys.stats
WHERE objectproperty (object_id, 'IsUserTable') = 1
      and (auto_created = 1 or user_created = 1)
order by 1, 3
go
```

table	name	stats_id

To remove a collection of statistics on one or more columns for a table in the current database, you use the `DROP STATISTICS` command, which has the following syntax:

```
DROP STATISTICS {table | view}.statistics_name
```

Be aware that dropping the column statistics could affect how your queries are optimized, and less efficient query plans might be chosen. Also, if the Auto Create Statistics option is

enabled for the database, SQL Server is likely to automatically create statistics on the columns the next time they are referenced in a SARG or join clause for a query.

String Summary Statistics

SQL Server 2008 supports string summary statistics for estimating the selectivity of LIKE conditions. String summary statistics are statistical summaries of substring frequency distribution for character columns. String summary statistics can be created on columns of type text, ntext, char, varchar, and nvarchar. String summary statistics allow SQL Server to estimate the selectivity of LIKE conditions, where the search string may have any number of wildcards in any combination, including LIKE conditions where the first character is a wildcard. In previous versions of SQL Server, row estimates could not be accurately obtained when the leading character of a search string was a wildcard character. String summary statistics allow SQL Server to estimate the selectivity of any of the following predicates:

- ▶ Column LIKE '*string*'
- ▶ Column LIKE '%*string*'
- ▶ Column LIKE '%*string*'
- ▶ Column LIKE '*str[abc]ing*'
- ▶ Column LIKE '%*abc*%*xy*'

String summary statistics include additional information beyond what is displayed by DBCC SHOW_STATISTICS for the histogram. You can determine whether string summary statistics have been created for a column or an index by examining the String Index column returned by DBCC SHOW_STATISTICS. If the value is YES, the statistics for that column or index also include a string summary. However, DBCC SHOW_STATISTICS does not display the actual contents of the string summary.

SQL Server Index Maintenance

SQL Server indexes are self-maintaining, which means that any time a data modification (such as an update, a delete, or an insert) takes place on a table, the index B-tree is automatically updated to reflect the correct data values and current rows. Generally, you do not have to do any maintenance of the indexes, but indexes and tables can become fragmented over time. There are two types of fragmentation: external fragmentation and internal fragmentation.

External fragmentation occurs when the logical order of pages does not match the physical order or the extents allocated to the table are not contiguous. These situations occur typically with clustered tables as a result of page splits and pages being allocated and linked into the page chain from other extents. External fragmentation is usually not much of an issue for most queries performing small result set retrievals via an index. It's more of a performance issue for ordered scans of all or part of a table or index. If the table is heavily fragmented and the pages are not contiguous, scanning the page chain is more expensive.

Internal fragmentation occurs when an index is not using up all the space within the pages in the table or index. Fragmentation within an index page can happen for the following reasons:

- ▶ As more records are added to a table, space is used on the data page and on the index page. As a result, the page eventually becomes completely full. If another insert takes place on that page and there is no more room for the new row, SQL Server splits the page into two, each page now being about 50% full. If the clustered key values being inserted are not evenly distributed throughout the table (as often happens with clustered indexes on sequential keys), this extra free space might not be used.
- ▶ Frequent update statements can cause fragmentation in the database at the data and index page level because the updates cause rows to move to other pages. Again, if future clustered key values inserted into the table are not evenly distributed throughout the table, the empty slots left behind might not be used.
- ▶ As rows are deleted, space becomes freed up on data and index pages. If no new rows within the range of deleted values on the page are inserted, the page remains sparse.

NOTE

Internal fragmentation is not always a bad thing. Although pages that are not completely full use up more space and require more I/O during retrieval, free space within a page allows for rows to be added without having to perform an expensive page split. For some environments where the activity is more insert intensive than query intensive, you might want more free space in pages. This can be accomplished by applying the fill factor when creating the index on the table. Applying the fill factor is described in more detail in the next section.

Usually, in a system, all these factors contribute to the fragmentation of data within the data pages and index pages. In an environment subject to a lot of data modification, you might see a lot of fragmentation on the data and index pages over a period of time. These sparse and fragmented pages remain allocated to the table or index even if they have only a single row or two, and the extent containing the page remains allocated to the table or index.

Data fragmentation can adversely affect performance for table or index scanning operations because the data is spread across more pages than necessary. More I/Os are required to retrieve the data. SQL Server provides a dynamic management view, `sys.dm_db_index_physical_stats`, which is a multistatement table-valued function that returns size and fragmentation information for the data and indexes of a specified table or view. The results from the function are returned by a normal `SELECT` statement and thus can be saved to a table for reporting purposes and historical analysis. The syntax of `dm_db_index_physical_stats` is as follows:

```
sys.dm_db_index_physical_stats (
    { database_id | NULL | 0 | DEFAULT }
```

```
, { object_id | NULL | 0 | DEFAULT }
, { index_id | NULL | 0 | -1 | DEFAULT }
, { partition_number | NULL | 0 | DEFAULT }
, { mode | NULL | DEFAULT } )
```

The parameters for `dm_db_index_physical_stats` are summarized in Table 34.9.

TABLE 34.9 **dm_db_index_physical_stats** Parameters

Parameter	Description
<i>database_id</i>	The ID of the database. The default is 0, which returns information for all databases. NULL, 0, and DEFAULT are equivalent values in this context. If you specify NULL or 0, for <i>database_id</i> , you must specify NULL for <i>object_id</i> , <i>index_id</i> , and <i>partition_number</i> .
<i>object_id</i>	The object ID of the table or view the index is on. Valid inputs are the ID number of a table or view, NULL, 0, or DEFAULT. The default is 0, which returns information for all tables and views in the specified database. NULL, 0, and DEFAULT are equivalent values in this context.
<i>index_id</i>	The ID of the index. Valid inputs are the ID number of an index, 0 if <i>object_id</i> is a heap, NULL, -1, or DEFAULT. The default is -1, which returns information for all indexes for a table or view. NULL, -1, and DEFAULT are equivalent values in this context. If you specify NULL for <i>index_id</i> , you must also specify NULL for <i>partition_number</i> .
<i>partition_number</i>	The partition number in the object. Valid inputs are the <i>partition_number</i> of an index or a heap, NULL, 0, or DEFAULT. The default is 0, which returns information for all partitions of the object. NULL, 0, and DEFAULT are equivalent values in this context. Use a <i>partition_number</i> of 1 for a nonpartitioned index or heap.
<i>mode</i>	The scan level used to obtain physical index statistics. Valid inputs are DEFAULT, NULL, LIMITED, SAMPLED, or DETAILED. The default mode is LIMITED. NULL and DEFAULT are equivalent values in this context.

The `sys.dm_db_index_physical_stats` function requires only an Intent-Shared table lock, regardless of the mode in which it runs. This provides for the capability to run the `sys.dm_db_index_physical_stats` function online without blocking update activity on a table.

The scan-level mode determines the level of scanning performed by the function to obtain the physical statistics for the index. The LIMITED mode is the fastest and scans the smallest number of pages. It scans all data pages for a heap but scans only leaf-level pages for an index. It also returns only a subset of the data columns, as shown in Table 34.10. The SAMPLED mode returns statistics based on a 1% sample of all the pages in the index or heap. If the index or heap has fewer than 10,000 pages, DETAILED mode is used instead of SAMPLED. The SAMPLED scan mode displays information for only data pages of a heap and leaf-level pages of an index. The DETAILED mode scans all pages and returns all statistics for all data and index levels.

TIP

The scan modes get progressively slower from LIMITED to DETAILED because more work is performed in each mode. To quickly gauge the size or fragmentation level of a table or an index, first use the LIMITED mode. It is the fastest and does not return a row for each nonleaf level in the IN_ROW_DATA allocation unit of the index.

Table 34.10 describes the result columns returned by the `dm_db_index_physical_stats` table-valued function.

TABLE 34.10 `dm_db_index_physical_stats` Result Columns

Column Name	Data Type	Description	Displayed in LIMITED Scan Mode
<i>database_id</i>	Smallint	A database ID database containing the table or view.	Yes
<i>object_id</i>	int	The object ID of the table or view where the index is located.	Yes
<i>index_id</i>	int	The index ID of the index. 0 indicates a heap.	Yes
<i>partition_number</i>	int	A partition number within the owning table, view, or index.	Yes
<i>index_type_desc</i>	nvarchar (60)	The index type. Values are HEAP, CLUSTERED INDEX, NONCLUSTERED INDEX, PRIMARY XML INDEX, and XML INDEX.	Yes
<i>alloc_unit_type_desc</i>	nvarchar (60)	A description of the allocation unit type. Values are IN_ROW_DATA, LOB_DATA, and ROW_OVERFLOW_DATA.	Yes
<i>index_depth</i>	tinyint	The number of index levels.	Yes
<i>index_level</i>	tinyint	The current level of the index. 0 indicates index leaf levels, heaps, and LOB_DATA or ROW_OVERFLOW_DATA allocation units.	Yes
<i>avg_fragmentation_in_percent</i>	float	The percentage of logical fragmentation (out-of-order pages in the index).	Yes

TABLE 34.10 **dm_db_index_physical_stats** Result Columns

Column Name	Data Type	Description	Displayed in LIMITED Scan Mode
<i>fragment_count</i>	bigint	The number of fragments (physically consecutive leaf pages) in the index.	Yes
<i>avg_fragment_size_in_pages</i>	float	The average number of pages in one fragment in an index.	Yes
<i>page_count</i>	bigint	The total number of index or data pages at the current level.	Yes
<i>avg_page_space_used_in_percent</i>	Float	The average percentage of available data storage space used in all pages.	No
<i>record_count</i>	Bigint	The total number of records at the current level.	No
<i>ghost_record_count</i>	Bigint	The number of ghost records ready for removal by the ghost cleanup task.	No
<i>version_ghost_record_count</i>	Bigint	The number of ghost records retained by an outstanding snapshot isolation transaction in an allocation unit.	No
<i>min_record_size_in_bytes</i>	Int	The minimum record size, in bytes.	No
<i>max_record_size_in_bytes</i>	Int	The maximum record size, in bytes.	No
<i>avg_record_size_in_bytes</i>	Float	The average record size, in bytes.	No
<i>forwarded_record_count</i>	Bigint	The number of forwarded records in a heap.	No
<i>compressed_page_count_</i>	Bigint	The number of compressed pages in a heap.	No

Listing 34.6 shows examples of running `sys.dm_db_index_physical_stats` on the `sales_big` table, using both `LIMITED` and `DETAILED` scan modes.

LISTING 34.6 **sys.dm_db_index_physical_stats** Examples

```
use bigpubs2008
go
select str(index_id,3,0) as indid,
       left(index_type_desc, 20) as index_type_desc,
       index_depth as idx_depth,
       index_level as idx_level,
       str(avg_fragmentation_in_percent, 5,2) as avg_frmnt_pct,
       str(page_count, 10,0) as pg_cnt
FROM sys.dm_db_index_physical_stats
     (db_id(), object_id('sales_big'),null, 0, 'LIMITED')

select str(index_id,3,0) as indid,
       left(index_type_desc, 20) as index_type_desc,
       index_depth as idx_depth,
       index_level as idx_level,
       str(avg_fragmentation_in_percent, 5,2) as avg_frmnt_pct,
       str(page_count, 10,0) as pg_cnt
FROM sys.dm_db_index_physical_stats
     (db_id(), object_id('sales_big'),null, 0, 'DETAILED')
go
```

indid	index_type_desc	idx_depth	idx_level	avg_frmnt_pct	pg_cnt
1	CLUSTERED INDEX	3	0	63.42	14519
2	NONCLUSTERED INDEX	3	0	14.90	4571

indid	index_type_desc	idx_depth	idx_level	avg_frmnt_pct	pg_cnt
1	CLUSTERED INDEX	3	0	63.42	14519
1	CLUSTERED INDEX	3	1	92.11	38
1	CLUSTERED INDEX	3	2	0.00	1
2	NONCLUSTERED INDEX	3	0	14.90	4571
2	NONCLUSTERED INDEX	3	1	87.50	8
2	NONCLUSTERED INDEX	3	2	0.00	1

Again, you can see from the output in Listing 34.6 that the logical fragmentation (`avg_frmnt_pct`) is 63.42% for the leaf level of the clustered index (`idx_level = 0`). This indicates that nearly two thirds of the data pages are out of sequence in relation to order-

ing of the clustered key values. If you want to improve the performance of table scans or clustered index scans for the `sales_big` table, you need to decide whether to rebuild the index or simply defragment the index.

The degree of fragmentation helps you decide which defragmentation method to use. A rough guideline to use to help decide is to examine the `avg_fragmentation_in_percent` value returned by the `sys.dm_db_index_physical_stats` function. If the `avg_fragmentation_in_percent` value is greater than 5% but less than 30%, you should reorganize the index. If the `avg_fragmentation_in_percent` value is greater than 30%, you should consider rebuilding the index. If you also have a dedicated maintenance window large enough to perform a rebuild instead of simply reorganizing the index, you may as well run a rebuild because it performs a more thorough defragmentation than reorganizing the index.

Another factor in determining whether an index needs to be defragmented is how the data is accessed. If your applications are performing primarily single-row lookups, randomly accessing individual rows of data, the internal or external fragmentation is not a factor when it comes to query performance. Accessing one row from a fragmented table is just as easy as from an unfragmented table. However, if your applications are performing ordered range scan operations and reading all or large numbers of the pages in a table, excessive fragmentation can greatly slow down the scan. The more contiguous and full the pages, the better the performance will be of the scanning operations.

TIP

If you have very low levels of fragmentation (less than 5%), it is recommended that you not bother with either a reorganization or a rebuild because the benefit of removing such a small amount of fragmentation is not enough to justify the cost of reorganizing or rebuilding the index.

In SQL Server 2008, the `ALTER INDEX` command provides options for defragmenting an index. Following is the syntax for the `ALTER INDEX` command:

```
ALTER INDEX { index_name | ALL }
  ON [ database_name. [ schema_name ] . | schema_name . ]
     table_or_view_name
  { REBUILD
    [ [PARTITION = ALL]
      [ WITH ( <rebuild_index_option> [ ,...n ] ) ]
    | [ PARTITION = partition_number
      [ WITH ( <single_partition_rebuild_index_option>
              [ ,...n ] )
        ]
    ]
  ]
  | DISABLE
```

```

    | REORGANIZE
      [ PARTITION = partition_number ]
      [ WITH ( LOB_COMPACTION = { ON | OFF } ) ]
    | SET ( <set_index_option> [ ,...n ] )
  }
[ ; ]

<rebuild_index_option > ::=
{
  PAD_INDEX = { ON | OFF }
  | FILLFACTOR = fillfactor
  | SORT_IN_TEMPDB = { ON | OFF }
  | IGNORE_DUP_KEY = { ON | OFF }
  | STATISTICS_NORECOMPUTE = { ON | OFF }
  | ONLINE = { ON | OFF }
  | ALLOW_ROW_LOCKS = { ON | OFF }
  | ALLOW_PAGE_LOCKS = { ON | OFF }
  | MAXDOP = max_degree_of_parallelism
  | DATA_COMPRESSION = { NONE | ROW | PAGE }
    [ ON PARTITIONS ( { <partition_number_expression> | <range> }
      [ , ...n ] ) ]
}

<range> ::=
<partition_number_expression> TO <partition_number_expression>
}

<single_partition_rebuild_index_option> ::=
{
  SORT_IN_TEMPDB = { ON | OFF }
  | MAXDOP = max_degree_of_parallelism
  | DATA_COMPRESSION = { NONE | ROW | PAGE } }
}

<set_index_option>::=
{
  ALLOW_ROW_LOCKS = { ON | OFF }
  | ALLOW_PAGE_LOCKS = { ON | OFF }
  | IGNORE_DUP_KEY = { ON | OFF }
  | STATISTICS_NORECOMPUTE = { ON | OFF }
}

```

The REORGANIZE option is always performed online, regardless of which edition of SQL Server 2008 you are running, allowing for other users to continue to update and query the underlying data in the table while the REORGANIZE process is running. The REBUILD option can be executed online only if you are running SQL Server 2008 Enterprise or Developer Editions. In all other editions of SQL Server 2008, the REBUILD option is

executed offline. When it is executed offline, SQL Server acquires exclusive locks on the underlying data and associated indexes so any data modifications to the table are blocked until the rebuild completes.

Reorganizing an index uses minimal system resources to defragment only the leaf level of clustered and nonclustered indexes of tables and views. The first phase of the reorganization process compacts the rows on the leaf pages, reapplying the current fill factor value to reduce the internal fragmentation. To view the current fill factor setting, you can run a query such as the following against the `sys.indexes` system catalog view:

```
select cast(name as varchar(30)) as name, index_id, fill_factor
       from sys.indexes
       where object_id = object_id('sales_big')
go
```

name	index_id	fill_factor
ci_sales_big	1	0
idx1	2	0

For more information on fill factor and how to set it, see the “Setting the Fill Factor” section, later in this chapter.

The second phase of the reorganization process involves the rearranging of the leaf-level pages so that the logical and physical order of the pages match, thereby reducing the external fragmentation of the leaf level of the index. SQL Server 2008 runs a `REORGANIZATION` of an index online because the second phase processes only two pages at a time, in an operation similar to a bubble sort. When defragmenting the index, SQL Server 2008 determines the first physical page belonging to the leaf level and the first logical page in the leaf level, and it swaps the data on those two pages. It then identifies the next logical and physical page and swaps them, and so on, until no more swaps need to be made. At this point, the logical page ordering matches the physical page ordering. While swapping the logical and physical pages, SQL Server uses an additional new page as a temporary storage area. After each page swap, SQL Server releases all locks and latches and saves the key of the last moved page.

The following example uses `ALTER TABLE` to reorganize the clustered index on the `sales_big` table:

```
ALTER INDEX ci_sales_big on sales_big REORGANIZE
```

After running this command, you can run a query similar to the query in Listing 34.6 to display the fragmentation of the `ci_sales_big` index on the `sales_big` table:

```
select str(s.index_id,3,0) as indid,
       left(i.name, 20) as index_name,
       left(index_type_desc, 20) as index_type_desc,
       index_depth as idx_depth,
       index_level as level,
       str(avg_fragmentation_in_percent, 5,2) as avg_frmgmt_pct,
```

```

    str(page_count, 10,0) as pg_cnt
FROM sys.dm_db_index_physical_stats
    (db_id('bigpubs2008'), object_id('sales_big'),1, 0, 'DETAILED') s
    join sys.indexes i on s.object_id = i.object_id and s.index_id = i.index_id
go

```

indid	index_name	index_type_desc	idx_depth	level	avg_frmnt_pct	pg_cnt
1	ci_sales_big	CLUSTERED INDEX	3	0	0.32	14519
1	ci_sales_big	CLUSTERED INDEX	3	1	92.11	38
1	ci_sales_big	CLUSTERED INDEX	3	2	0.00	1

As you can see, the average fragmentation percentage is down to .32% from 63.42%, indicating that the index is now mostly defragmented. However, the average fragmentation percentage of the intermediate level of the index (level = 1) is still 92.11%, indicating that it is heavily fragmented. To defragment the nonleaf levels of the index, you need to rebuild the index. The following example shows how to rebuild the index using the ALTER INDEX command:

```
ALTER INDEX ci_sales_big on sales_big REBUILD
```

After running this command, you can again run a query similar to the query in Listing 34.6 to display the fragmentation of the ci_sales_big index on the sales_big table:

```

select str(s.index_id,3,0) as indid,
    left(i.name, 20) as index_name,
    left(index_type_desc, 20) as index_type_desc,
    index_depth as idx_depth,
    index_level as level,
    str(avg_fragmentation_in_percent, 5,2) as avg_frmnt_pct,
    str(page_count, 10,0) as pg_cnt
FROM sys.dm_db_index_physical_stats
    (db_id('bigpubs2008'), object_id('sales_big'),1, 0, 'DETAILED') s
    join sys.indexes i on s.object_id = i.object_id and s.index_id = i.index_id
go

```

indid	index_name	index_type_desc	idx_depth	level	avg_frmnt_pct	pg_cnt
1	ci_sales_big	CLUSTERED INDEX	3	0	0.01	14520
1	ci_sales_big	CLUSTERED INDEX	3	1	5.26	38
1	ci_sales_big	CLUSTERED INDEX	3	2	0.00	1

You can see from these results that the REBUILD option performs a more thorough defragmentation of the ci_sales_big index than REORGANIZE. The average fragmentation percentage of both the leaf and intermediate levels is significantly less.

NOTE

When you rebuild a nonclustered index, the rebuild operation requires enough temporary disk space to store both the old and new indexes. However, if the index is disabled before being rebuilt, the disk space made available by disabling the index can be reused by the subsequent rebuild or any other operation. No additional space is required except for temporary disk space for sorting, which is typically only about 20% of the index size.

Therefore, if disk space is limited, it may be helpful to disable a nonclustered index before rebuilding it. For more information on disabling indexes, see the “Disabling Indexes” section, later in this chapter.

One of the other options to the `CREATE INDEX` and `ALTER INDEX` commands is the `FILLFACTOR` option. The fill factor allows you to specify, as a percentage, the fullness of the pages at the data and leaf index page levels, essentially deciding how much free space to create in the index and data pages to make room for new rows and avoid page splits.

Setting the Fill Factor

Fill factor is a setting you can use when creating an index to specify, as a percentage, how full you want your data pages or leaf-level index pages to be when the index is created. A lower fill factor has the effect of spreading the data and leaf index rows across a greater number of pages by leaving more free space in the pages. This reduces page splitting and dynamic reorganization of index and data pages, which can improve performance in environments where there are a lot of inserts and updates to the data, while at the same time reducing performance for queries because an increased number of pages need to be read to retrieve multiple rows. A higher fill factor has the effect of packing more data and index rows per page by leaving less free space in the pages. Using a higher fill factor is useful in environments where the data is relatively static because it reduces the number of pages required for storing the data and its indexes, and it helps improve performance for queries by reducing the number of pages that need to be accessed.

By default, when you create an index on a table, if you don't specify a value for `FILLFACTOR`, the default value is 0. With a `FILLFACTOR` setting of 0, or 100, the data pages for a clustered index and the leaf pages for a nonclustered index are created completely full. However, space is left within the nonleaf nodes of the index for one or two more rows. The default fill factor to be used when creating indexes is a server-level configuration option. If you want to change the server-wide default for the fill factor, you use the `sp_configure` command:

```
sp_configure 'fill factor',N
```

It is generally recommended that you leave the server-wide default for fill factor as 0 and specify your `FILLFACTOR` settings on an index-by-index basis. You can specify a

specific fill factor value for an index by including the FILLFACTOR option for the CREATE INDEX statement:

```
CREATE [UNIQUE] [CLUSTERED | NONCLUSTERED] INDEX index_name
    ON [ [database_name.][schema_name.]] table_or_view_name
    [ WITH ( <relational_index_option> [ ,...n ] ) ]
<relational_index_option> ::=
{ PAD_INDEX = { ON | OFF }
  | FILLFACTOR = fillfactor
  | SORT_IN_TEMPDB = { ON | OFF }
  | IGNORE_DUP_KEY = { ON | OFF }
  | STATISTICS_NORECOMPUTE = { ON | OFF }
  | DROP_EXISTING = { ON | OFF }
  | ONLINE = { ON | OFF }
  | ALLOW_ROW_LOCKS = { ON | OFF }
  | ALLOW_PAGE_LOCKS = { ON | OFF }
  | MAXDOP = max_degree_of_parallelism }
```

The FILLFACTOR option for the CREATE INDEX command allows you to specify, as a percentage, how full the data or leaf-level index pages should be when you create an index on a table. The specified percentage can be from 1 to 100. Specifying a value of 80 would mean that each data or leaf page would be filled approximately 80% full at the time you create the index. It is important to note that as more data gets modified or added to a table, the fill factor is not maintained at the level specified during the CREATE INDEX command. Over a period of time, you will find that each page has a different percentage of fullness as rows are added and deleted.

TIP

A fill factor setting specified when creating a nonclustered index affects only the nonclustered index pages and doesn't affect the data pages. To apply a fill factor to the data pages in a table, you must provide a fill factor setting when creating a clustered index on the table. Also, it is important to remember that the fill factor is applied only at index creation time and is *not* maintained by SQL Server. When you begin updating and inserting data, the fill factor is eventually lost. Therefore, specifying a fill factor when creating your indexes is useful only if the table already contains data or if you simply want to set a default fill factor for the index other than 0 that will be used when indexes are rebuilt or reorganized by ALTER INDEX.

If you specify only the FILLFACTOR option, only the data or leaf-level index pages are affected by the fill factor. To specify the level of fullness for nonleaf pages, use the PAD_INDEX option together with FILLFACTOR. This option allows you to specify how much space to leave open on each node of the index, which can help to reduce page splits within the

nonleaf levels of the index. You don't specify a value for `PAD_INDEX`; it uses the same percentage value specified with the `FILLFACTOR` option. For example, to apply a 50% fill factor to the leaf and nonleaf pages in a nonclustered index on `title_id` in the `titles` table, you would execute the following:

```
CREATE INDEX title_id_index on titles (title_id)
    with (FILLFACTOR = 50, PAD_INDEX = ON)
```

TIP

When you use `PAD_INDEX`, the value specified by `FILLFACTOR` cannot be such that the number of rows on each index node falls below two. If you do specify such a value, SQL Server internally overrides it so that the number of rows on an intermediate index page is never less than two.

Reapplying the Fill Factor

When might you need to reestablish the fill factor for your indexes or data? As data gets modified in a table, the value of `FILLFACTOR` is not maintained at the level specified in the `CREATE INDEX` statement. As a result, each page can reach a different level of fullness. Over a period of time, this can lead to heavy fragmentation in the database if insert/delete activity is not evenly spread throughout the table, and it could affect performance. In addition, if a table becomes very large and then very small, rows could become isolated within data pages. This space will likely not be recovered until the last row on the page is deleted and the page is marked as unused. To either spread out rows or to reclaim space by repacking more rows per page, you need to reapply the fill factor to your clustered and nonclustered indexes.

In environments where insert activity is heavy, reapplying a low fill factor might help performance by spreading out the data and leaving free space on the pages, which helps to minimize page splits and possible page-locking contention during heavy OLTP activity. You can use Performance Monitor to monitor your system and determine whether excessive page splits are occurring. (See Chapter 39, "Monitoring SQL Server Performance" for more information on using Performance Monitor.)

A DBA must manually reapply the fill factor to improve the performance of the system. This can be done by using the `ALTER INDEX` command discussed earlier or by dropping and re-creating the index. `ALTER INDEX` is preferred because, by default, it applies the original fill factor specified when the index was created, or you can provide a new fill factor to override the default. The original fill factor for an index is stored in `sys.indexes` in the `fill_factor` column. In addition, if you use the `ALTER INDEX` command to reorganize or rebuild your table or index, it attempts to reapply the index's original fill factor when it reorganizes the pages.

Disabling Indexes

Another feature available in SQL Server 2008 is the capability to set an index as disabled. When an index is disabled, the definition of the index is maintained in the system catalogs, but the index itself contains no index key rows. Disabling an index prevents user access to the index. Disabling a clustered index also prevents access to the underlying table data.

You can manually disable an index at any time by using the `ALTER INDEX DISABLE` statement:

```
ALTER INDEX titleidind ON sales DISABLE
```

The reasons you might want to disable an index include the following:

- ▶ Correcting a disk I/O or allocation error on an index page and then rebuilding the index later
- ▶ Temporarily removing the index for troubleshooting purposes
- ▶ Saving temporary disk space while rebuilding nonclustered indexes

When you disable an index, the index is not maintained while it is disabled, and the Query Optimizer does not consider the index when creating query execution plans. However, statistics on a disabled nonclustered index remain in place and are updated automatically if the `AutoStats` option is in effect.

If you disable a clustered index, all nonclustered indexes on the table are automatically disabled as well. The nonclustered index cannot be re-enabled until the clustered index is either enabled or dropped. After you enable the clustered index, the nonclustered indexes must be explicitly enabled unless the clustered index was enabled by using the `ALTER INDEX ALL REBUILD` statement. Because the data rows of the table cannot be accessed while the clustered index is disabled, the following operations cannot be performed on the table:

- ▶ `SELECT`, `UPDATE`, `DELETE`, and `INSERT`
- ▶ `CREATE INDEX`
- ▶ `CREATE STATISTICS`
- ▶ `UPDATE STATISTICS`
- ▶ `ALTER TABLE` statements that modify table columns or constraints

After an index is disabled, it remains in a disabled state until it is rebuilt or dropped. You can enable a disabled index by rebuilding it by using one of the following methods:

- ▶ `ALTER INDEX` statement with the `REBUILD` clause
- ▶ `CREATE INDEX` with the `DROP_EXISTING` clause
- ▶ `DBCC DBREINDEX`

To determine whether an index is currently disabled, you can use the `INDEXPROPERTY` function (a value of 1 indicates the index is disabled):

```
select indexproperty(object_id('sales'), 'titleidind', 'IsDisabled')
```

.....

Managing Indexes with SSMS

So far, you've seen the commands necessary for index management. In addition to these commands, SSMS provides tools for managing indexes.

To reorganize or rebuild an index using SSMS, in the Object Explorer, connect to an instance of the SQL Server 2008 Database Engine and then expand that instance. Then expand Databases, expand the database that contains the table with the specified index, and expand Tables. Next, expand the table in which the index belongs and then expand Indexes. Finally, right-click the index to rebuild and then click Rebuild or Reorganize. To rebuild or reorganize all indexes on a table, right-click Indexes and select Rebuild All or Reorganize All.

You can also disable indexes in SSMS. In the Object Explorer, right-click the index you want to disable and then select the Disable option. To disable all indexes on a table, right-click on Indexes and select Disable All.

You can also use SSMS to modify indexes. In the Object Explorer, right-click the index you want to modify and then click Properties. In the Properties dialog that appears (see Figure 34.27), you can add or remove columns from the index, change the uniqueness setting, set the index option, set the fill factor, rebuild the index, view the index fragmentation, reorganize the index, and so on.

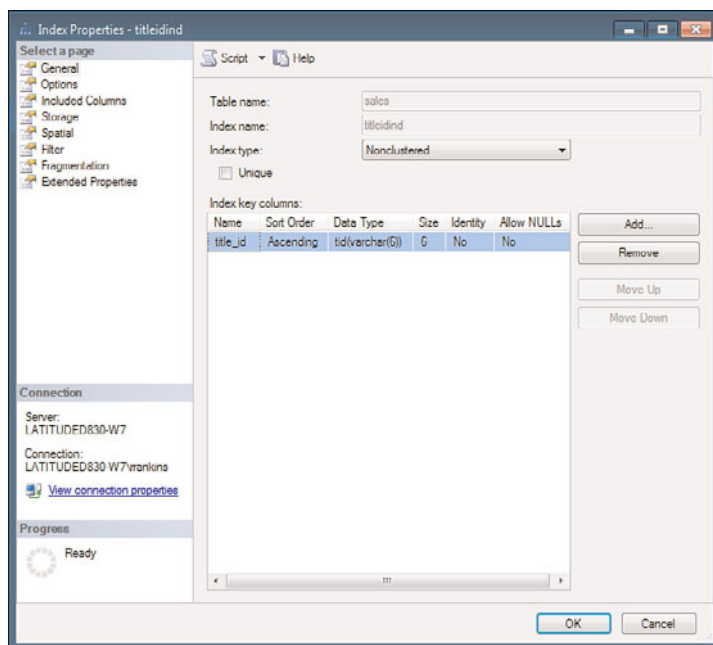

FIGURE 34.27 Setting and viewing index properties in SSMS.

Index Design Guidelines

SQL Server indexes are mostly transparent to end users and T-SQL developers. Indexes are typically not specified in queries unless you use table hints to force the Query Optimizer to use a particular index. (Although forcing indexes is generally not advised, using Query Optimizer table hints is covered in more detail in Chapter 35.) Normally, based on the index key histogram or density values, the SQL Server cost-based Query Optimizer automatically chooses the index that is least expensive from an I/O standpoint.

Chapter 35 goes into greater detail on how the Query Optimizer estimates I/O and determines the most efficient query plan. In the meantime, the following are some of the main guidelines to follow in creating useful indexes that the Query Optimizer can use effectively:

- ▶ For composite indexes, try to keep the more selective columns leftmost in the index. The first element in the index should be the most unique (if possible), and index column order in general should be from most to least unique. However, remember that selectivity doesn't help if the first ordered index column is not specified in your SARGs or join clauses. To ensure that the index is used for the largest number of queries, be sure the first ordered column is the column used most often in your queries.
- ▶ Be sure to index columns used in joins. Joins are processed inefficiently if no index on the column(s) is specified in a join. Remember that a PRIMARY KEY constraint automatically creates an index on a column, but a FOREIGN KEY constraint does not. You should create indexes on your foreign key columns if your queries commonly join between the primary key and foreign key tables.
- ▶ Tailor your indexes for your most critical queries and transactions. You cannot index for every possible query that might be run against your tables. However, your applications will perform better if you can identify your critical and most frequently executed queries and design indexes to support them. SQL Server Profiler, which is covered in Chapter 6, is a useful tool for identifying the most frequently executed queries. SQL Server Profiler can also help identify slow-running queries that might benefit from improved index design.
- ▶ Avoid indexes on columns that have poor selectivity. The Query Optimizer is not likely to use the indexes, so they would simply take up space and add unnecessary overhead during inserts, updates, and deletes. One possible exception occurs when the index can be used to cover a query. Index covering is discussed in more detail in the "Index Covering" section, later in this chapter.
- ▶ Choose your clustered and nonclustered indexes carefully. The next two sections discuss tips and guidelines for choosing between clustered or nonclustered indexes, based on the data contained in the columns and the types of queries executed against the columns.

Clustered Index Indications

Searching for rows via a clustered index is almost always faster than searching for rows via a nonclustered index—for two reasons. One reason is that a clustered index contains only pointers to pages rather than pointers to individual data rows; therefore, a clustered index is more compact than a nonclustered index. Because a clustered index is smaller and doesn't require an additional lookup via the row locator to find the matching rows, the rows can be found with fewer page reads than with a similarly defined nonclustered index. The second reason is that because the data in a table with a clustered index is physically sorted on the clustered key, searching for duplicate values or for a range of clustered key values is faster; the rows are adjacent to each other, and SQL Server can simply locate the first qualifying row and then search the rows in sequence until the last qualifying row is found. However, because you are allowed to create only one clustered index per table, you must judiciously choose the column or columns on which to define the clustered index.

If you require only a single index on a table, it's typically advantageous to make it a clustered index; the resulting overhead of maintaining clustered indexes during updates, inserts, and deletes can be considerably less than the overhead incurred by nonclustered indexes.

By default, the primary key on a table is defined as a clustered unique index. In most applications, the primary key column on a table is almost always retrieved in single-row lookups. For single-row lookups, a nonclustered index usually costs you only a few more I/Os than a similar clustered index. Are you or the users really going to notice a difference between three page reads to retrieve a single data row versus four- to six-page reads to retrieve a single data row? Not at all. However, if you have to perform a range retrieval, such as a lookup on last name, will you notice a difference between scanning 10% of the table versus having to find the rows using a full table scan? Most definitely. With this in mind, you might want to consider creating your primary key as a unique nonclustered index and choosing another candidate for your clustered index.

Following are guidelines to consider for other potential candidates for clustered indexes:

- ▶ **Columns with a number of duplicate values searched frequently (for example, `WHERE last_name = 'Smith'`)**—Because the data is physically sorted, all the duplicate values are kept together. Any query that tries to fetch records against such keys finds all the values, using a minimum of I/O. SQL Server locates the first row that matches the SARG and then scans the data rows in order until it finds the last row matching the SARG.
- ▶ **Columns often specified in the `ORDER BY` clause**—Because the data is already sorted, SQL Server can avoid having to re-sort the data if the `ORDER BY` is on the clustered index key and the data is retrieved in clustered key order. Remember that even for a table scan, the data is retrieved in clustered key order because the data in the table is in clustered key order. The only exception is if a parallel query operation is used to retrieve the data rows; in that case, the results need to be re-sorted when the result sets from each parallel thread are merged. (For more information on parallel query strategies, see Chapter 35.)

- ▶ **Columns often searched for within a range of values (for example, `WHERE price between $10 and $20`)**—A clustered index can be used to locate the first qualifying row in the range of values. Because the rows in the table are in sorted order, SQL Server can simply scan the data pages in order until it finds the last qualifying row within the range. When the result set within the range of values is large, a clustered index scan is significantly more efficient in terms of total logical I/O performed than repeated row locator lookups via a nonclustered index.
- ▶ **Columns, other than the primary key, frequently used in join clauses**—Clustered indexes tend to be smaller than nonclustered indexes; the amount of page I/O required per lookup is generally less for a clustered index than for a nonclustered index. It can be a significant difference when joining many records. An extra page read or two might not seem like much for a single-row retrieval, but add those additional page reads to 100,000 join iterations, and you're looking at a total of 100,000 to 200,000 additional page reads.

When you consider columns for a clustered index, you might want to try to keep your clustered indexes on relatively static columns to minimize the re-sorting of data rows when an indexed column is updated. Any time a clustered index key value changes, the entire data row has to be moved to keep the clustered data values in physical sort order. In addition, all nonclustered indexes using the clustered key as the row locator to that row also need to be updated.

You should also avoid creating clustered indexes on wide keys that are made up of several columns, especially several large-size columns. The reason is that the clustered key values are incorporated in all nonclustered indexes as the row locator. Because the nonclustered index entries contain the clustering key in addition to the key columns defined for that nonclustered index, the nonclustered indexes end up being significantly larger and less efficient in terms of I/O.

Because you can physically sort the data in a table in only one way, you can have only one clustered index per table. Any other columns you want to index have to be defined with nonclustered indexes.

Nonclustered Index Indications

SQL Server allows you to create a maximum of 999 nonclustered indexes on a table. Until tables become extremely large, the actual space taken by a nonclustered index is a minor expense compared to the increased access performance. You need to keep in mind, however, that as you add more indexes to the system, database modification statements get slower due to the index maintenance overhead.

Also, when defining nonclustered indexes, you typically want to define indexes on columns that are more selective (that is, columns with low density values) so that they can be used effectively by the Query Optimizer. A high number of duplicate values in a

nonclustered index can often make it more expensive (in terms of I/O) to process the query using the nonclustered index than a table scan. Let's look at a hypothetical example:

```
select title from titles
  where price between $5. and $10.
```

Assume that you have 1 million rows within the range; those 1 million rows could be randomly scattered throughout the table. Although the index leaf level has all the index rows in sorted order, reading all data rows one at a time would require a separate lookup via the row locator for each row in the worst-case scenario.

Thus, the worst-case I/O estimate for range retrievals using a nonclustered index is as follows:

Number of levels in the nonclustered index
 + Number of index pages scanned to find all matching rows
 + (Number of matching rows × Number of pages per lookup via the row locator)

If you have no clustered index on the table, the row locator is simply a page and row pointer and requires one data page read to find the matching data row. If 1 million rows are in the range, the worst-case cost estimate to search via the nonclustered index with no clustered index on the table would be as follows:

Number of index page reads to find all the row locators
 + (1 million matching rows × 1 data page read)
 = 1 million + I/O

If you have a clustered index on the table, the row locator is a clustered index key for the data row. Using the row locator to find the matching row requires searching the clustered index tree to locate the data row. Assuming that the clustered index has two nonleaf levels, it would cost three pages to find each qualifying row on a data page. If the range has 1 million rows, the worst-case cost estimate to search via the nonclustered index with a clustered index on the table would be as follows:

Number of index page reads to find all the row locators
 + (1 million matching rows × 3 pages per lookup via the row locator)
 = 3 million + I/O

Contrast each of these scenarios with the cost of a table scan. If the entire table takes up 50,000 pages, a full table scan would cost only 50,000 in terms of I/O. Therefore, in this example, doing a table scan would actually be more efficient than using the nonclustered index.

The following guidelines help you identify potential candidates for nonclustered indexes for your environment:

- ▶ Columns referenced in SARGs or join clauses that have a relatively high selectivity (the density value is low).

- Columns referenced in both the `WHERE` clause and the `ORDER BY` clause. When the data rows are retrieved using a nonclustered index, they are retrieved in nonclustered index key order. If the result set is to be ordered by the nonclustered index key(s) as well, SQL Server can avoid having to re-sort the result set, resulting in a more efficient query. In the following sample query, SQL Server can avoid the extra step of sorting the result set if a nonclustered index is on state and the index is used to retrieve the matching rows:

```
select * from authors
    where state like 'C%'
    order by state
```

In general, nonclustered indexes are useful for single-row lookups, joins, queries on columns that are highly selective, or queries with small range retrievals. Also, when considering your nonclustered index design, you should not overlook the benefits of index covering, as described in the following section.

Index Covering

Index covering is a situation in which all the information required by the query in the `SELECT` and `WHERE` clauses can be found entirely within the nonclustered index itself. Because the nonclustered index contains a leaf row corresponding to every data row in the table, SQL Server can satisfy the query from the leaf rows of the nonclustered index. This results in faster retrieval of data because all the information can come directly from the index page, and SQL Server avoids lookups of the data pages.

Because the leaf pages in a nonclustered index are linked together, the leaf level of the index can be scanned just like the data pages in a table. Because the leaf index rows are typically much smaller than the data rows, a nonclustered index that covers a query will be faster than a clustered index on the same columns because fewer pages would need to be read.

In the following example, a nonclustered index on the `au_lname` and `au_fname` columns of the authors table would cover the query because the result columns and the SARGs can all be derived from the index itself:

```
Select au_lname, au_fname
    From authors
    Where au_lname like 'M%'
Go
```

Many other queries that use an aggregate function (such as `MIN`, `MAX`, `AVG`, `SUM`, and `COUNT`) or simply check for existence of criteria also benefit from index covering. The following aggregate query samples can take advantage of index covering:

```
select count(au_lname) from authors where au_lname like 'M%'
```

```
select count(*) from authors where au_lname like 'M%'
```

```
select count(*) from authors
```

You might wonder how the last query, which doesn't even specify a SARG, can use an index. SQL Server knows that by its nature, a nonclustered index contains a row for every data row in the table; it can simply count all the rows in any of the nonclustered indexes instead of scanning the whole table. For the last query, SQL Server chooses the smallest nonclustered index—that is, the one with the smallest number of leaf pages.

Index covering can sometimes occur when you are not expecting it. As discussed previously in this chapter, when you have a clustered index defined on a table, the clustered key is carried into all the nonclustered indexes to be used as the row locator to locate the actual data row. Having the additional clustered key column values in the nonclustered index provides more data values that can be used in index covering.

For example, assume that the authors table has a clustered index on au_lname and au_fname and a nonclustered primary key defined on au_id. Each row in the nonclustered index on au_id would contain the clustered key values for au_lname and au_fname for its corresponding data row. Because of this, the following query would actually be covered by the nonclustered index on au_id:

```
select au_lname, au_fname
       from authors
       where au_id like '123%'
```

Explicitly adding additional columns to nonclustered indexes to promote the occurrence of index covering has historically been a common method of improving query response time. Consider the following query:

```
select royalty from titles
       where price between $10 and $20
```

If you create an index on only the price column, SQL Server can find the rows in the index where price is between \$10 and \$20, but it has to access the data rows to retrieve royalty. With 100 rows in the range, the worst-case I/O cost to retrieve the data rows would be as follows:

```
Number of index levels
+ Number of index pages to find the 100 matching rows
+ (100 × Number of pages per lookup via the row locator)
```

If the royalty column were added to the index on the price column, SQL Server could scan the index to retrieve the results instead of having to perform the lookups via the row locator against the table, resulting in faster query response. The I/O cost using index covering would be lower, as follows:

```
Number of index levels
+ Number of index pages to scan to find the 100 matching rows
```

If you are considering padding your indexes to take advantage of index covering, beware of making an index too wide. As index row width approaches data row width, the benefits of covering are lost as the number of pages in the leaf level increases. As the number of leaf-level index pages approaches the number of pages in the table, the number of index levels also increases, increasing the I/O cost of using the index to locate data.

You should also avoid adding to the index columns that are frequently updated. Remember that any changes to the columns in the data rows cascade into the indexes as well. This increases the index maintenance overhead, which can adversely affect update performance.

As an alternative to adding columns to the nonclustered index key to encourage index covering, you might want to consider taking advantage of the included columns feature in SQL Server 2008.

Included Columns

A feature available for nonclustered indexes in SQL Server 2008 is included columns. Included columns allow you to add nonkey columns to the leaf level of a nonclustered index for the purpose of index covering.

One advantage of included columns is that because the nonkey columns are stored only in the leaf level of the index, the nonleaf rows of the index are smaller, which helps reduce the overall size of the index, thereby helping reduce the I/O cost of using the index. Another advantage is that this feature allows you to exceed the SQL Server maximum limits of 16 index key columns and 900-byte index key size. The included nonkey columns are not factored in when calculating the number of index key columns or index key size. All data types are allowed as included columns except for the text, ntext, and image data types. To add included columns to an index, specify the `INCLUDE` clause to the `CREATE INDEX` statement:

```
CREATE INDEX NC_titles_price on titles (price) INCLUDE (royalty)
```

An additional advantage of included columns is that you can add columns to a unique index for index covering purposes without affecting the uniqueness of the actual index key(s) and without having to create a second index on the unique key column(s) and the additional covering columns. For example, consider that you have a large number of queries that search titles by `title_id` to retrieve the price value. Creating a covering index on `title_id` and `price` could improve performance of these queries. However, creating a unique index on `title_id` and `price` would not enforce uniqueness on `title_id` alone (it would allow the insertion of multiple rows with the same `title_id` as long as they had different prices). Without using included columns, you would have to create a unique index on `title_id` and an additional nonunique index on `title_id` and `price` to enforce uniqueness on `title_id` and also have a covering index on `title_id` and `price`. However, with the included column feature, you can create just a single unique index on `title_id` with `price` as an included column:

```
CREATE INDEX UQ_titleid_price on titles (title_id) INCLUDE (price)
```

TIP

If you have existing nonclustered indexes with a large index key size, you might want to consider redesigning them so that only columns used for searching and lookups are key columns. You should make all other columns that were added for index covering into included columns. This way, you still have all columns needed to cover your queries, but the index key itself is smaller and more efficient.

You still should be careful to avoid adding unnecessary columns as included columns of an index. Adding too many index columns, key or nonkey, can adversely affect performance for the following reasons:

- ▶ Fewer index leaf rows fit on a page, which can increase I/O costs to search the leaf level of the index and also reduce data cache efficiency.
- ▶ Because of the increased leaf row size, more disk space is required to store the index, especially if you are adding `varchar(max)`, `nvarchar(max)`, `varbinary(max)`, or `xml` data types as nonkey index columns. Because the column values are also copied into the index leaf level, you are essentially storing the data values twice.
- ▶ Changes to the included columns in the data rows cascade into the leaf rows of the index as well. This increases the index maintenance overhead, which can adversely affect performance of data modifications.

Wide Indexes Versus Multiple Indexes

As an index key gets wider, the selectivity of the key generally becomes higher as well. It might seem that creating wide indexes would result in better performance. This is not necessarily true. The reason is that the wider the key, the fewer rows SQL Server stores on the index pages, requiring more pages at each level; this results in a higher number of levels in the index B-tree. To get to specific rows, SQL Server must perform more I/O.

To get better performance from queries, instead of creating a few wide indexes, you should consider creating multiple narrower indexes. The advantage here is that with smaller keys, the Query Optimizer can quickly scan through multiple indexes to determine the most efficient access plan. SQL Server has the option of performing multiple index lookups within a single query and merging the result sets together to generate an intersection of the indexes. Also, with more indexes, the Query Optimizer can choose from a wider variety of query plan alternatives.

If you are considering creating a wide key, you should individually check the distribution of values for each member of the composite key. If the selectivity on the individual columns is high, you might want to break up the index into multiple indexes. If the selectivity of individual columns is low but is high for combined columns, it makes sense to have wider keys on the table. To get to the right combination, you can populate your table with real-world data, experiment with creating multiple indexes, and check the

distribution of values for each column. Based on the histogram steps and index density, you can make the decisions for an index design that works best for your environment.

Indexed Views

As discussed in Chapter 27, “Creating and Managing Views,” SQL Server 2008 allows you to create indexed views. An *indexed view* is any view that has a clustered index defined on it. When a `CREATE INDEX` statement is executed on a view, the result set for the view is materialized and stored in the database with the same structure as a table with a clustered index. Changes made to the data in the underlying tables of the view are automatically reflected in the view the same way any changes to a table are reflected in its indexes. In addition to a clustered index, you can create additional nonclustered indexes on indexed views to provide additional query performance. Additional indexes on views might provide more options for the Query Optimizer to choose from during the optimization process.

In the Developer and Enterprise Editions of SQL Server 2008, when an indexed view exists on a table and you access the view directly within a query, the Query Optimizer automatically considers using the index on the view to improve query performance, just as an index on a table is used to improve performance. The Query Optimizer also considers using the indexed view, even for queries that do not directly name the view in the `FROM` clause. In other words, when a query might benefit from using the indexed view, the Query Optimizer can use the indexed view to satisfy the query in place of an existing index on the table itself. (For more information on how indexed views are used in query plans, see Chapter 35.)

It is important to note that although indexed views can be created in all editions of SQL Server 2008, only the Developer and Enterprise Editions automatically use indexed views to optimize queries. In the other editions, indexed views are not used to improve query performance unless the view is explicitly specified in the query and the `NOEXPAND` hint is specified as well. Without the `NOEXPAND` hint, SQL Server expands the view to its underlying base tables and optimizes based on the table indexes. The following example shows the use of the `NOEXPAND` option to force SQL Server to use the indexed view specified in the query:

```
select * from sales_Qty_Rollup WITH (NOEXPAND)
    where stor_id between 'B914' and 'B999' SET ARITHABORT ON
```

Indexed views add overhead and can be more complex for SQL Server to maintain over time than normal indexes. Each time an underlying table of a view is modified, SQL Server has to update the view result set and potentially the index on that view. The scope of a view's index can be larger than that of any single table's index, especially if the view is defined on several large tables. The overhead associated with maintaining a view and its index during updates can negate any benefit that queries gain from the indexed view. Because of this additional maintenance overhead, you should create indexes only on

views where the advantage provided by the improved speed in retrieving the results outweighs the increased maintenance overhead.

Following are some guidelines to consider when you design indexed views:

- ▶ Create indexes on views where the underlying table data is relatively static.
- ▶ Create indexed views that will be used by several queries.
- ▶ Keep the indexes small. As with table indexes, a smaller index allows SQL Server to access the data more efficiently.
- ▶ Create indexed views that will be significantly smaller than the underlying table(s). An indexed view might not provide significant performance gains if its size is similar to the size of the original table.
- ▶ You need to specify the `NOEXPAND` hint in editions of SQL Server other than the Developer and Enterprise Editions of SQL Server; otherwise, the indexed view is not used to optimize the query.

Indexes on Computed Columns

SQL Server 2008 allows you to build indexes on computed columns in your tables. Computed columns can participate at any position of an index, along with your other table columns, including in a `PRIMARY KEY` or `UNIQUE` constraint. To create an index on computed columns, you must set the following session options as shown:

- ▶ `SET CONCAT_NULL_YIELDS_NULL ON`
- ▶ `SET QUOTED_IDENTIFIER ON`
- ▶ `SET ANSI_NULLS ON`
- ▶ `SET ANSI_PADDING ON`
- ▶ `SET ANSI_WARNINGS ON`
- ▶ `SET NUMERIC_ROUNDABORT OFF`

If any of these six `SET` options were not in effect when you created the table, you get the following message when you try to create an index on the computed column:

```
Server: Msg 1934, Level 16, State 1, Line 2
CREATE INDEX failed because the following SET options
have incorrect settings: '<OPTION NAME>'.
```

In addition, the functions in the computed column must be deterministic. A *deterministic* function is one that returns the same result every time it is called with the same set of input parameters.

When you create a clustered index on a computed column, it is no longer a virtual column in the table. The computed value for the column is stored in the data rows of the table. If you create a nonclustered index on a computed column, the computed value is stored in the nonclustered index rows but not in the data rows, unless you also have a clustered index on the computed column.

Be aware of the overhead involved with indexes on computed columns. Updates to the columns that the computed columns are based on result in updates to the index on the computed column as well.

Indexes on computed columns can be useful when you need an index on large character fields. As discussed earlier, the smaller an index, the more efficient it is. You could create a computed column on the large character field by using the `CHECKSUM()` function. `CHECKSUM()` generates a 4-byte integer that is relatively unique for character strings but not absolutely unique. (Different character strings can generate the same checksum, so when searching against the checksum, you need to include the character string as an additional search argument to ensure that you are matching the right row.) The benefit is that you can create an index on the 4-byte integer generated by the `CHECKSUM()` that can be used to search against the character string instead of having to create an index on the large character column itself. Listing 34.7 shows an example of applying this solution.

LISTING 34.7 Using an Index on a Computed Checksum Column

DISABLE TRIGGER ALL ON DATABASE
go
-- First add the computed column to the table
alter table titles add title_checksum as CHECKSUM(title)
go

-- Next, create an index on the computed column
create index NC_titles_titlechecksum on titles(title_checksum)
go

-- In your queries, include both the checksum column and the title column in
-- your search argument
select title_id, ytd_sales
  from titles
 where title_checksum = checksum('Fifty Years in Buckingham Palace Kitchens')
       and title = 'Fifty Years in Buckingham Palace Kitchens'
```

SQL Server 2008 also supports persisted computed columns. With persisted computed columns, SQL Server stores the computed values in the table without requiring an index on the computed column. Like indexed computed columns, persisted computed columns are updated when any other columns on which the computed column depends are updated.

Persisted computed columns allow you to create an index on a computed column that is defined with a deterministic, but imprecise, expression. This option enables you to create an index on a computed column when SQL Server cannot determine with certainty whether a function that returns a computed column expression—for example, a CLR function that is created in the Microsoft .NET Framework—is both deterministic and precise.

Filtered Indexes and Statistics

As discussed earlier in this chapter, a nonclustered index contains a row for every row in the table, even rows with a large number of duplicate key values where the nonclustered index will not be an effective method for finding those rows. For these situations, SQL Server 2008 introduces filtered indexes. Filtered indexes are an optimized form of nonclustered indexes, created by specifying a search predicate when defining the index. This search predicate acts as a filter to create the index on only the data rows that match the search predicate. This reduces the size of the index and essentially creates an index that covers your queries, which return only a small percentage of rows from a well-defined subset of data within your table.

Filtered indexes can provide the following advantages over full-table indexes:

- ▶ **Improved query performance and plan quality**—A well-designed filtered index improves query performance and execution plan quality because it is smaller than a full-table nonclustered index and has filtered statistics. Filtered statistics are more accurate than full-table statistics because they cover only the rows contained in the filtered index.
- ▶ **Reduced index maintenance costs**—Filtered indexes are maintained only when data modifications affect the data values contained in the index. Also, because a filtered index contains only the frequently accessed data, the smaller size of the index reduces the cost of updating the statistics.
- ▶ **Reduced index storage costs**—Filtered indexes can reduce disk storage for nonclustered indexes when a full-table index is not necessary. You can replace a full-table nonclustered index with multiple filtered indexes without significantly increasing the storage requirements.

Following are some of the situations in which filtered indexes can be useful:

- ▶ When a column contains mostly NULL values, but your queries search only for rows where data values are NOT NULL.
- ▶ When a column contains a large number of duplicate values, but your queries typically ignore those values and search only for the more unique values.

- ▶ When you want to enforce uniqueness on a subset of values—for example, a column on which you want to allow NULL values. A unique constraint allows only one NULL value; however, a filtered index can be defined as unique over only the rows that are NOT NULL.
- ▶ When queries retrieve only a particular range of data values and you want to index these values but not the entire table. For example, you have a table that contains a large number of historical values, but you want to search only values for the current year or quarter. You can create a filtered index on the desired range of values and possibly even use the INCLUDE option to add columns so your index fully covers your queries.

Now, you may be asking, “Can’t some of the preceding solutions be accomplished using indexed views?” Yes, they can, but filtered indexes provided a better alternative. The most significant advantage is that filtered indexes can be used in any edition of SQL Server 2008, whereas indexed views are chosen by the optimizer only in the Developer, Enterprise, and Datacenter Editions unless you use the NOEXPAND hint in other editions. In addition, filtered indexes have reduced index maintenance costs (the query processor uses fewer CPU resources to update a filtered index than an indexed view); the Query Optimizer considers using a filtered index in more situations than the equivalent indexed view; you can perform online rebuilds of filtered indexes (online index rebuilds are not supported for indexed views); and filtered indexes can be nonunique, whereas indexed views must be unique.

Based on these advantages, it is recommended that you use filtered indexes instead of indexed views when possible. Consider replacing indexed views with filtered indexes when the view references only one table, the view query doesn’t return computed columns, and the view predicate uses simple comparison logic and doesn’t contain a view.

Creating and Using Filtered Indexes

To define filtered indexes, you use the normal CREATE INDEX command but include a WHERE condition as a search predicate to specify which data rows the filtered index should include. In the current implementation, you can specify only simple search predicates such as IN; the comparison operators IS NULL, IS NOT NULL, =, <>, !=, >, >=, !>, <, <=, !<; and the logical operator AND. In addition, filtered indexes cannot be created on computed columns, user-defined data types, Hierarchyid, or spatial types.

For example, assume you need to search only the sales table in the bigpubs2008 database for sales since 9/1/2008. The majority of the rows in the sales table have order dates prior to 9/1/2008. To create a filtered index on the ord_date column, you would execute a command like the following:

```
create index ord_date_filt on sales (ord_date)
    WHERE ord_date >= '2008-09-01 00:00:00.000'
```

Now, let's look at a couple queries that may or may not use the new filtered index. First, let's consider the following query looking for any sales for 9/15/2008:

```
select * from sales
where ord_date = '9/15/2008'
```

If you look at the execution plan in Figure 34.28, you can see that the filtered index, `ord_date_filt`, is used to locate the qualifying row values. The clustered index, `UPKCL_sales`, is used as the row locator to retrieve the data rows (as described earlier in the “Nonclustered Indexes” section).

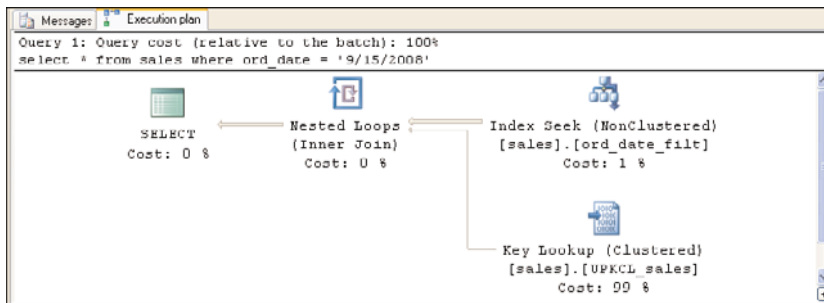

FIGURE 34.28 Query plan for a query that uses a filtered index.

NOTE

For more information on understanding and analyzing query plans, see Chapter 36.

If you run the following query using a data value that's outside the range of values stored in the filtered index, you see that the filtered index is not used (see Figure 34.29):

```
select * from sales
where ord_date = '9/15/2007'
```

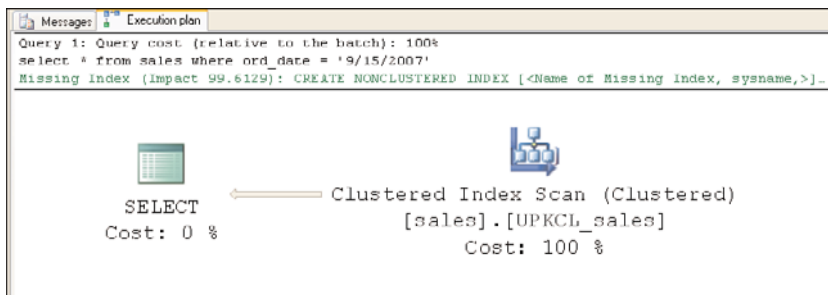

FIGURE 34.29 Query plan for a query using a value not in the filtered index.

Now let's consider a query that you might expect would use the filtered index but does not:

```
select stor_id, qty from sales
where ord_date > '9/15/2008'
```

Now, you might expect that this query would use the filtered index because the data values are within the range of values for the filtered index, but due to the number of rows that match, SQL Server determines that the I/O cost of using the filtered nonclustered index to locate the matching rows and then retrieve the data rows using the clustered index row locators requires more I/Os than simply performing a clustered index scan of the entire table (the same query plan as shown in Figure 34.29).

In this case, you might want to use included columns on the filtered index so that the data values for the query can be retrieved using index covering without incurring the extra cost of using the row locators to retrieve the actual data rows. The following example creates a filtered index on `ord_date` that includes `stor_id` and `qty`:

```
create index ord_date_filt2 on sales (ord_date)
INCLUDE (qty, stor_id)
WHERE ord_date >= '2008-09-01 00:00:00.000'
```

If you rerun the same query and examine the query plan, you see that the filtered index is used this time, and SQL Server uses index covering (see Figure 34.30). You can tell that it's using index covering with the `ord_dat_filt2` index because there is no use of the clustered index to retrieve the data rows. Using the row locators is unnecessary because all the information requested by the query can be retrieved from the index leaf rows that contain the values of the included columns as well.

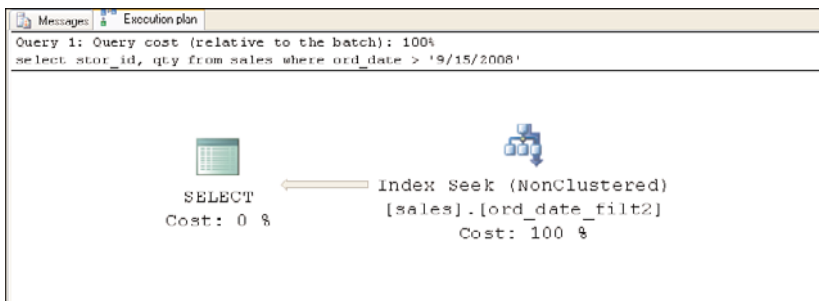

FIGURE 34.30 Query plan using index covering on a filtered index with included columns.

Creating and Using Filtered Statistics

Similar to the way you use filtered indexes, SQL Server 2008 also lets you create filtered statistics. Like filtered indexes, filtered statistics are also created over a subset of rows in the table based on a specified filter predicate. Creating a filtered index on a column autocreates the corresponding filtered statistics. In addition, filtered statistics can be created explicitly by including the `WHERE` clause with the `CREATE STATISTICS` statement.

Filtered statistics can be used to avoid a common issue with statistics where the cardinality estimation is skewed due to a large number of NULL or duplicate values, or due to a data correlation between columns. For example, let's consider the `titles` table in the `bigpubs2008` database. All the cooking books (`type = 'trad_cook'` or `'mod_cook'`) are published by a single publisher (`pub_id = '0877'`). However, SQL Server stores column-level statistics on each of these columns independent of each other. Based on the statistics, SQL Server estimates there are six rows in the `titles` table where `pub_id = '0877'`, and five rows where the type is either `'trad_cook'` or `'mod_cook'`.

However, let's assume you were to execute the following query:

```
select * from titles where pub_id = '0877'
and type in ('trad_cook', 'mod_cook')
```

When the Query Optimizer estimates the selectivity of this query where each search predicate is part of an AND condition, it assumes the conditions are independent of one another and estimates the number of matching rows by taking the intersection of the two conditions. Essentially, it multiplies the selectivity of each of the two conditions together to determine the total selectivity. The selectivity of each is 0.011 (6/537) and 0.009 (5/537), which, when multiplied together, comes out to approximately 0.0001, so the optimizer estimates at most only a single row will match. However, because all five cooking books are published by `pub_id '0877'`, in actuality a total of five rows match.

Now, in this example, the difference between one row and five rows is likely not significant enough to make a big difference in query performance, but a similar estimation error could be quite large with other data sets, leading the optimizer to possibly choose an inappropriate, and considerably more expensive, query plan.

Filtered statistics can help solve this problem by letting you capture these types of data correlations in your column statistics. For example, to capture the fact that all cooking books are also published by the same publisher, you could create the filtered statistics using the following statement:

```
create statistics pub_id_type on titles (pub_id, type)
where pub_id = '0877' and type in ('trad_cook', 'mod_cook')
```

When these filtered statistics are defined and the same query is run, SQL Server uses the filtered statistics to determine that the query will match five rows instead of only one.

Although using this solution could require having to define a number of filtered statistics, it can be effective to help fix your most critical queries where cardinality estimates due to data correlation or data skew issues are causing the Query Optimizer to choose poorly performing query plans.

Choosing Indexes: Query Versus Update Performance

I/O is the primary factor in determining query performance. The challenge for a database designer is to build a physical data model that provides efficient data access. Creating

indexes on database tables allows SQL Server to access data with fewer I/Os. Defining useful indexes during the logical and physical data modeling step is crucial. The SQL Server Query Optimizer relies heavily on index key distribution and index density to determine which indexes to use for a query. The Query Optimizer in SQL Server can use multiple indexes in a query (through index intersection) to reduce the I/O required to retrieve information. In the absence of indexes, the Query Optimizer performs a table scan, which can be costly from an I/O standpoint.

Although indexes provide a means for faster access to data, they slow down data modification statements due to the extra overhead of having to maintain the index during inserts, updates, and deletes.

In a DSS environment, defining many indexes can help your queries and does not create much of a performance issue because the data is relatively static and doesn't get updated frequently. You typically load the data, create the indexes, and forget about it until the next data load. As long as you have the necessary indexes to support the user queries and they're getting decent response time, the penalties of having too many indexes in a DSS environment are the space wasted for indexes that possibly won't be used, the additional time required to create the excessive indexes, and the additional time required to back up and run DBCC checks on the data.

In an OLTP environment, on the other hand, too many indexes can lead to significant performance degradation, especially if the number of indexes on a table exceeds four or five. Think about it for a second. Every single-row insert is at least one data page write and one or more index page writes (depending on whether a page split occurs) for every index on the table. With eight nonclustered indexes, that would be a minimum of nine writes to the database for a single-row insert. Therefore, for an OLTP environment, you want as few indexes as possible—typically only the indexes required to support the update and delete operations and your critical queries, and to enforce your uniqueness constraints.

The natural solution, in a perfect world, would be to create a lot of indexes for a DSS environment and as few indexes as possible in an OLTP environment. Unfortunately, in the real world, you typically have an environment that must support both DSS and OLTP applications. How do you resolve the competing indexing requirements of the two environments? Meeting the indexing needs of DSS and OLTP applications requires a bit of a balancing act, with no easy solution. It often involves making hard decisions as to which DSS queries might have to live with table scans and which updates have to contend with additional overhead.

One solution is to have two separate databases: one for DSS applications and another for OLTP applications. Obviously, this method requires some method of keeping the databases in sync. The method chosen depends on how up-to-date the DSS database has to be. If you can afford some lag time, you could consider using a dump-and-load mechanism, such as Log Shipping or periodic full database restores. If the DSS system requires up-to-the-minute concurrency, you might want to consider using replication or database mirroring.

Another possible alternative is to have only the required indexes in place during normal processing periods to support the OLTP requirements. At the end of the business day, you can create the indexes necessary to support the DSS queries and reports, and they can run

as batch jobs after normal processing hours. When the DSS reports are complete, you can drop the additional indexes, and you're ready for the next day's processing. Note that this solution assumes that the time required to create the additional indexes is offset by the time saved by the faster running of the DSS queries. If the additional indexes do not result in substantial time savings, they are probably not necessary and need not be created in the first place. The queries need to be more closely examined to select the appropriate indexes to best support your queries.

As you can see, it is important to choose indexes carefully to provide a good balance between data search and data modification performance. The application environment usually governs the choice of indexes. For example, if the application is mainly OLTP with transactions requiring fast response time, creating too many indexes might have an adverse impact on performance. On the other hand, the application might be a DSS with few transactions doing data modifications. In that case, it makes sense to create a number of indexes on the columns frequently used in queries.

Identifying Missing Indexes

When developing an index design for your database and applications, you should make sure you create appropriate indexes for the various queries that will be executed against your tables. However, it can be quite a chore to identify all the queries you may need to create indexes for. Fortunately, SQL Server 2008 provides a couple of tools to help you identify any indexes you may need in your database: The Database Engine Tuning Advisor and the missing index dynamic management objects.

The Database Engine Tuning Advisor

The Database Engine Tuning Advisor is a tool that can analyze a SQL Script file or a set of queries captured in a SQL Profiler trace and recommend changes to your indexing scheme. After performing its analysis, the Database Engine Tuning Advisor provides recommendations for new or more effective indexes, indexed views, and partitioning schemes, along with the estimated improvement in execution time should the recommendation be implemented. You can choose to implement the recommendations immediately or later, or you can save the SQL statements to a script file. For detailed information on using the Database Engine Tuning Advisor, see Chapter 55.

Although the Database Engine Tuning Advisor is a useful tool, and improvements have been made since it was introduced in SQL Server 2005 to improve its recommendations, it does still have some limitations. For one, because the Database Engine Tuning Advisor gathers statistics by sampling the data, repeatedly running the tool on the same workload may produce different results as different samples are used. In addition, if you impose constraints, such as specifying maximum disk space for tuning recommendations, the Database Engine Tuning Advisor may be forced to drop certain existing indexes, and the resulting recommendation may produce a negative expected improvement. The Database Engine Tuning Advisor may also not make recommendations under the following circumstances:

- ▶ The table being tuned contains fewer than 10 data pages.

- ▶ The recommended indexes would not offer enough improvement in query performance over the current physical database design.
- ▶ The user who runs the Database Engine Tuning Advisor is not a member of the `db_owner` database role or the `sysadmin` fixed server role.

Missing Index Dynamic Management Objects

In addition to the Database Engine Tuning Advisor, SQL Server 2008 introduces the missing index dynamic management objects to help identify potentially missing indexes in your database. The *missing index dynamic management objects* are a set of new dynamic management objects introduced in SQL Server 2008:

- ▶ **sys.dm_db_missing_index_group_stats**—Returns summary information about missing index groups, such as the performance improvements that could be gained by implementing a specific group of missing indexes.
- ▶ **sys.dm_db_missing_index_groups**—Returns information about a specific group of missing indexes, such as the group identifier and identifiers of all missing indexes contained in that group.
- ▶ **sys.dm_db_missing_index_columns**—Returns detailed information about a missing index; for example, it returns the name and identifier of the table where the index is missing, and the columns and column types that should make up the missing index.
- ▶ **sys.dm_db_missing_index_details**—Returns information about the database table columns missing an index.

After running a typical workload on SQL Server, you can query the dynamic management functions to retrieve information about possible missing indexes. Listing 34.8 provides a sample query that displays the missing index information for a query on the sales table that was run between 10:30 and 10:40 p.m. on 2/21/2010.

LISTING 34.8 Querying the Missing Index Dynamic Management Objects

```
SELECT
    mig.index_group_handle as handle,
    convert(varchar(30), statement) AS table_name,
        convert(varchar(12), column_name) AS Column_name,
        convert(varchar(10), column_usage) as ColumnUsage,
        avg_user_impact as avg_impact
FROM sys.dm_db_missing_index_details AS mid
CROSS APPLY sys.dm_db_missing_index_columns (mid.index_handle)
INNER JOIN sys.dm_db_missing_index_groups AS mig
ON mig.index_handle = mid.index_handle
inner join sys.dm_db_missing_index_group_stats AS migs
ON migs.group_handle = mig.index_group_handle
where mid.object_id = object_id('sales')
and last_user_seek between '2010-02-21 22:30' and '2010-02-21 22:40'
```

```
ORDER BY mig.index_group_handle, mig.index_handle, column_id;
GO
```

handle	table_name	Column_name	ColumnUsage	avg_impact
2	[bigpubs2008].[dbo].[sales]	stor_id	INCLUDE	87.46
2	[bigpubs2008].[dbo].[sales]	qty	INEQUALITY	87.46

In this example, the optimizer recommends an index on the qty column to support an inequality operator. It is also recommended that the stor_id column be specified as an included column in the index. This index is estimated to improve performance by 87.46%.

Although the missing index feature provides some helpful information for identifying potentially missing indexes in your database, it too has a few limitations:

- ▶ It is not intended to fine-tune the existing indexes, only to recommend additional indexes when no useful index is found that can be used to satisfy a search or join condition.
- ▶ It reports only included columns for some queries. You need to determine whether the included columns should be specified as additional index key columns instead.
- ▶ It may return different costs for the same missing index group for different executions.
- ▶ It does not suggest filtered indexes.
- ▶ It is unable to provide recommendations for clustered indexes, indexed views, or table partitioning (you should use the Database Engine Tuning Advisor instead for these recommendations).

Probably the key limitation is that although the missing index feature is helpful for identifying indexes that may be useful for you to define, it's not a substitute for a well-thought-out index design.

Missing Index Feature Versus Database Engine Tuning Advisor

The missing indexes dynamic management objects are a lightweight, server-side, always-on feature for identifying and correcting potential indexing oversights. The Database Engine Tuning Advisor, on the other hand, is a comprehensive client-side tool that can be used to assess the physical database design and recommend new physical design structures for improving performance, including not only indexes, but also indexed views or partitioning schemes.

The Database Engine Tuning Advisor and missing indexes feature can possibly return different recommendations, even for a single-query workload. The reason is that the missing indexes dynamic management objects' index key column recommendations are not order sensitive. On the other hand, the Database Engine Tuning Advisor recommendations include ordering of the key columns for indexes to optimize query performance.

Table 34.11 details some other differences between the missing indexes feature and Database Engine Tuning Advisor in greater detail.

TABLE 34.11 Differences Between Missing Index Features and Database Engine Tuning Advisor

Comparison Point	Missing Indexes Feature	Database Engine Tuning Advisor
Execution method	Server side, always on	Client-side, standalone application
Scope of analysis	Quick, ad hoc analysis, providing limited information about missing indexes only	Thorough workload analysis, providing full recommendation report about the best physical database design configuration in the context of a submitted workload
Statements analyzed	SELECT statements only	SELECT, UPDATE, INSERT, and DELETE
Available disk storage space	Not factored into analysis	Factored into analysis; recommendations are not provided if they would exceed available storage space
Columns ordering	Recommended index column order not provided	Optimal index column order determined based on query execution cost
Index type	Nonclustered only	Both clustered and nonclustered index recommendations provided
Indexed views recommendations	Not provided	Recommended in supported editions
Partitioning recommendations	Not provided	Recommended in supported editions
Impact analysis	An approximate impact of adding a missing index is reported via the <code>sys.dm_db_missing_index_group_stats</code> dynamic management view (DMV)	Up to 15 different analysis reports generated to provide information about the impact of implementing recommendations

Identifying Unused Indexes

As mentioned previously in this chapter, each index on a table adds additional overhead for data modifications because the indexes also need to be maintained as changes are made to index key columns. In an OLTP environment, excessive indexes on your tables can be almost as much of a performance issue as missing indexes. To improve OLTP performance, you should limit the number of indexes on your tables to only those absolutely needed; you definitely should eliminate any unnecessary and unused indexes that may be defined on your tables to eliminate the overhead they introduce.

Fortunately, SQL Server provides a DMV that you can use to identify which indexes in your database are not being used: `sys.dm_db_index_usage_stats`. The columns in the `sys.dm_db_index_usage_stats` are shown in Table 34.12.

TABLE 34.12 Columns in the **sys.dm_db_index_usage_stats** DMV

Column Name	Description
<code>database_id</code>	ID of the database on which the table or view is defined
<code>object_id</code>	ID of the table or view on which the index is defined
<code>index_id</code>	ID of the index
<code>user_seeks</code>	Number of seeks by user queries
<code>user_scans</code>	Number of scans by user queries
<code>user_lookups</code>	Number of bookmark lookups by user queries
<code>user_updates</code>	Number of updates by user queries
<code>last_user_seek</code>	Time of last user seek
<code>last_user_scan</code>	Time of last user scan
<code>last_user_lookup</code>	Time of last user lookup
<code>last_user_update</code>	Time of last user update
<code>system_seeks</code>	Number of seeks by system queries
<code>system_scans</code>	Number of scans by system queries
<code>system_lookups</code>	Number of lookups by system queries
<code>system_updates</code>	Number of updates by system queries
<code>last_system_seek</code>	Time of last system seek
<code>last_system_scan</code>	Time of last system scan
<code>last_system_lookup</code>	Time of last system lookup
<code>last_system_update</code>	Time of last system update

Every individual seek, scan, lookup, or update on an index by a query execution is counted as a use of that index, and the corresponding counter in the view is incremented. Thus, you can run a query against this DMV to see whether there are any indexes that your queries are not using, that is, indexes that either have no rows in the DMV or have 0 values in the `user_seeks`, `user_scans`, or `user_lookups` columns (or the time values of the `last_user_*` columns are significantly in the past). You especially need to focus on any indexes that don't show any user query activity but do have a high value in the `last_user_update` column. This indicates an index that's adding significant update overhead but not being used by any queries for locating data rows.

For example, the query shown in Listing 34.9 returns all indexes in the current database that have never been accessed; that is, they would have no records at all in the `sys.dm_db_index_usage_stats` table.

LISTING 34.9 A Query for Unused Indexes

```

SELECT  convert(varchar(12), OBJECT_SCHEMA_NAME(I.OBJECT_ID)) AS SchemaName,
        convert(varchar(20), OBJECT_NAME(I.OBJECT_ID)) AS ObjectName,
        convert(varchar(30), I.NAME) AS IndexName
FROM    sys.indexes I
WHERE   -- only get indexes for user created tables
        OBJECTPROPERTY(I.OBJECT_ID, 'IsUserTable') = 1
        -- ignore heaps
        and I.index_id > 0
        -- find all indexes that exist but are NOT used
        AND NOT EXISTS (
            SELECT  index_id
            FROM    sys.dm_db_index_usage_stats
            WHERE   OBJECT_ID = I.OBJECT_ID
                    AND I.index_id = index_id
                    AND database_id = DB_ID())
ORDER BY SchemaName, ObjectName, IndexName

```

Also, you should be aware that that the information is reported in the DMV both for operations caused by user-submitted queries and for operations caused by internally generated queries, such as scans for gathering statistics. If you run `UPDATE STATISTICS` on a table, the `sys.dm_db_index_usage_stats` table will have a row for each index for the system scan performed by the `UPDATE STATISTICS` command. However, the index may still be unused by any queries in your applications. Consequently, you might want to modify the previous query to look for indexes with 0 values in the `last_user_*` columns instead of indexes with no row at all in the DMV. Listing 34.10 provides an alternative query.

LISTING 34.10 A Query for Indexes Unused by Appliation Queries

```
SELECT  convert(varchar(12), OBJECT_SCHEMA_NAME(I.OBJECT_ID)) AS SchemaName,
        convert(varchar(20), OBJECT_NAME(I.OBJECT_ID)) AS ObjectName,
        convert(varchar(30), I.NAME) AS IndexName
FROM    sys.indexes I
        LEFT OUTER JOIN
        sys.dm_db_index_usage_stats u
        on I.index_id = u.index_id
        and u.database_id = DB_ID()
WHERE   -- only get indexes for user created tables
        OBJECTPROPERTY(I.OBJECT_ID, 'IsUserTable') = 1
        -- ignore heaps
        and I.index_id > 0
        -- find all indexes that exist but are NOT used
        and isnull(u.last_user_seek, 0) = 0
        and isnull(u.last_user_scan, 0) = 0
        and isnull(u.last_user_lookup, 0) = 0
ORDER BY SchemaName, ObjectName, IndexName
```

Note that the information returned by `sys.dm_db_index_usage_stats` is useful only if your server has been running long enough and has processed a sufficient amount of your standard and peak workflow. Also, you should be aware that the data in the DMV is cleared each time SQL Server is restarted, or if a database is detached and reattached. To prevent losing useful information, you might want to create a scheduled job that periodically queries the DMVs and saves the information to your own tables so you can track the information over time for more thorough and complete analysis.

Summary

One of the most important aspects of improving SQL Server performance is proper table and index design. Choosing the appropriate indexes for SQL Server to use to process queries involves thoroughly understanding the queries and transactions being run against the database, understanding the bias of the data, understanding how SQL Server uses indexes, and staying aware of the performance implications of overindexing tables in an OLTP environment. In general, you should consider using clustered indexes to support range retrievals or when data needs to be sorted in clustered index order; you should use nonclustered indexes for single- or discrete-row retrievals or when you can take advantage of index covering.

To really make good index design choices, you should have an understanding of the SQL Server Query Optimizer to know how it uses indexes and index statistics to develop query plans. This would be a good time to continue on and read Chapter 35.

CHAPTER 35

Understanding Query Optimization

Query optimization is the process SQL Server goes through to analyze individual queries and determine the best way to process them. To achieve this end, SQL Server uses a cost-based Query Optimizer. As a cost-based Query Optimizer, the Query Optimizer's purpose is to determine the query plan that will access the data with the least amount of processing time in terms of CPU and logical and physical I/O. The Query Optimizer examines the parsed SQL queries and, based on information about the objects involved (for example, number of pages in the table, types of indexes defined, index statistics), generates a query plan. The query plan is the set of steps to be carried out to execute the query.

To allow the Query Optimizer to do its job properly, you need to have a good understanding of how the Query Optimizer determines query plans for queries. This knowledge will help you to understand what types of queries can be optimized effectively and to learn techniques to help the Query Optimizer choose the best query plan. This knowledge will help you write better queries, choose better indexes, and detect potential performance problems.

NOTE

To better understand the concepts presented in this chapter, you should have a reasonable understanding of how data structures and indexes affect performance. If you haven't already read Chapter 34, "Data Structures, Indexes, and Performance," it is recommended that you review it now.

IN THIS CHAPTER

- ▶ What's New in Query Optimization
- ▶ What Is the Query Optimizer?
- ▶ Query Compilation and Optimization
- ▶ Query Analysis
- ▶ Row Estimation and Index Selection
- ▶ Join Selection
- ▶ Execution Plan Selection
- ▶ Query Plan Caching
- ▶ Other Query Processing Strategies
- ▶ Parallel Query Processing
- ▶ Common Query Optimization Problems
- ▶ Managing the Optimizer

NOTE

Occasionally throughout this chapter, graphical execution plans are used to illustrate some of the principles discussed. Chapter 36, “Query Analysis,” provides a more detailed discussion of the graphical execution plan output and describes the information contained in the execution plans and how to interpret it. In this chapter, the execution plans are provided primarily to give you an idea of what you can expect to see for the different types of queries presented when you are doing your own query analysis.

What’s New in Query Optimization

SQL Server 2008 introduces a few new features and capabilities related to query optimization and query performance in an attempt to deliver on the theme of “predictable performance.” The primary new features and enhancements are as follows:

- ▶ An enhancement has been added to the `OPTIMIZE FOR` query hint option to include a new `UNKNOWN` option, which specifies that the Database Engine use statistical data to determine the values for one or more local variables during query optimization, instead of the initial values.
- ▶ Table hints can now be specified as query hints in the context of plan guides to provide advanced query performance tuning options
- ▶ A new `FORCESEEK` table hint has been added. This hint specifies that the query optimizer should use only an index seek operation as the access path to the data referenced in the query.
- ▶ Hash values are available for finding and tuning similar queries. The `sys.dm_exec_query_stats` and `sys.dm_exec_requests` catalog views provide query hash and query plan hash values that you can use to help determine the aggregate resource usage for similar queries and similar query execution plans. This can help you find and tune similar queries that individually consume minimal system resources but collectively consume significant system resources.
- ▶ The new filtered indexes feature in SQL Server 2008 is considered for estimating index usefulness.
- ▶ Parallel query processing on partitioned objects has been improved.

One of the key improvements in SQL Server 2008 is the simplification of the creation and use of plan guides:

- ▶ The `sp_create_plan_guide` stored procedure now accepts XML execution plan output directly via the `@hints` parameter instead of having to embed the output in the `USE PLAN` hint.
- ▶ A new stored procedure, `sp_create_plan_guide_from_handle`, allows you to create one or more plan guides from an existing query plan in the plan cache.
- ▶ You can create multiple `OBJECT` or `SQL` plan guides for the same query and batch or module although only one of these plan guides can be enabled at any given time.

- ▶ A new system function, `sys.fn_validate_plan_guide`, enables you to validate a plan guide.
- ▶ New SQL Profiler event classes, Plan Guide Successful and Plan Guide Unsuccessful, enable you to verify whether plan guides are being used by the Query Optimizer.
- ▶ New Performance Monitor counters in the SQL Server, SQL Statistics Object—Guided Plan Executions/sec and Misguided Plan Executions/sec—can be used to monitor the number of plan executions in which the query plan has been successfully or unsuccessfully generated by using a plan guide.
- ▶ Built-in support is now available for creating, deleting, enabling, disabling, or scripting plan guides in SQL Server Management Studio (SSMS). Plan guides now are located in the Programmability folder in Object Explorer.

NOTE

Many of the internals of the Query Optimizer and its costing algorithms are considered proprietary and have not been made public. Much of the information provided here is based on analysis and observation of query plans generated for various queries and search values.

The intent of this chapter is therefore not so much to describe the specific steps, algorithms, and calculations implemented by the Query Optimizer, but rather to provide a general overview of the query optimization process in SQL Server 2008 and what goes into estimating and determining an efficient query plan. Also, there are a number of possible ways SQL Server can optimize and process queries. The examples presented in this chapter focus on some of the more common optimization strategies.

What Is the Query Optimizer?

For any given SQL statement, the source tables can be accessed in many ways to return the desired result set. The Query Optimizer analyzes all the possible ways the result set can be generated and chooses the most appropriate method, called the *query plan* or *execution plan*. SQL Server uses a cost-based Query Optimizer. The Query Optimizer assigns a cost to every possible execution plan in terms of CPU resource usage and page I/O. The Query Optimizer then chooses the execution plan with the lowest associated cost.

Thus, the primary goal of the Query Optimizer is to find the least expensive execution plan that minimizes the total time required to process a query. Because I/O is the most significant factor in query processing time, the Query Optimizer analyzes the query and primarily searches for access paths and techniques to minimize the number of logical and physical page accesses as much as possible. The lower the number of logical and physical I/Os performed, the faster the query should run.

The process of query optimization in SQL Server is extremely complicated and is based on sophisticated costing models and data access algorithms. It is beyond the scope of a single chapter to explain in detail all the various costing algorithms that the Query Optimizer

currently employs. This chapter is intended to help you better understand some of the concepts related to how the Query Optimizer chooses an execution strategy and provide an overview of the query optimization strategies employed to improve query processing performance.

Query Compilation and Optimization

Query compilation is the complete process from the submission of a query to its actual execution. There are many steps involved in query compilation—one of which is optimization. All T-SQL statements are compiled, but not all are optimized. Primarily, only the standard SQL Data Manipulation Language (DML) statements—SELECT, INSERT, UPDATE, and DELETE—require optimization. The other procedural constructs in T-SQL (IF, WHILE, local variables, and so on) are compiled as procedural logic but do not require optimization. DML statements are set-oriented requests that the Query Optimizer must translate into procedural code that can be executed efficiently to return the desired results.

NOTE

SQL Server also optimizes some Data Definition Language (DDL) statements, such as CREATE INDEX or ALTER TABLE, against the data tables. For example, a displayed query plan for the creation of an index shows optimization steps for accessing the table, sorting data, and inserting into the index tree. However, the focus in this chapter is on optimization of DML statements.

Compiling DML Statements

When SQL Server compiles an execution plan for a DML statement, it performs the following basic steps:

1. The query is parsed and checked for proper syntax, and the T-SQL statements are parsed into keywords, expressions, operators, and identifiers to generate a query tree. The query tree (sometimes referred to as the *sequence tree*) is an internal format of the query that SQL Server can operate on. It is essentially the logical steps needed to transform the query into the desired result.
2. The query tree is then normalized and simplified. During normalization, the tables and columns are verified, and the metadata (data types, null properties, index statistics, and so on) about them is retrieved. In addition, any views are resolved to their underlying tables, and implicit conversions are performed (for example, an integer compared with a float value). Also during this phase, any redundant operations (for example, unnecessary or redundant joins) are removed, and the query tree is simplified.
3. The Query Optimizer analyzes the different ways the source tables can be accessed and selects the series of steps that return the results fastest while typically using the fewest resources. The query tree is updated with the optimized series of steps, and an execution plan (also referred to as query plan) is generated from the final, optimized version of the sequence tree.

4. After the optimized execution plan is generated, SQL Server stores the optimized plan in the procedure cache.
5. SQL Server reads the execution plan from the procedure cache and executes the query plan, returning the result set (if any) to the client.

The optimized execution plan is then left in the procedure cache. If the same query or stored procedure is executed again and the plan is still available in the procedure cache, the steps to optimize and generate the execution plan are skipped, and the stored query execution plan is reused to execute the query or stored procedure.

Optimization Steps

When the query tree is passed to the Query Optimizer, the Query Optimizer performs a series of steps to break down the query into its component pieces for analysis to generate an optimal execution plan:

1. **Query analysis**—The query is analyzed to determine search arguments and join clauses. A search argument is defined as a `WHERE` clause that compares a column to a constant. A join clause is a `WHERE` clause that compares a column from one table to a column from another table.
2. **Row estimation and index selection**—Indexes are selected based on search arguments and join clauses (if any exist). Indexes are evaluated based on their distribution statistics and are assigned a cost.
3. **Join selection**—The join order is evaluated to determine the most appropriate order in which to access tables. In addition, the Query Optimizer evaluates the most appropriate join algorithm to match the data.
4. **Execution plan selection**—Execution costs are evaluated, and a query execution plan is created that represents the most efficient solution found by the optimizer.

The next four sections of this chapter examine each of these steps in more detail.

NOTE

Unless stated otherwise, the examples presented in this chapter operate on the tables in the `bigpubs2008` database. A copy of the `bigpubs2008` database is available on the CD included with this book. Instructions on how to install the database are presented in the Introduction.

Query Analysis

The first step in query optimization is to analyze each table in the query to identify all search arguments (SARGs), `OR` clauses, and join clauses. The SARGs, `OR` clauses, and join clauses are used in the second step, index selection, to select useful indexes to satisfy a query.

Identifying Search Arguments

A SARG is defined as a WHERE clause that compares a column to a constant. The format of a SARG is as follows:

```
Column operator constant_expression [and...]
```

SARGs provide a way for the Query Optimizer to limit the rows searched to satisfy a query. The general goal is to match a SARG with an index to avoid a table scan. Valid operators for a SARG are =, >, <, >=, and <=, BETWEEN, and LIKE. Multiple SARGs can be combined with the AND clause. (A single index might match some or all of the SARGs ANDed together.) Following are examples of SARGs:

- ▶ flag = 7
- ▶ salary > 100000
- ▶ city = 'Saratoga' and state = 'NY'
- ▶ price between \$10 and \$20 (the same as price > = \$10 and price <= \$20)
- ▶ 100 between lo_val and hi_val (the same as lo_val <= 100 and hi_val >= 100)
- ▶ au_lname like 'Sm%' (the same as au_lname >= 'Sm' and au_lname < 'Sn')

In some cases, the column in a SARG might be compared with a constant expression rather than a single constant value. The constant expression can be an arithmetic operation, a built-in function, a string concatenation, a local variable, or a subquery result. As long as the left side of the SARG contains a column, it's considered an optimizable SARG.

Identifying OR Clauses

The next statements the Query Optimizer looks for in the query are OR clauses. OR clauses are SARGable expressions combined with an OR condition rather than an AND condition and are treated differently than standard SARGs. The format of an OR clause is

```
SARG or SARG [or ...]
```

with all columns involved in the OR belonging to the same table.

This IN statement

```
column in ( constant1, constant2, ...)
```

is also treated as an OR clause, becoming this:

```
column = constant1 or column = constant2 or ...
```

Some examples of OR clauses are as follows:

```
where au_lname = 'Smith' or au_fname = 'Fred'
where (type = 'business' and price > $25) or pub_id = "1234"
where au_lname in ('Smith', 'Jones', 'N/A')
```

An OR clause is a disjunction; all rows matching either of the two criteria appear in the result set. Any row matching both criteria should appear only once.

The main issue is that an OR clause cannot be satisfied by a single index search. Consider the first example just presented:

```
where au_lname = 'Smith' or au_fname = 'Fred'
```

An index on au_lname and au_fname helps SQL Server find all the rows where au_lname = 'Smith' AND au_fname = 'Fred', but searching the index tree does not help SQL Server efficiently find all the rows where au_fname = 'Fred' and the last name is any value. Unless an index on au_fname exists as well, the only way to find all rows with au_fname = 'Fred' is to search every row in the table or scan every row in a nonclustered index that contains au_fname as a nonleading index key.

An OR clause can typically be resolved by either a table scan or by using the OR strategy. Using a table scan, SQL Server reads every row in the table and applies each OR criteria to each row. Any row that matches any one of the OR criteria is put into the result set.

A table scan is an expensive way to process a query, so the Query Optimizer looks for an alternative for resolving an OR. If an index can be matched against all SARGs involved in the OR clause, SQL Server evaluates the possibility of applying the index union strategy described later in this chapter, in the section “Using Multiple Indexes.”

Identifying Join Clauses

The next type of clause the Query Optimizer looks for during the query analysis phase is the join clause. A join condition is specified in the FROM clause using the JOIN keyword, as follows:

```
FROM table1 JOIN table2 on table1.column = table2.column
```

Alternatively, join conditions can be specified in the WHERE clause using the old-style join syntax, as shown in the following example:

```
Table1.Column Operator Table2.Column
```

A join clause always involves two tables, except in the case of a self-join, but even in a self-join, you must specify the table twice in the query. Here’s an example:

```
select employee = e.LastName + ', ' + e.FirstName,
       manager = m.LastName + ', ' + m.FirstName
   from Northwind..Employees e left outer join Northwind..Employees m
   on e.ReportsTo = m.EmployeeID
  order by 2, 1
```

SQL Server treats a self-join just like a normal join between two different tables.

In addition to join clauses, the Query Optimizer also looks for subqueries, derived tables, and common table expressions and makes the determination whether they need to be flattened into joins or processed using a different strategy. Subquery optimization is discussed later in this chapter.

Row Estimation and Index Selection

When the query analysis phase of optimization is complete and all SARGs, OR clauses, and join clauses have been identified, the next step is to determine the selectivity of the expressions (that is, the estimated number of matching rows) and to determine the cost of finding the rows. The costs are measured primarily in terms of logical and physical I/O, with the goal of generating a query plan that results in the lowest estimated I/O and processing cost. Primarily, the Query Optimizer attempts to identify whether an index exists that can be used to locate the matching rows. If multiple indexes or search strategies can be considered, their costs are compared with each other and also against the cost of a table or clustered index scan to determine the least expensive access method.

An index is typically considered useful for an expression if the first column in the index is used in the expression and the search argument in the expression provides a means to effectively limit the search. If no useful indexes are found for an expression, typically a table or clustered index scan is performed on the table. A table or clustered index scan is the fallback tactic for the Query Optimizer to use if no lower-cost method exists for returning the matching rows from a table.

Evaluating SARG and Join Selectivity

To determine selectivity of a SARG, which helps in determining the most efficient query plan, the Query Optimizer uses the statistical information stored for the index or column, if any. If no statistics are available for a column or index, SQL Server automatically creates statistics on nonindexed columns specified in a SARG if the `AUTO_CREATE_STATISTICS` option is enabled for the database. SQL Server also automatically generates and updates the statistics for any indexed columns referenced in a SARG if the `AUTO_UPDATE_STATISTICS` option is enabled. In addition, you can explicitly create statistics for a column or set of columns in a table or an indexed view by using the `CREATE STATISTICS` command. Both index statistics and column statistics (whether created automatically or manually with the `CREATE STATISTICS` command) are maintained and kept up-to-date, as needed, if the `AUTO_UPDATE_STATISTICS` option is enabled or if the `UPDATE STATISTICS` command is explicitly run for a table, index, or column statistics. Available and up-to-date statistics allow the Query Optimizer to more accurately assess the cost of different query plans and choose a high-quality plan.

If no statistics are available for a column or an index and the `AUTO_CREATE_STATISTICS` and `AUTO_UPDATE_STATISTICS` options have been disabled for the database or table, SQL Server cannot make an informed estimate of the number of matching rows for a SARG

and resorts to using some built-in percentages for the number of matching rows for various types of expressions. These percentages currently are as follows:

Operator	Row Estimate
=	(# of rows in table) ⁷⁵
between, > and <	9% (closed-range search)
>, <, >=, <=	30% (open-range search)

Using these default percentages almost certainly results in inappropriate query execution plans being chosen. You should always try to ensure that you have up-to-date statistics available for any columns referenced in your SARGs and join clauses.

When the value of a SARG can be determined at the time of query optimization, the Query Optimizer uses the statistics histogram to estimate the number of matching rows for the SARG. The histogram contains a sampling of the data values in the column and stores information on the number of matching rows for the sampled values, as well as for values that fall between the sampled values. If the statistics are up-to-date, this is the most accurate estimate of the number of matching rows for a SARG. (For a more detailed discussion of index and column statistics and the information contained in them, see Chapter 34.)

If the SARG contains an expression that cannot be evaluated until runtime (for example, a local variable or scalar function) but is an equality expression (=), the Query Optimizer uses the density information from the statistics to estimate the number of matching rows. The density value reflects the overall uniqueness of the data values in the column or index. Density information does not estimate the number of matching rows as accurately as the histogram because its value is determined across the entire range of values in a column or an index key and can be skewed higher by one or more values that have a high number of duplicates. Expressions that cannot be evaluated until runtime include comparisons against local variables or function expressions that cannot be evaluated until query execution.

If an expression cannot be evaluated at the time of optimization and the SARG is not an equality search but a closed- or open-range search, the density information cannot be used. The same percentages are used for the row estimates as when no statistics are available (9% for a closed-range search and 30% for an open-range search).

As a special case, if a SARG contains the equality (=) operator and a unique index exists that matches the SARG, based on the nature of a unique index, the Query Optimizer knows, without having to analyze the index statistics, that one and only one row can match the SARG.

If the query contains a join clause, SQL Server determines whether any usable indexes or column statistics exist that match the column(s) in the join clause. Because the Query Optimizer has no way of determining what value(s) will join between rows in the table at

optimization time, it can't use the statistics histogram on the join column to estimate the number of matching rows. Instead, it uses the density information, as it does for SARGs that are unknown during optimization.

A lower density value indicates a more selective index. As the density approaches 1, the join condition becomes less selective. For example, if a nonclustered index has a high density value, it will likely be more expensive in terms of I/O to retrieve the matching rows using the nonclustered index than to perform a table scan or clustered index scan and the index likely will not be used.

NOTE

For a more thorough and detailed discussion of indexes and index and column statistics, see Chapter 34.

SARGs and Inequality Operators

In previous versions of SQL Server, when a SARG contained an inequality operator (\neq or $\lt\gt$), the selectivity of the SARG could not be determined effectively for the simple reason that index or column statistics can help you estimate only the number of matching rows for a specific value, not the number of nonmatching rows. However, for some SARGs with inequality operators, if index or column statistics are available, SQL Server 2008 is able to estimate the number of matching rows. For example, consider the following SARG:

```
WHERE qty <> 1000
```

Without any available index or column statistics on the qty column, SQL Server would treat the inequality SARG as a SARG with no available statistics. Potentially every row in the table could satisfy the search criteria, so it would estimate the number of matching rows as all rows in the table.

However, if index or column statistics were available for the qty column, the Query Optimizer would look up the search value (1000) in the statistics and estimate the number of matching rows for the search value and then determine the number of matching rows for the query as the total number of rows in the table minus the estimated number of matching rows for the search value. For example, if there are 150,000 rows in the table and the statistics indicate that 1,570 rows match, where $qty = 1000$, the number of matching rows would be calculated as follows:

150,000	rows
- 1,570	rows (where $qty = 1000$)
= 148,430	rows (where $qty <> 1000$)

In this example, with the large number of estimated rows where $qty <> 1000$, SQL Server would likely end up performing a table scan to resolve the query. However, if the Query Optimizer estimates that there is a very small number of rows where $qty <> 1000$, the Query Optimizer might determine that it would be more efficient to use an index to find

the nonmatching rows. You may be wondering how SQL Server efficiently searches the index for the rows where `qty <> 1000` without having to look at every row. In this case, internally, it converts the inequality SARG into two range retrievals by using an OR condition:

```
WHERE qty < 1000 OR qty > 1000
```

NOTE

Even if an inequality SARG is optimizable, that doesn't necessarily mean an index will be used. It simply allows the Query Optimizer to make a more accurate estimate of the number of rows that will match a given SARG. More often than not, an inequality SARG will result in a table or clustered index scan. You should try to avoid using inequality SARGs whenever possible.

SARGs and LIKE Clauses

In SQL Server versions prior to SQL Server 2005, the Query Optimizer would estimate the selectivity of a LIKE clause only if the first character in the string was a constant. Every row would have to be examined to determine if it was a match. SQL Server 2008 uses string summary statistics, which were introduced in SQL Server 2005, for estimating the selectivity of LIKE conditions.

String summary statistics provide a statistical summary of substring frequency distribution for character columns. String summary statistics can be created on columns of type `text`, `ntext`, `char`, `varchar`, and `nvarchar`. String summary statistics allow SQL Server to estimate the selectivity of LIKE conditions where the search string may have any number of wildcards in any combination, including when the first character is a wildcard. In versions of SQL Server prior to 2005, row estimates could not be accurately obtained when the leading character of a search string was a wildcard character. SQL Server 2008 can estimate the selectivity of LIKE predicates similar to the following:

- ▶ `au_lname LIKE 'Smith%'`
- ▶ `stor_name LIKE '%Books'`
- ▶ `title LIKE '%Cook%'`
- ▶ `title_id LIKE 'BU[1234567]001'`
- ▶ `title LIKE '%Cook%Chicken'`

The string summary statistics result in fairly accurate row estimates. However, if there is a user-specified escape character in a LIKE pattern (for example, `stor_name LIKE '%abc#_%' ESCAPE '#'`), SQL Server 2008 has to guess at the selectivity of the SARG.

The values generated for string summary statistics are not visible via `DBCC SHOW_STATISTICS`. However, `DBCC SHOW_STATISTICS` does indicate if string summary statistics have been calculated; if the value `YES` is specified in the `String Index` field in the first rowset returned by `DBCC SHOW_STATISTICS`, the statistics also include a string summary. Also, if

the strings are more than 80 characters in length, only the first and last 40 characters are used for creating the string summary statistics. Accurate frequency estimates cannot be determined for substrings that do not appear in the first and last 40 characters of a string.

SARGs on Computed Columns

In versions of SQL Server prior to 2005, for a SARG to be optimizable, there had to be no computations on the column itself in the SARG. In SQL Server 2008, expressions involving computations on a column might be treated as SARGs during optimization if SQL Server can simplify the expression into a SARG. For example, the SARG

```
ytd_sales/12 = 1000
```

can be simplified to this:

```
ytd_sales = 12000
```

The simplified expression is used only during optimization to determine an estimate of the number of matching rows and the usefulness of the index. During actual execution, the conversion is not done while traversing the index tree because it won't be able to do the repeated division by 12 for each row while searching through the tree. However, doing the conversion during optimization and getting a row estimate from the statistics helps the Query Optimizer decide on other strategies to consider, such as index scanning versus table scanning, or it might help to determine an optimal join order if it's a multi-table query.

SQL Server 2008 supports the creation, update, and use of statistics on computed columns. The Query Optimizer can make use of the computed column statistics even when a query doesn't reference the computed column by name but rather contains an expression that matches the computed column expression. This feature avoids the need to rewrite the SARGs in queries with expressions that match a computed column expression to SARGs that explicitly contain the computed column itself.

When the SARG has a more complex operation performed on it, such as a function, it can potentially prevent effective optimization of the SARG. If you cannot avoid using a function or complex expression on a column in the search expression, you should consider creating a computed column on the table and creating an index on the computed column. This materializes the function result into an additional column on the table that can be indexed for faster searching, and the index statistics can be used to better estimate the number of matching rows for the SARG expression that references the function.

An example of using this approach would be for a query that has to find the number of orders placed in a certain month, regardless of the year. The following is a possible solution:

```
select distinct stor_id
   from sales
  where datepart(month, ord_date) = 6
```

This query gets the correct result set but ends up having to do so with a full table or index scan because the function on the `ord_date` column prevents the Query Optimizer from using an index seek against any index that might exist on the `ord_date` column.

If this query is used frequently in the system and quick response time is critical, you could create a computed column on the function and index it as follows:

```
alter table sales add ord_month as datepart(month, ord_date)
create index nc_sales_ordmonth on sales(ord_month)
```

Now, when you run the query on the table again, if you specify the computed column in the `WHERE` clause, the Query Optimizer can use the index on the computed column to accurately estimate the number of matching rows and possibly use the nonclustered index to find the matching rows and avoid a table scan, as it does for the following query:

```
select distinct stor_id
   from sales
  where ord_month = 6
```

Even if the query still ends up using a table scan, it at least has statistics available to know how many rows it can expect to match where the month matches the value specified. In addition, if a computed column exists that exactly matches the SARG expression, SQL Server 2008 can still use the statistics and index on the computed column to optimize the query, even if the computed column is not specified in the query itself. For example, with the `ord_month` column defined on the `sales` table and an index created on it, the following query can also use the statistics and index to optimize the query:

```
select distinct stor_id
   from sales
  where datepart(month, ord_date) = 6
```

TIP

The automatic matching of computed columns in SQL Server 2008 enables you to create and exploit computed columns without having to change the queries in your application. Be aware, though, that computed column matching is based on identical comparison. For example, a computed column of the form $A + B + C$ does not match an expression of the form $A + C + B$.

Estimating Access Path Cost

After the selectivity of each of the SARGs, `OR` clauses, and join clauses is determined, the next phase of optimization is estimating the access path cost of the query. The Query Optimizer attempts to identify the total cost of various access paths to the data and determine which path results in the lowest cost to return the matching rows for an expression.

The primary cost of an access path, especially for single-table queries, is the number of logical I/Os required to retrieve the data. Using the available statistics and the information stored in SQL Server regarding the average number of rows per page and the number of pages in the table, the Query Optimizer estimates the number of logical page reads necessary to retrieve the estimated number of rows using a table scan or any of the candidate indexes. It then ranks the candidate indexes to determine which access path would retrieve the matching data rows with the lowest cost, typically the access path that requires the fewest number of logical and physical I/Os.

NOTE

A logical I/O occurs every time a page is accessed. If the page is not in cache, a physical I/O is first performed to bring the page into cache memory, and then a logical I/O is performed against the page. The Query Optimizer has no way of knowing whether a page will be in memory when the query actually is executed, so it always assumes a cold cache, that the first read of a page will be from disk. In a very few cases (for example, small OLTP queries), this assumption may result in a slightly slower plan being chosen that optimizes for the number of initial I/Os required to process the query. However, the cold cache assumption is a minor factor in the query plan costing, and it's actually the total number of logical I/Os that is the primary factor in determining the cost of the access path.

TIP

The following sections assume a general understanding of SQL Server index structures. If you haven't done so already, now is a good time to read through Chapter 34.

Clustered Index Cost

Clustered indexes are efficient for lookups because the rows that match the SARGs are clustered on the same page or over a range of adjacent pages. SQL Server needs only to find its way to the first page and then read the rows from that page and any subsequent pages in the page chain until no more matching rows are found.

Therefore, the I/O cost estimate for a clustered index is calculated as follows:

- Number of index levels in the clustered index
- + Number of pages to scan within the range of values

The number of pages to scan is based on the estimated number of matching rows divided by the number of rows per page. For example, if SQL Server can store 250 rows per page for a table, and 600 rows are within the range of values being searched, SQL Server would estimate that it requires at least three page reads to find the qualifying rows. If the index is three levels deep, the logical I/O cost would be as follows:

- 3 (index levels to find the first row)
- + 3 (data pages: 600 rows divided by 250 rows per page)
- = 6 logical page I/Os

For a unique clustered index and an equality operator, the logical I/O cost estimate is one data page plus the number of index levels that need to be traversed to access the data page.

When a clustered index is used to retrieve the data rows, you see a query plan similar to the one shown in Figure 35.1.

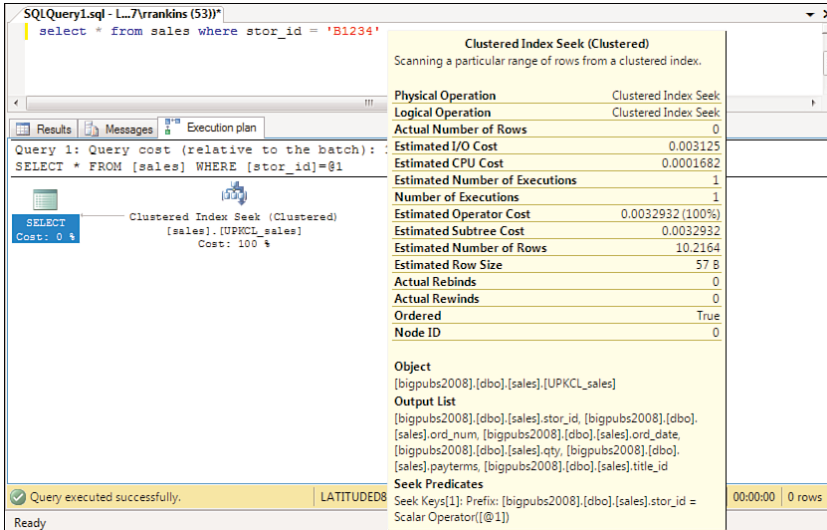

FIGURE 35.1 An execution plan for a clustered index seek.

Nonclustered Index Cost

When searching for values using a nonclustered index, SQL Server reads the index key values at the leaf level of the index and uses the bookmark to locate and read the data row. SQL Server has no way of knowing if matching search values will be on the same data page until it has read the bookmark. It is possible that while retrieving the rows, SQL Server might find all data rows on different data pages, or it might revisit the same data page multiple times. Either way, a separate logical I/O is required each time it visits the data page.

The I/O cost is therefore based on the depth of the index tree, the number of index leaf rows that need to be scanned to find the matching key values, and the number of matching rows. The cost of retrieving each matching row depends on whether the table is clustered or is a heap table (that is, a table with no clustered index defined on it). For a heap table, the nonclustered row bookmark is the page and row pointer (the row ID [RID]) to the actual data row. A single I/O is required to retrieve the data row. Therefore, the worst-case logical I/O cost for a heap table can be estimated as follows:

- Number of nonclustered index levels
- + Number of leaf pages to be scanned
- + Number of qualifying rows (each row represents a separate data page read)

NOTE

This estimate assumes that the data rows have not been forwarded. In a heap table, when a row has been forwarded, the original row location contains a pointer to the new location of the data row; therefore, an additional page read is required to retrieve the actual data row. The actual I/O cost would be one page greater per row than the estimated I/O cost for any rows that have been forwarded.

When a nonclustered index is used to retrieve the data rows from a heap table with a clustered index, you see a query plan similar to the one shown in Figure 35.2. Notice that in SQL Server 2008, the bookmark lookup operator is replaced by a RID lookup, essentially as a join with the RIDs returned by the nonclustered index seek.

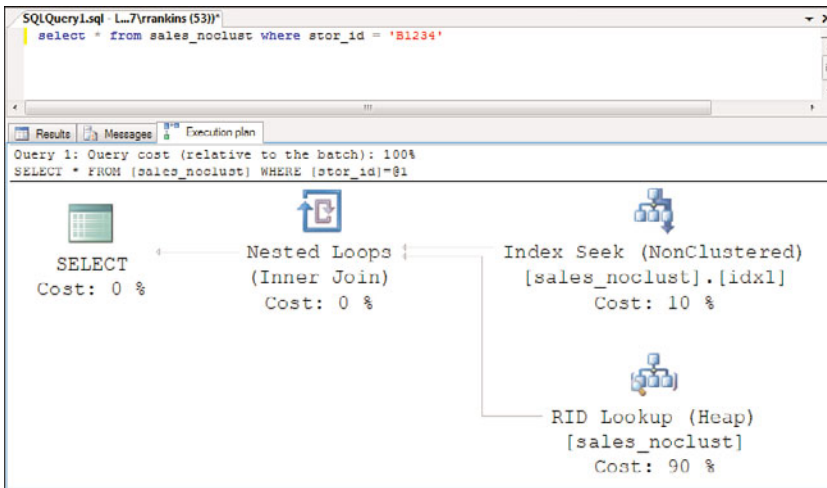

FIGURE 35.2 An execution plan for a nonclustered index seek against a heap table.

If the table is clustered, the row bookmark is the clustered key for the data row. The number of I/Os to retrieve the data row depends on the depth of the clustered index tree because SQL Server has to use the clustered index to find each row. The logical I/O cost of finding a row using the nonclustered index on a clustered table is therefore as follows:

- Number of nonclustered index levels
- + Number of leaf pages to be scanned
- + Number of qualifying rows × Number of page reads to find a single row via the clustered index

For example, consider a heap table with a nonclustered index on last name. Assume that the index holds 800 rows per page (they're really big last names!), and 1,700 names are within the range you are looking for. If the index is three levels deep, the estimated logical I/O cost for the nonclustered index would be as follows:

```

3          (index levels)
+ 3        (leaf pages: 1,700 leaf rows/800 rows per page)
+ 1,700    (data page reads)
= 1,706    total logical I/Os

```

Now, assume that the table has a clustered index on it, and the size of the nonclustered index is the same. If the clustered index is three levels deep, including the data page, the estimated logical I/O cost of using the nonclustered index would be as follows:

```

3          (nonclustered index levels)
+ 3        (leaf pages: 1,700 leaf rows/800 rows per page)
+ 5,100    (1,700 rows × 3 clustered page reads per row)
= 5,106    (total logical I/Os)

```

NOTE

Although the I/O cost is greater for bookmark lookups in a nonclustered index when a clustered index exists on the table, the cost savings during row inserts, updates, and deletes using the clustered index as the bookmark are substantial, whereas the couple extra logical I/Os per row during retrieval do not substantially impact query performance.

For a unique nonclustered index using an equality operator, the I/O cost is estimated as the number of index levels traversed to access the bookmark plus the number of I/Os required to access the data page via the bookmark.

When a nonclustered index is used to retrieve the data rows on a table with a clustered index, you see a query plan similar to the one shown in Figure 35.3. Notice that in SQL Server 2008, the bookmark lookup operator is replaced by a clustered index seek, essentially

as a join between the clustered index and the clustered index keys returned by the nonclustered index seek.

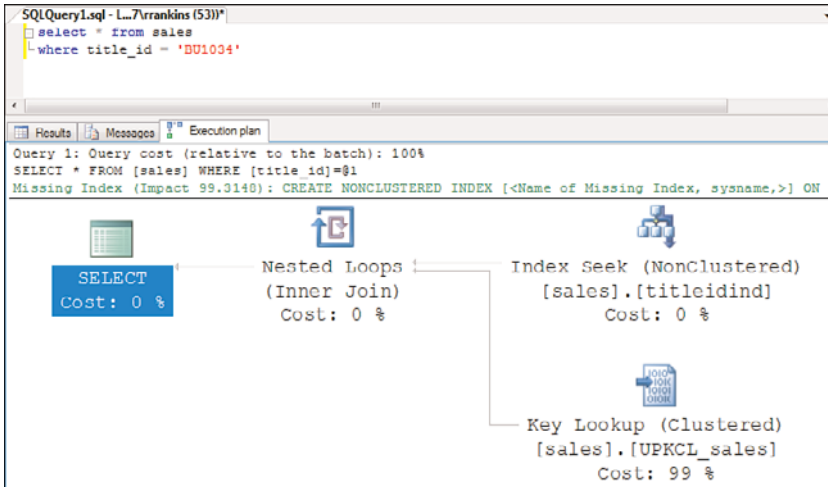

FIGURE 35.3 An execution plan for a nonclustered index seek against a table with a clustered index.

Covering Nonclustered Index Cost

When analyzing a query, the Query Optimizer considers any possibility to take advantage of index covering. *Index covering* is a method of using the leaf level of a nonclustered index to resolve a query when all the columns referenced in the query (in both the column list and WHERE clause, as well as any GROUP BY columns) are included in the index leaf row as either index key columns or included columns.

Index covering can save a significant amount of I/O because the query doesn't have to access the data page to return the requested information. In most cases, a nonclustered index that covers a query is faster than a similarly defined clustered index on the table because of the greater number of rows per page in the index leaf level compared to the number of rows per page in the table itself. (As the nonclustered leaf row size approaches the data row size, the I/O cost savings are minimal, if any.)

If index covering can take place in a query, the Query Optimizer considers it and estimates the I/O cost of using the nonclustered index to cover the query. The estimated I/O cost of index covering is as follows:

- Number of index levels
- + Number of leaf level index pages to scan

The number of leaf-level pages to scan is based on the estimated number of matching rows divided by the number of leaf index rows per page. For example, if index covering could be used on the nonclustered index on `title_id` for the query in the previous example, the I/O cost would be the following:

```

3      (nonclustered index levels)
+ 3    (leaf pages: 1,700 leaf rows/800 rows per page)
= 6    total logical I/Os

```

NOTE

For more information on index covering and when it can take place, as well as the included columns feature introduced in SQL Server 2008, see Chapter 34.

When index covering is used to retrieve the data rows, you might see a query plan similar to the one shown in Figure 35.4. If the entire leaf level of the index is searched, it displays as an index scan, as shown in this example.

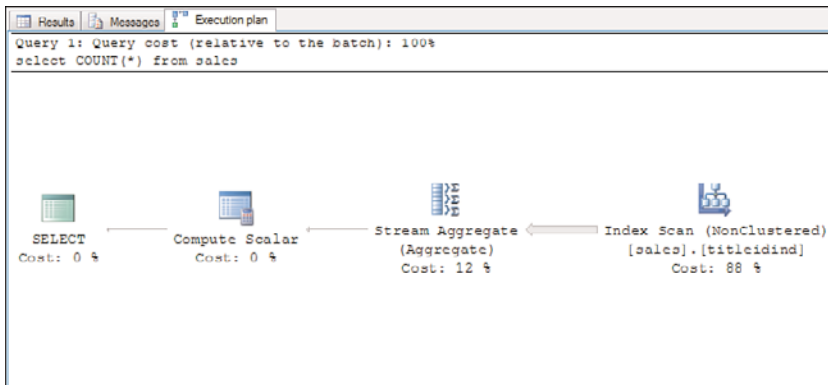

FIGURE 35.4 An execution plan for a covered index scan without limits on the search.

Other times, if the index keys can be searched to limit the range, you might see an index seek used, as shown in Figure 35.5. Note that the difference here from a normal index lookup is the lack of the RID or clustered index lookup because SQL Server does not need to go to the data row to find the needed information.

Table Scan Cost

If no usable index exists that can be matched with a SARG or a join clause, the Query Optimizer's only option is to perform a table scan. The estimate of the total I/O cost is simply the number of pages in the table, which is stored in the system catalogs and can be viewed by querying the `used_page_count` column of the `sys.dm_db_partition_stats` dynamic management view (DMV):

```

select used_page_count
  from sys.dm_db_partition_stats
  where object_id = object_id('sales_noclust')
         and (index_id = 0      -- data pages for heap table
              or index_id = 1) -- data pages for clustered table
go

used_page_count
-----
1244

```

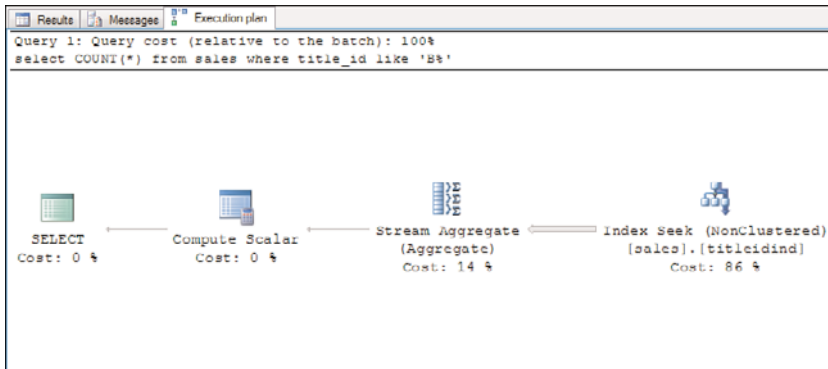

FIGURE 35.5 An execution plan for a covered index seek with limits on the search.

Keep in mind that there are instances (for example, large range retrievals on a nonclustered index column) in which a table scan might be cheaper than a candidate index in terms of total logical I/O. For example, in the previous nonclustered index example, if the index does not cover the query, it costs between 1,706 and 5,106 logical I/Os to retrieve the matching rows using the nonclustered index, depending on whether a clustered index exists on the table. If the total number of pages in the table is less than either of these values, a table scan would be more efficient in terms of total logical I/Os than using a nonclustered index.

When a table scan is used to retrieve the data rows from a heap table, you see a query plan similar to the one shown in Figure 35.6.

When a table scan is used to retrieve the data rows from a clustered table, you see a query plan similar to the one shown in Figure 35.7. Notice that it displays as a clustered index scan because the table is the leaf level of the clustered index.

Using Multiple Indexes

SQL Server allows the creation of multiple indexes on a table. If a query has multiple SARGs that can each be efficiently searched using an available index, the Query Optimizer in SQL Server can make use of multiple indexes by intersecting the indexes or using the index union strategy.

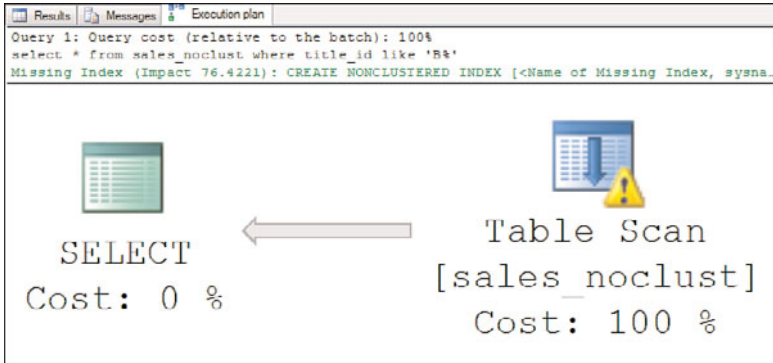

FIGURE 35.6 A table scan on a heap table.

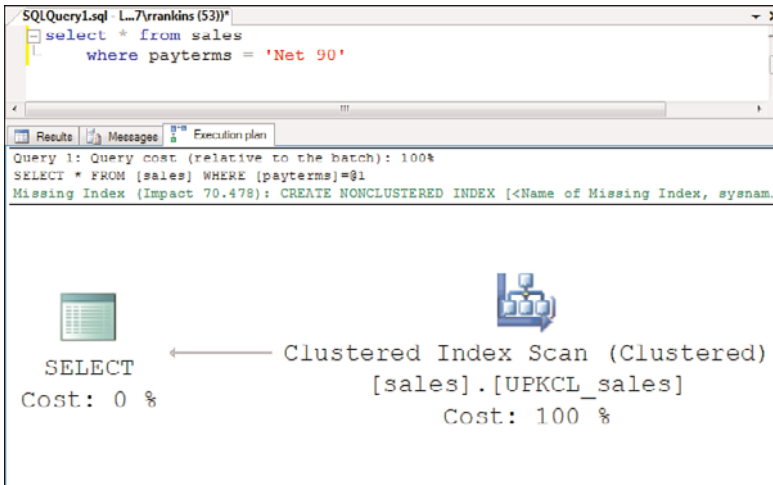

FIGURE 35.7 A table scan on a clustered table.

Index Intersection

Index intersection is a mechanism that allows SQL Server to use multiple indexes on a table when you have two or more SARGs in a query and each can be efficiently satisfied using an index as the access path. Consider the following example:

```
--First, create 2 additional indexes on sales to support the query
create index ord_date_idx on sales(ord_date)
create index qty_idx on sales(qty)
go
select * from sales
```

```
where qty = 816
and ord_date = '1/2/2008'
```

In this example, two additional nonclustered indexes are created on the `sales` table: one on the `qty` column and one on the `ord_date` column. In this example, the Query Optimizer considers the option of searching the index leaf rows of each index to find the rows that meet each of the search conditions and joining on the matching bookmarks (either the clustered index key or RIDs if it's a heap table) for each result set. It then performs a merge join on the bookmarks and uses the output from that to retrieve the actual data rows for all the bookmarks that are in both result sets.

The index intersection strategy is applied only when the cost of retrieving the bookmarks for both indexes and then retrieving the data rows is less than that of retrieving the qualifying data rows using only one of the indexes or using a table scan.

You can go through the same analysis as the Query Optimizer to determine whether an index intersection makes sense. For example, the `sales` table has a clustered index on `stor_id`, `ord_num`, and `title_id`, and this clustered index is the bookmark used to retrieve the data rows for the matching data rows found via the nonclustered indexes. Assume the following statistics:

- ▶ There are 1,200 rows estimated to match where `qty = 816`.
- ▶ There are approximately 215 index rows per leaf page for the index on `qty`.
- ▶ There are 212 rows estimated to match where `ord_date = '1/2/2008'`.
- ▶ There are approximately 185 index rows per leaf page for the index on `ord_date`.
- ▶ The Query Optimizer estimates that the overlap between the two result sets is 1 row.
- ▶ The number of levels in the index on `qty` is 3.
- ▶ The number of levels in the index on `ord_date` is 3.
- ▶ The number of levels in the clustered index on the `sales` table is 3.
- ▶ The `sales` table is 1,252 pages in size.

Using this information, you can calculate the I/O cost for the different strategies the Query Optimizer can consider.

A table scan would cost 1,252 pages.

A standard data row retrieval via the nonclustered index on `qty` would have the following approximate cost:

2	index page reads (root and intermediate pages to locate first leaf page)
+ 6	leaf page reads (1200 rows / 215 rows per page)
+ 3600	(1,200 rows × 3 pages per bookmark lookup via the clustered index)
= 3,608	pages

A standard data row retrieval via the nonclustered index on `ord_date` would have the following approximate cost:

```

2          nonclustered index page reads (root and intermediate pages)
+ 2          nonclustered leaf page reads (212 rows / 185 rows per page)
+ 636       (212 rows × 3 pages per bookmark lookup via clustered index)
= 640       pages

```

The index intersection is estimated to have the following cost:

```

8          pages (1 root page + 1 intermediate page + the 6 leaf pages to find all the bookmarks
              for the 1,200 matching index rows on qty)
+ 4          pages (1 root page + 1 intermediate page + 2 leaf pages to find all the bookmarks for
              the 212 matching index rows on ord_date)
+ 3          page reads to find the 1 estimated overlapping row between the two indexes using the
              clustered index
= 15        pages

```

As you can see from these examples, the index intersection strategy is definitely the cheapest approach. If at any point the estimated intersection cost reaches 640 pages, SQL Server just uses the single index on `ord_date` and checks both search criteria against the 212 matching rows for `ord_date`. If the estimated cost of using an index in any way ever exceeds 1,252 pages, a table scan is likely to be performed, with the criteria checked against all rows.

When an index intersection is used to retrieve the data rows from a table with a clustered index, you see a query plan similar to the one shown in Figure 35.8.

If the table does not have a clustered index (that is, a heap table like the `sales_noclust` table in the `bigpubs2008` database) and has supporting nonclustered indexes for an index intersection, you see a query plan similar to the one shown in Figure 35.9.

Notice that in the example shown in Figure 35.9, the Query Optimizer performs a hash join rather than a merge join on the RIDs returned by each nonclustered index seek and uses the results from the hash join to perform an RID lookup to retrieve the matching data rows.

NOTE

To duplicate the query plan shown in Figure 35.9, you need to create the following two additional indexes on the `sales_noclust` table:

```

create index ord_date_idx on sales_noclust(ord_date)
create index qty_idx on sales_noclust(qty)

```

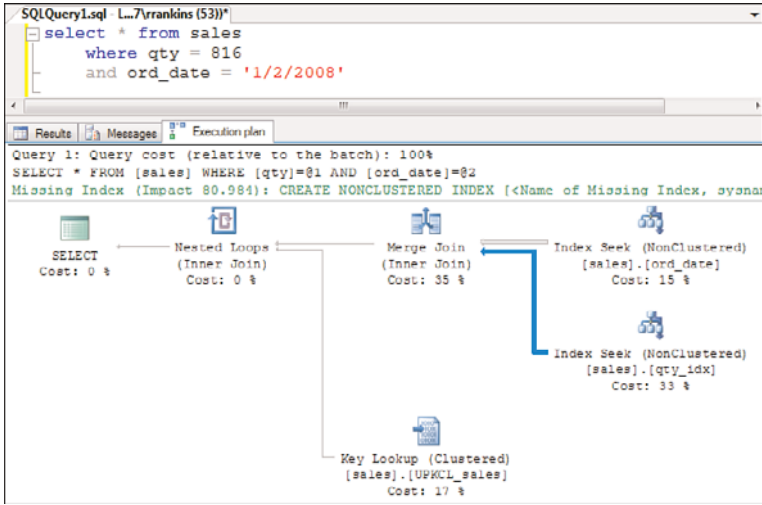

FIGURE 35.8 An execution plan for an index intersection on a clustered table.

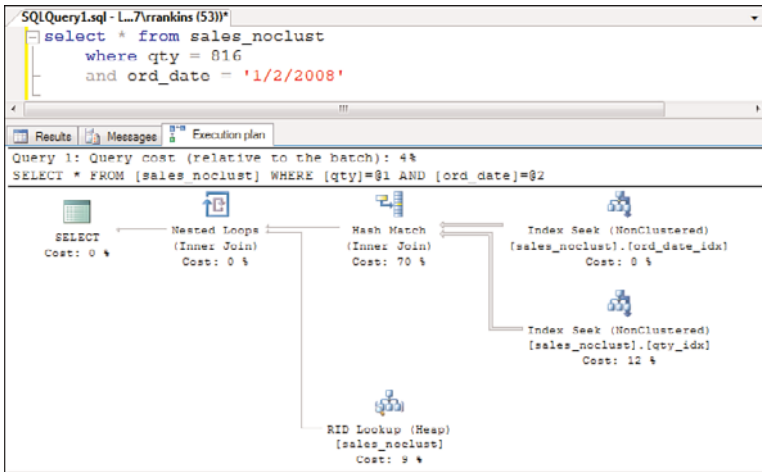

FIGURE 35.9 An execution plan for an index intersection on a heap table.

The Index Union Strategy

You see a strategy similar to an index intersection applied when you have an OR condition between your SARGs, as in the following query:

```
select * from sales
  where title_id = 'DR8514'
     or ord_date = '2006-01-01 00:00:00.000'
```

The index union strategy (often referred to as the OR strategy) is similar to an index intersection, with one slight difference. With the index union strategy, SQL Server executes

each part separately, using the index that matches the SARG, but after combining the results with a merge join, it removes any duplicate bookmarks for rows that match both search arguments. It then uses the unique bookmarks to retrieve the result rows from the base table.

When the index union strategy is used on a table with a clustered index, you see a query plan similar to the one shown in Figure 35.10. Notice the addition of the stream aggregation step, which differentiates it from the index intersection query plan. The stream aggregation step performs a grouping on the bookmarks returned by the merge join to eliminate the duplicate bookmarks.

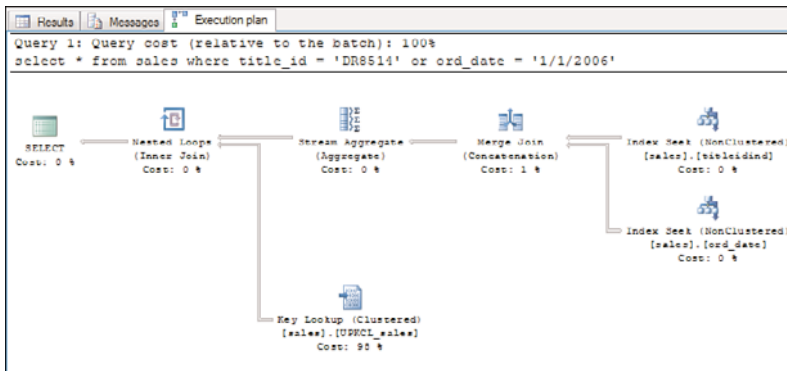

FIGURE 35.10 An execution plan for an index union strategy on a clustered table.

The following steps describe how SQL Server determines whether to use the index union strategy:

1. Estimate the cost of a table scan and the cost of using the index union strategy. If the cost of the index union strategy exceeds the cost of a table scan, stop here and simply perform a table scan. Otherwise, continue with the succeeding steps to perform the index union strategy.
2. Break the query into multiple parts, as in this example:

```
select * from sales where title_id = 'DR8514'
      select * from sales where ord_date = '2006-01-01 00:00:00.000'
```
3. Match each part with an available index.
4. Execute each piece and perform a join on the row bookmarks.
5. Remove any duplicate bookmarks.
6. Use the resulting list of unique bookmarks to retrieve all qualifying rows from the base table.

If any one of the OR clauses needs to be resolved via a table scan for any reason, SQL Server simply uses a table scan to resolve the whole query rather than applying the index union strategy.

When the index union strategy is used on a heap table (such as the `sales_noclust` table), you see a query plan similar to the one shown in Figure 35.11. Notice that the merge join is replaced with a concatenation operation, and the stream aggregate is replaced with distinct sort operation. Although the steps are slightly different from the index intersection strategy, the result is similar: a list of unique RIDs is returned, and they are used to retrieve the matching data rows in the table itself.

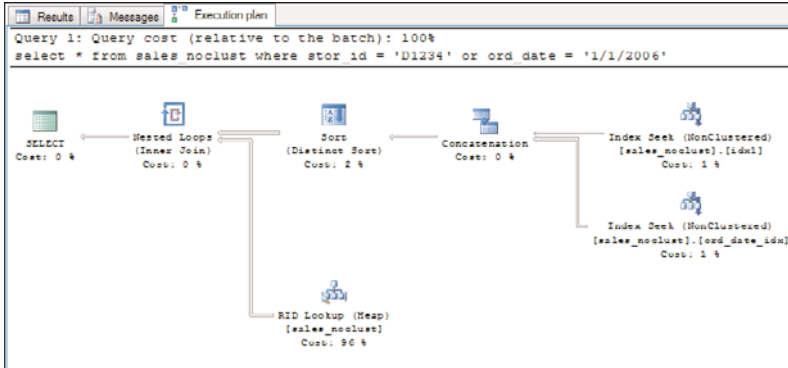

FIGURE 35.11 An execution plan for an index union strategy on a heap table.

When the `OR` in the query involves only a single column and a nonclustered index exists on the column, the Query Optimizer in SQL Server 2008 typically resolves the query with an index seek against the nonclustered index and then a bookmark lookup to retrieve the data rows. Consider the following query:

```
select * from sales
  where ord_date in ('6/15/2005', '9/28/2008', '6/25/2008')
```

This query is the same as the following:

```
select * from sales
  where ord_date = '6/15/2005'
     or ord_date = '9/28/2008'
     or ord_date = '6/25/2008'
```

To process this query, SQL Server performs a single index seek that looks for each of the search values and then joins the list of bookmarks returned with either the clustered index or the RIDs of the target table. No removal of duplicates is necessary because each `OR` condition matches a distinct set of rows. Figure 35.12 shows an example of the query plan for multiple `OR` conditions against a single column.

Index Joins

Besides using the index intersection and index union strategies, another way of using multiple indexes on a single table is to join two or more indexes to create a covering index. This is similar to an index intersection, except that the final bookmark lookup is not required because the merged index rows contain all the necessary information. Consider the following example:

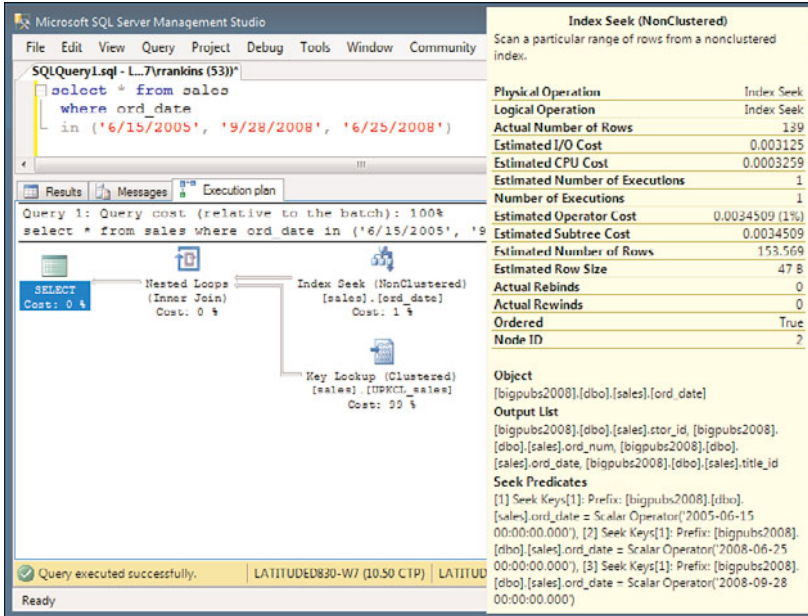

FIGURE 35.12 An execution plan using index seek to retrieve rows for an **OR** condition on a single column.

```

select stor_id from sales
where qty = 816
and ord_date = '1/2/2008'
    
```

Again, the sales table contains indexes on both the qty and ord_date columns. Each of these indexes contains the clustered index as a bookmark, and the clustered index contains the stor_id column. In this instance, when the Query Optimizer merges the two indexes using a merge join, joining them on the matching clustered indexes, the index rows in the merge set have all the information needed to resolve the query because stor_id is part of the nonclustered indexes. There is no need to perform a bookmark lookup on the data page. By joining the two index result sets, SQL Server creates the same effect as having one covering index on qty, ord_date, and stor_id on the table. If you use the same numbers as in the “Index Intersection” section presented earlier, the cost of the index join would be as follows:

- 8 pages (1 root page + 1 intermediate page + the 6 leaf pages to find all the bookmarks for the 1,200 matching index rows on qty)
- + 4 pages (1 root page + 1 intermediate page + 2 leaf pages to find all the bookmarks for the 212 matching index rows on ord_date)
- = 12 pages

Figure 35.13 shows an example of the execution plan for an index join. Notice that it does not include the bookmark lookup present in the index intersection execution plan (refer to Figure 35.8).

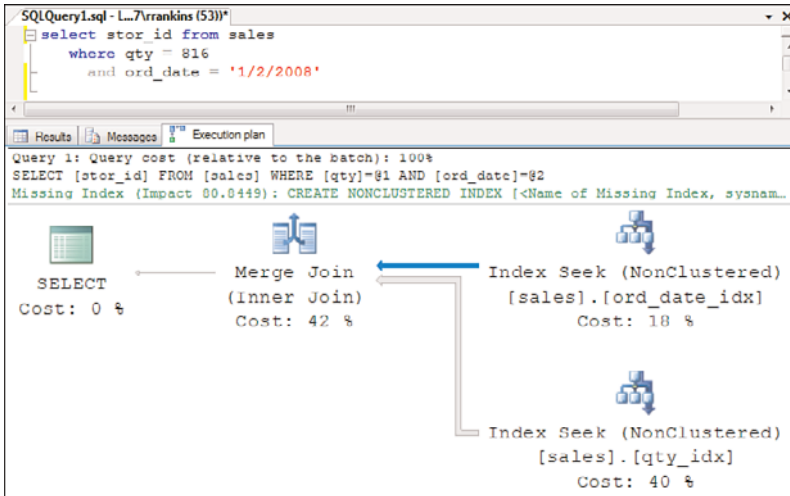

FIGURE 35.13 An execution plan for an index join.

Optimizing with Indexed Views

In SQL Server 2008, when you create a unique clustered index on a view, the result set for the view is materialized and stored in the database with the same structure as a table that has a clustered index. Changes made to the data in the underlying tables of the view are automatically reflected in the view the same way as changes to a table are reflected in its indexes. In the Developer and Enterprise Editions of SQL Server 2008, the Query Optimizer automatically considers using the index on the view to speed up access for queries run directly against the view. The Query Optimizer in the Developer and Enterprise Editions of SQL Server 2008 also looks at and considers using the indexed view for searches against the underlying base table, when appropriate.

NOTE

Although indexed views can be created in any edition of SQL Server 2008, they are considered for query optimization only in the Developer and Enterprise Editions of SQL Server 2008. In other editions of SQL Server 2008, indexed views are not used to optimize the query unless the view is explicitly referenced in the query and the `NOEXPAND` Query Optimizer hint is specified. For example, to force the Query Optimizer to consider using the `sales_Qty_Rollup` indexed view in the Standard Edition of SQL Server 2008, you execute the query as follows:

```
select * from sales_Qty_Rollup WITH (NOEXPAND)
    where stor_id between 'B914' and 'B999'
```

The NOEXPAND hint is allowed only in SELECT statements, and the indexed view must be referenced directly in the query. (Only the Developer and Enterprise Editions consider using an indexed view that is not directly referenced in the query.) As always, you should use Query Optimizer hints with care. When the NOEXPAND hint is included in the query, the Query Optimizer cannot consider other alternatives for optimizing the query.

Consider the following example, which creates an indexed view on the sales table, containing stor_id and sum(qty) grouped by stor_id:

```
set quoted_identifier on
go

if object_id('sales_Qty_Rollup') is not null
    drop view sales_Qty_Rollup
go
create view sales_qty_rollup
with schemabinding
as
    select stor_id, sum(qty) as total_qty, count_big(*) as id
    from dbo.sales
    group by stor_id
go

create unique clustered index idx1 on sales_Qty_Rollup (stor_id)
go
```

The creation of the clustered index on the view essentially creates a clustered table in the database with the three columns stor_id, total_qty, and id. As you would expect, the following query on the view itself uses a clustered index seek on the view to retrieve the result rows from the view instead of having to scan or search the sales table itself:

```
select * from sales_Qty_Rollup
    where stor_id between 'B914' and 'B999'
```

However, the following query on the sales table uses the indexed view sales_qty_rollup to retrieve the result set as well:

```
select stor_id, sum(qty)
    from sales
    where stor_id between 'B914' and 'B999'
    group by stor_id
```

Essentially, the Query Optimizer recognizes the indexed view essentially as another index on the sales table that covers the query. The execution plan in Figure 35.14 shows the indexed view being searched in place of the table.

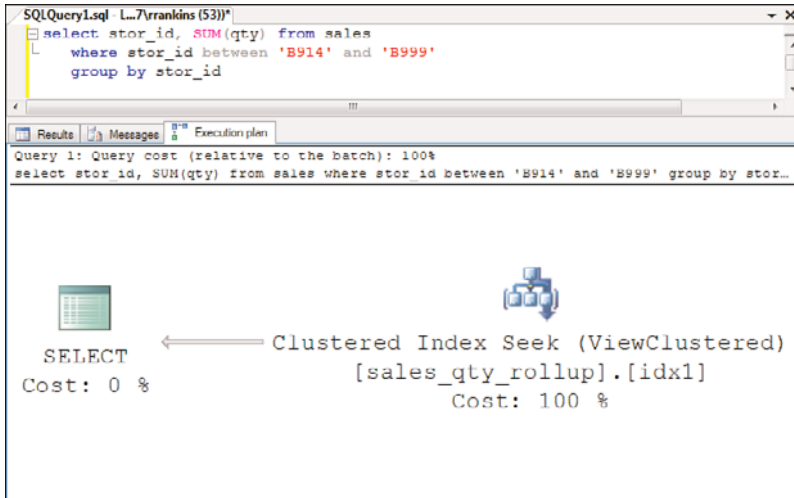

FIGURE 35.14 An execution plan showing an indexed view being searched to satisfy a query on a base table.

NOTE

In addition to the seven required SET options that need to be set appropriately when the indexed view is created, they must also be set the same way for a session to be able to use the indexed view in queries. The required SET option settings are as follows:

```
SET ARITHABORT ON
SET CONCAT_NULL_YIELDS_NULL ON
SET QUOTED_IDENTIFIER ON
SET ANSI_NULLS ON
SET ANSI_PADDING ON
SET ANSI_WARNINGS ON
SET NUMERIC_ROUNDABORT OFF
```

If these SET options are not set appropriately for the session running a query that could make use of an indexed view, the indexed view is not used, and the table is searched instead.

For more information on indexed views, see Chapters 27, “Creating and Managing Views,” and 34, “Data Structures, Indexes, and Performance.”

You might find rare situations when using the indexed view in the Enterprise, Datacenter, or Developer Editions of SQL Server 2008 leads to poor query performance, and you might want to avoid having the Query Optimizer use the indexed view. To force the Query Optimizer to ignore the indexed view(s) and optimize the query using the indexes on the underlying base tables, you specify the `EXPAND VIEWS` query option, as follows:

```
select * from sales_Qty_Rollup
    where stor_id between 'B914' and 'B999'
    OPTION (EXPAND VIEWS)
```

Optimizing with Filtered Indexes

SQL Server 2008 introduces the capability to define filtered indexes and statistics on a subset of rows rather than on the entire rowset in a table. This is done by specifying simple predicates in the `index create` statement to restrict the set of rows included in the index. Filtered statistics help solve a common problem in estimating the number of matching rows when the estimates become skewed due to a large number of duplicate values (or NULLS) in an index or due to data correlation between columns. Filtered indexes provide query optimization benefits when you frequently query specific subsets of your data rows.

If a filtered index exists on a table, the optimizer recognizes when a search predicate is compatible with the filtered index; it considers using the filtered index to optimize the query if the selectivity is good.

For example, the `titles` table in the `bigpubs2008` database contains a large percentage of rows where `ytd_sales` is 0. A nonclustered index typically doesn't help for searches in which `ytd_sales` is 0 because the selectivity isn't adequate, and a table scan would be performed. An advantageous approach then is to create a filtered index on `ytd_sales` without including the values of 0 to reduce the size of the index and make it more efficient.

For example, first create an unfiltered index on `ytd_sales` on the `titles` table:

```
create index ytd_sales_unfiltered on titles (ytd_sales)
```

Then, execute the following two queries:

```
select * from titles where ytd_sales = 0
select * from titles where ytd_sales = 10
```

As you can see by the query plan displayed in Figure 35.15, a query where `ytd_sales = 0` still uses a table scan instead of the index because the selectivity is poor, whereas it uses the index for `ytd_sales = 10`.

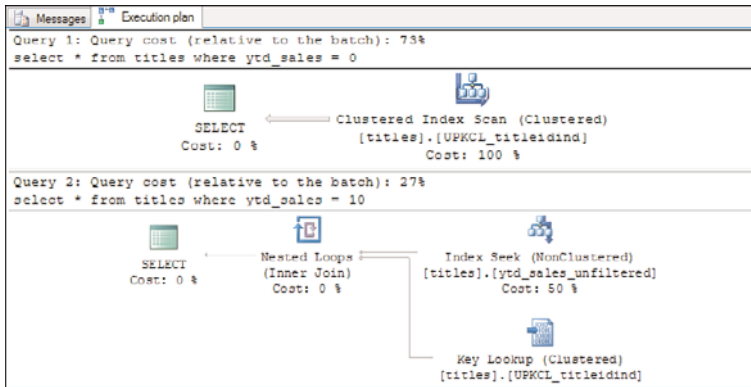

FIGURE 35.15 An execution plan showing index not being used due to poor selectivity.

Now, drop the unfiltered index and re-create a filtered index that excludes values of 0:

```
drop index titles.ytd_sales_unfiltered
go
create index ytd_sales_filtered on titles (ytd_sales)
where ytd_sales <> 0
```

Re-run the queries and examine the query plan again. Figure 35.16 shows that the query where `ytd_sales = 0` still uses a table scan as before, but the query where `ytd_sales = 10` is able to use the filtered index.

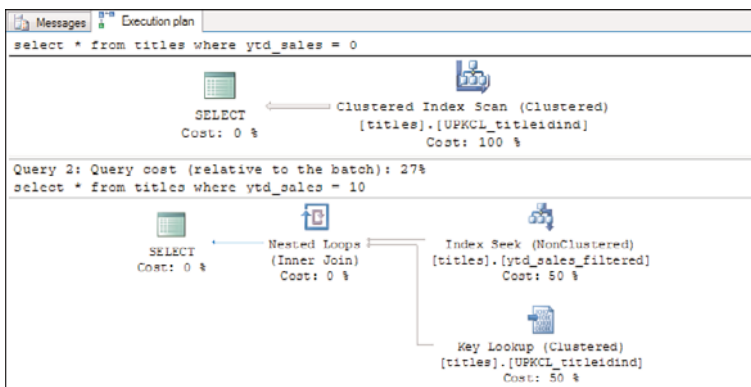

FIGURE 35.16 An execution plan showing the filtered index being used.

In this case, it may be beneficial to define the filtered index instead of a normal index on `ytd_sales` because the filtered index will require less space and be a more efficient index

by excluding all the rows with `ytd_sales` values of 0, especially if the majority of the queries against the table are searching for `ytd_sales` values that are nonzero.

NOTE

For more information on creating and using filtered indexes, see Chapter 34.

Join Selection

The job of the Query Optimizer is incredibly complex. The Query Optimizer can consider literally thousands of options when determining the optimal execution plan. The statistics are simply one of the tools that the Query Optimizer can use to help in the decision-making process.

In addition to examining the statistics to determine the most efficient access paths for SARGs and join clauses, the Query Optimizer must consider the optimum order in which to access the tables, the appropriate join algorithms to use, the appropriate sorting algorithms, and many other details too numerous to list here. The goal of the Query Optimizer during join selection is to determine the most efficient join strategy.

As mentioned at the beginning of this chapter, delving into the detailed specifics of the various join strategies and their costing algorithms is beyond the scope of a single chapter on optimization. In addition, some of these costing algorithms are proprietary and not publicly available. The goal of this section, then, is to present an overview of the most common query processing algorithms that the Query Optimizer uses to determine an efficient execution plan.

Join Processing Strategies

If you are familiar with SQL, you are probably very familiar with using joins between tables in creating SQL queries. A join occurs any time the SQL Server Query Optimizer has to compare two inputs to determine an output. The join can occur between one table and another table, between an index and a table, or between an index and another index (as described previously, in the section “Index Intersection”).

The SQL Server Query Optimizer uses three primary types of join strategies when it must compare two inputs: nested loops joins, merge joins, and hash joins. The Query Optimizer must consider each one of these algorithms to determine the most appropriate and efficient algorithm for a given situation.

Each of the three supported join algorithms could be used for any join operation. The Query Optimizer examines all the possible alternatives, assigns costs to each, and chooses the least expensive join algorithm for a given situation. Merge and hash joins often

greatly improve the query processing performance for very large data tables and data warehouses.

Nested Loops Joins

The nested loops join algorithm is by far the simplest of the three join algorithms. The nested loops join uses one input as the “outer” loop and the other input as the “inner” loop. As you might expect, SQL Server processes the outer input one row at a time. For each row in the outer input, the inner input is searched for matching rows.

Figure 35.17 illustrates a query that uses a nested loops join.

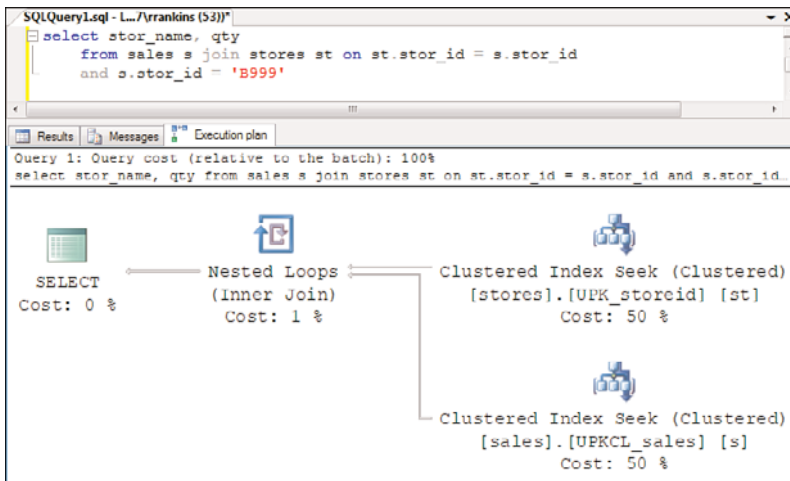

FIGURE 35.17 An execution plan for a nested loops join.

Note that in the graphical execution plan, the outer loop is represented as the top input table, and the inner loop is represented as the bottom input table. In most instances, the Query Optimizer chooses the input table with the fewest number of qualifying rows to be the outer loop to limit the number of iterative lookups against the inner table. However, the Query Optimizer may choose the input table with the greater number of qualifying rows as the outer table if the I/O cost of searching that table first and then performing the iterative loops on the other table is lower than the alternative.

The nested loop join is the easiest join strategy for which to estimate the I/O cost. The cost of the nested loop join is calculated as follows:

$$\begin{aligned}
 & \text{Number of I/Os to read in outer input} \\
 + & \text{Number of matching rows} \times \text{Number of I/Os per lookup on inner input} \\
 = & \text{Total logical I/O cost for query}
 \end{aligned}$$

The Query Optimizer evaluates the I/O costs for the various possible join orders as well as the various possible access paths and indexes available to determine the most efficient

join order. The nested loops join is efficient for queries that typically affect only a small number of rows. As the number of rows in the outer loop increases, the effectiveness of the nested loops join strategy diminishes. The reason is the increased number of logical I/Os required as the number of qualifying rows increases.

Also, if there are no useful indexes on the join columns, the nested loop join is not an efficient join strategy because it requires a table scan lookup on the inner table for each row in the outer table. Lacking useful indexes for the join, the Query Optimizer often opts to perform a merge or hash join.

Merge Joins

The merge join algorithm is much more effective than the nested loops join for dealing with large data volumes or when the lack of limiting SARGs or useful indexes on SARGs leads to a table scan of one or both tables involved in the join. A merge join works by retrieving one row from each input and comparing them, matching on the join column(s). Figure 35.18 illustrates a query that uses a merge join.

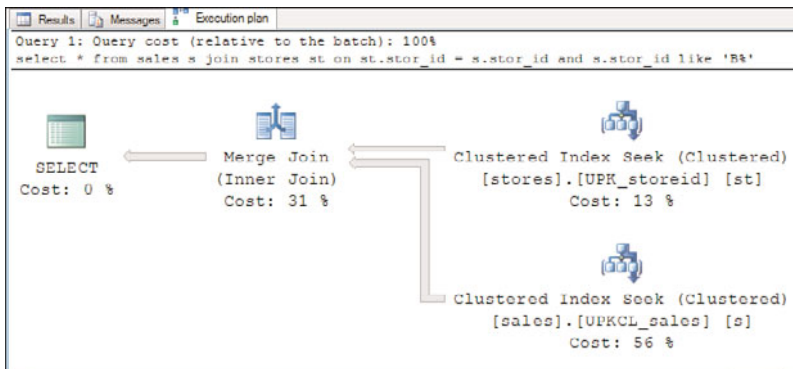

FIGURE 35.18 An execution plan for a merge join.

A merge join requires that both inputs be sorted on the merge columns—that is, the columns specified in the equality (ON) clauses of the join predicate. A merge join does not work if both inputs are not sorted. In the query shown in Figure 35.18, both tables have a clustered index on `stor_id`, so the merge column (`stor_id`) is already sorted for each table. If the merge columns are not already sorted, a separate sort operation may be required before the merge join operation. When the input is sorted, the merge join operation retrieves a row from each input and compares them, returning the rows if they are equal. If the inputs are not equal, the lower-value row is discarded, and another row is obtained from that input. This process repeats until all rows have been processed.

Usually, the Query Optimizer chooses a merge join strategy, as in this example, when the data volume is large and both columns are contained in an existing presorted index, such as a clustered primary key. If either of the inputs is not already sorted, the Query Optimizer has to perform an explicit sort before the join. Figure 35.19 shows an example of a sort being performed before the merge join is performed.

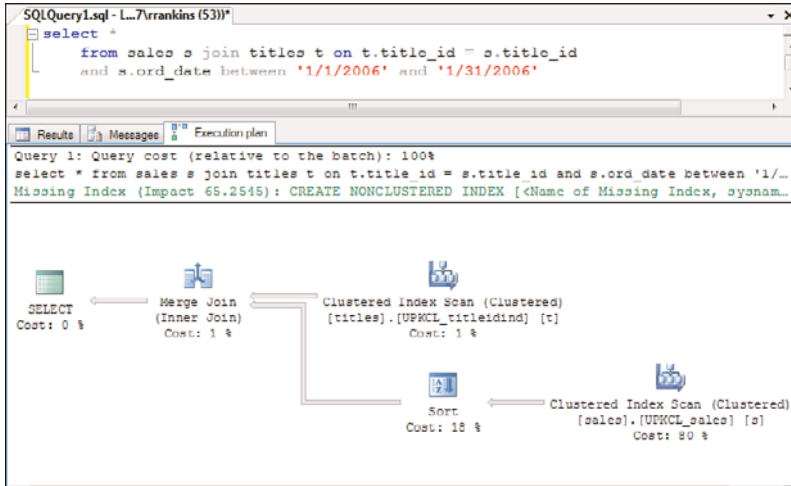

FIGURE 35.19 An execution plan for a merge join with a preliminary sort step.

In the query in Figure 35.19, the `titles` table is already sorted on the primary key on `title_id`, but the rows being returned from the `sales` table are being returned initially in `stor_id` order. (`stor_id` is the leading column in the clustered primary key on `sales`.) The resulting rows matching the search criteria on `ord_date` via the clustered index scan on the `sales` table are then re-sorted by `title_id`, and then the merge join is performed with the rows retrieved from the `titles` table.

If one or more of the inputs to the merge join is not sorted, and the additional sorting causes the merge join to be too expensive to perform, the Query Optimizer may consider using the hash join strategy instead.

Hash Joins

The final—and most complicated—join algorithm is the hash join. The hash join is an effective join strategy for dealing with large data volumes where the inputs might not be sorted and when no useful indexes exist on your tables for performing the join. Figure 35.20 illustrates a query that uses a hash join.

The basic hash join algorithm involves separating the two inputs into a build input and probe input. The Query Optimizer usually attempts to assign the smaller input as the build input. The hash join scans the build input and creates a hash table. Each row from the build input is inserted into the hash table based on a hash key value, which is computed. The probe input is then scanned, one row at a time. A hash key value is computed for each row in the probe, and the hash table is scanned for matches. The hash join is an effective join strategy when dealing with large data volumes and unsorted data inputs.

In a hash join, the keys that are common between the two tables are hashed into a hash bucket, using the same hash function. This bucket usually starts out in memory and then moves to disk, as needed. The type of hashing that occurs depends on the amount of

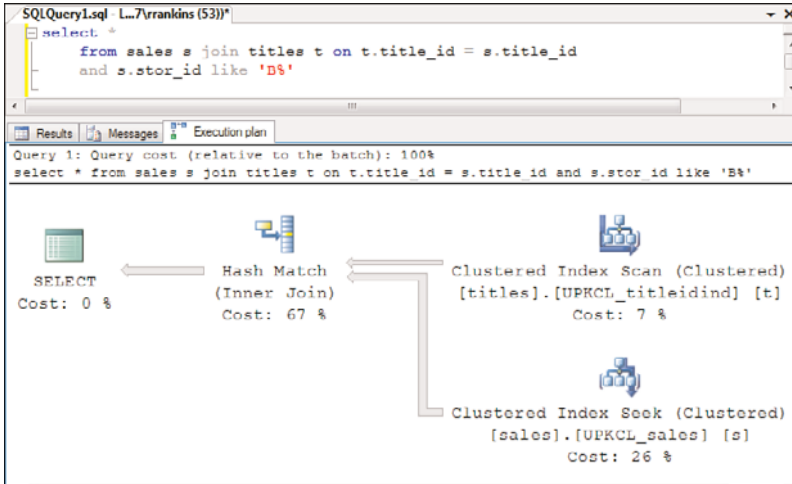

FIGURE 35.20 An execution plan for a hash join.

memory required. Hashing is commonly used for inner and outer joins, intersections, unions, and differences. The Query Optimizer often uses hashing for intermediate processing.

Pseudocode for a simple hash join might look like this:

```
create an empty hash table
for each row in the input table
    read the row
    hash the key value
    insert the hashed key into the hash bucket
for each row in the larger table
    read the row
    hash the key value
    if hashed key value is found in the hash bucket
        output hash key and both row identifiers
drop the hash table
```

Although hashing is useful when no useful indexes are on the tables for a join, the Query Optimizer still might not choose it as the join strategy if it has a high cost in terms of memory required. If the entire hash table doesn't fit in memory, SQL Server has to split both the build and probe inputs into partitions, each containing a different set of hash keys, and write those partitions out to disk. As each partition is needed, it is brought into memory. This increases the amount of I/O and general processing time for the query.

If you want to use the hashing strategy efficiently, it is best if the smaller input is used as the build input. If, during execution, SQL Server discovers that the build input is actually larger than the probe input, it might switch the roles of the build and probe input midstream. The Query Optimizer usually doesn't have a problem determining which input

is smaller if the statistics on the columns involved in the query are current. Column-level statistics can also help the Query Optimizer determine the estimated number of rows matching a SARG, even if no actual index will be used.

Grace Hash Joins If the two inputs are too large to fit into memory for a normal hash join, SQL Server might use a modified method, called the *grace hash join*. This method partitions the smaller input table (also referred to as the *build input*) into a number of buckets. The total number of buckets is calculated by determining the bucket size that will fit in memory and dividing it into the number of rows in the table. The larger table (also referred to as the *probe input*) is then also partitioned into the same number of buckets. Each bucket from each input can then be read into memory and the matches made.

A *hybrid join* is a join method that uses elements of both a simple in-memory hash and grace hash.

NOTE

Hash and merge join strategies can be applied only when the join is an equijoin—that is, when the join condition compares columns from two inputs with the equality (=) operator. If the join is not based on an equality, (for example, using a BETWEEN clause), using nested loop joins is the only strategy that can be employed.

Determining the Optimal Join Order

In addition to determining the best join strategies, the Query Optimizer also evaluates and determines the optimal join order that would result in the most efficient query plan. In the query's execution plan, you might find that the order of the tables in the execution plan is a different order than specified in the query. Regardless of the join strategy used, the Query Optimizer needs to determine which table is the outer input and which is the inner input to the join strategy chosen. For example, consider the following query:

```
select a.au_lname, t.title, pubdate
  from authors a
  join titleauthor ta on a.au_id = ta.au_id
  join titles t on ta.title_id = t.title_id
```

In addition to the possible access paths and join strategies available, the server can consider the following pool of possible join orders:

```
authors → titleauthor → titles
titles → titleauthor → authors
titleauthor → titles → authors
```

```

titleauthor → authors → titles
authors → titles → titleauthor
titles → authors → titleauthor

```

For each of these join orders, the Query Optimizer considers the various access paths available for each table as well as the different join strategies available. For example, the Query Optimizer could consider the following possible join strategies:

- ▶ Perform a table scan on the authors table and for each row perform an index seek against the `auaidind` index on `titleauthor` to find the matching rows by `au_id`. And for each matching row in `titleauthor`, perform an index seek against the primary key of the `titles` table to find the matching rows in `titles` by `title_id`.
- ▶ Perform a table scan on the titles table and for each row perform an index seek against the `titleidind` index on `titleauthor` to find the matching rows by `title_id`. And for each matching row in `titleauthor`, perform an index seek against the primary key of the authors table to find the matching rows in authors by `au_id`.
- ▶ Perform an index scan of the `titleidind` of the `titleauthor` table and use a hash join to match it with a clustered index scan of the `titles` table. And for each of the qualifying rows from this hash join, perform another hash join with an index scan of the `auaidind` index of the authors table.

NOTE

If you run this query yourself and examine the query plan, you'll likely see that the third alternative is the one chosen by the Query Optimizer. Index scans are performed on the `authors` and `titleauthor` tables because the nonclustered indexes on those tables cover the join query. That is, the nonclustered indexes contain all the columns necessary to satisfy the join conditions as well as the requested result columns.

These are just three of the possibilities. There are many more options for the Query Optimizer to consider as execution plans for processing this join. For example, for each of the three options, there are other indexes to consider, and there are other possible join orders and strategies to consider as well.

As you can see, there can be a large number of execution plan options for the Query Optimizer to consider for processing a join, and this example is a relatively simple three-table join. The number of options increases exponentially as the number of tables involved in the query increases. The “Execution Plan Selection” section, later in this chapter, describes how the Query Optimizer deals with the large number of possible execution plan options.

Subquery Processing

SQL Server optimizes subqueries differently, depending on how they are written. For example, SQL Server attempts to flatten some subqueries into joins when possible, to allow the Query Optimizer to select the optimal join order rather than be forced to process the query inside-out. The following sections examine the different types of subqueries and how SQL Server optimizes them.

IN, ANY, and EXISTS Subqueries

In SQL Server, any query that contains a subquery introduced with an IN, = ANY, or EXISTS predicate is usually flattened into an existence join unless the outer query also contains an OR clause or unless the subquery is correlated or contains one or more aggregates.

An existence join is optimized the same way as a regular join, with one exception: With an existence join, as soon as a matching row is found in the inner table, the value TRUE is returned, and SQL Server stops looking for further matches for that row in the outer table and moves on to the next row. A normal join would continue processing to find all matching rows. The following query provides an example of an existence join and a quantified predicate subquery that will be converted to an existence join:

```
select pub_name from publishers p
  where exists (select 1 from titles t
              where type = 'business'
              and t.pub_id = p.pub_id)
```

```
select pub_name from publishers
  where pub_id in (select pub_id from titles
                 where type = 'business')
```

Figure 35.21 shows an example of the execution plan for both of these queries. You can see that the query plans are the same, providing proof that the quantified predicate subquery is being flattened into an existence join.

Materialized Subqueries

If an outer query is comparing a column against the result of a subquery using any of the comparison operators (=, >, <, >=, <=, !=), and the subquery is not correlated, the results of the subquery are often resolved—that is, materialized—before comparison against the outer table column. For these types of queries, the Query Optimizer processes the query inside-out.

An example of this type of query is as follows:

```
select title from titles
  where ytd_sales = (select max(qty) from sales)
```

In this example, the subquery is resolved first to find the maximum qty value from the sales table to compare against ytd_sales in the outer query. Figure 35.22 shows an example of a query plan for this materialized subquery.

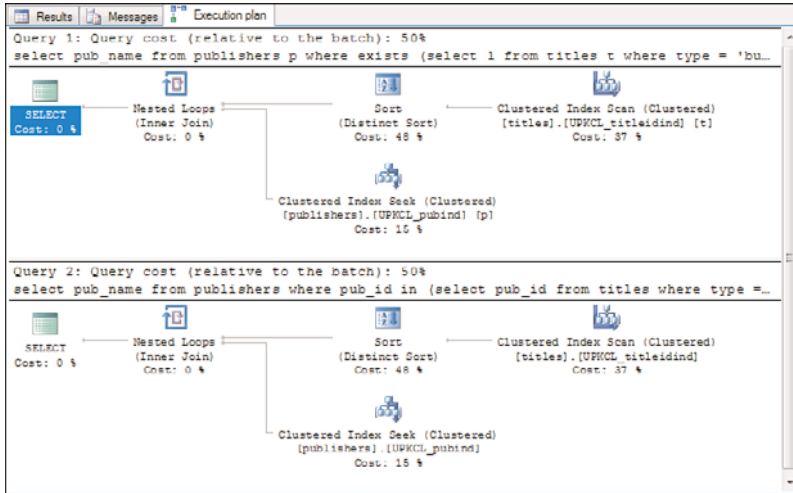

FIGURE 35.21 An execution plan for an existence join and a quantified predicate subquery flattened into an existence join.

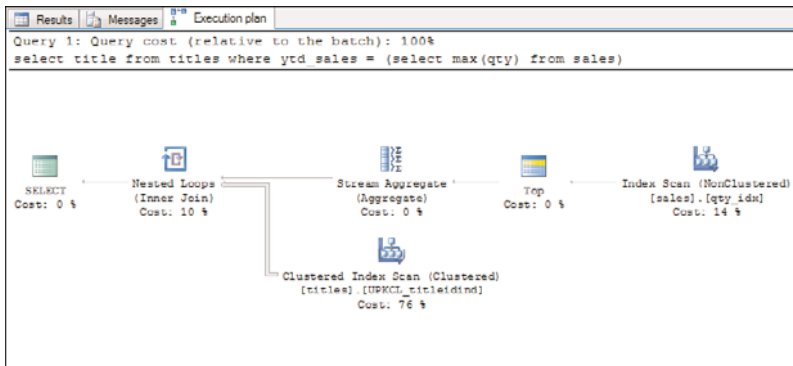

FIGURE 35.22 An execution plan for a materialized subquery.

The following query is an interesting case in which the subquery is not materialized first:

```
select title from titles
  where ytd_sales = (select max(ytd_sales) from titles)
```

In this example, with no index on the `ytd_sales` column, the Query Optimizer recognizes that a table scan is required on the `titles` table to find the maximum `ytd_sales` value. Rather than run the subquery first using a table scan and then use the value returned to perform another lookup against the `titles` table, it simply scans the `titles` table and returns and sorts the `ytd_sales` value in descending order. It then simply returns the rows with the top matching values because these rows are the ones where the `ytd_sales` value

is the maximum. Figure 35.23 shows an example of a query plan for this subquery processing strategy.

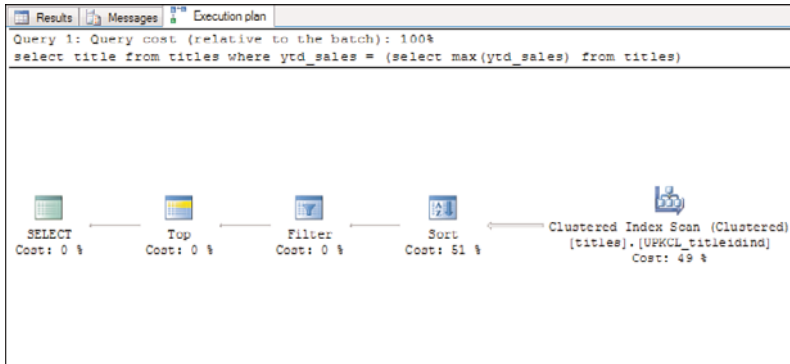

FIGURE 35.23 An execution plan for a subquery flattened into a table scan with sort.

Correlated Subqueries

A correlated subquery contains a reference to an outer table in a join clause in the subquery. Following is an example of a correlated subquery:

```
SELECT title_id, price
FROM titles
WHERE ytd_sales IN
    (SELECT qty
     FROM sales
     WHERE titles.title_id = sales.title_id)
```

Because correlated subqueries depend on values from the outer query for resolution, they cannot be processed independently. Instead, SQL Server usually processes correlated subqueries repeatedly, once for each qualifying outer row. Often, a correlated subquery looks like a nested loop join. A sample execution plan for the preceding correlated subquery example is shown in Figure 35.24. Notice that an inner join using a left semi join is performed. *Semi joins* are joins that return rows from one table based on the existence of related rows in the other table. A *left semi join* operation returns each row from the first (top or left) input when there is a matching row in the second (bottom or right) input. If the attributes are returned from the bottom (or right) table, it's referred to as a *right semi join*.

NOTE

The inverse of a semi join is an anti-semi join. An anti-semi join looks for rows in one table based on their nonexistence in the other, such as for a `NOT IN` or `NOT EXISTS` type subquery, or for some outer join queries.

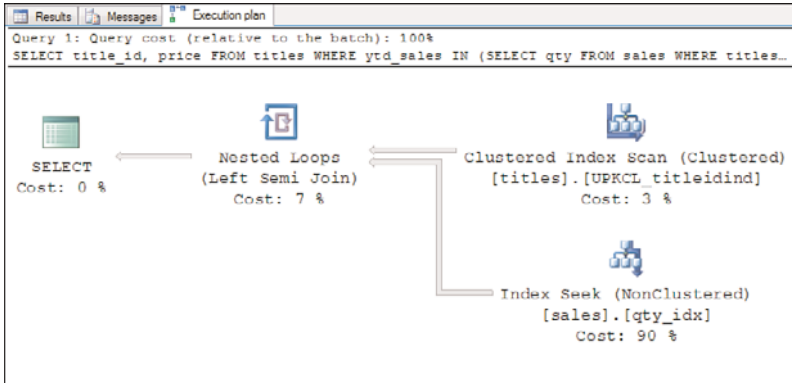

FIGURE 35.24 An execution plan for a correlated subquery.

However, if there is no useful index on the correlated columns to find the matching rows, the Query Optimizer may choose to perform a single search against each table separately and perform a hash join against the results.

Execution Plan Selection

At this point in the query optimization process, the Query Optimizer has examined the entire query and estimated the costs of all possible access paths for the SARGs and join clauses and also the various join orders and query-processing strategies. It now needs to choose which plan to pass on to SQL Server for execution.

For a single table query, choosing the best query plan typically involves choosing the access path and query processing strategy that results in the most efficient execution plan; usually, this is the plan that requires the fewest number of logical I/Os and typically requiring the least resources to process the query on that table. However, sometimes the Query Optimizer may choose a plan that returns rows faster to the user but with a greater, but reasonable, cost in resources (I/O plus CPU and memory). For example, processing a query in parallel (that is, using multiple CPUs simultaneously for the same query) typically requires more resources than processing it via a single CPU, but the query may complete much faster when processed in parallel. The Query Optimizer may choose to use such a parallel plan for execution if the load on the server is not adversely affected.

For a multitable query, choosing the best plan involves not only determining the cheapest access path and query processing strategy for each table individually but also determining the best access paths in conjunction with the optimal join strategy that results in the lowest estimated query cost, as discussed in the earlier section on join selection.

In addition, if any UNION, ORDER BY, GROUP BY, or DISTINCT clauses are present, the Query Optimizer chooses the most efficient method to process them.

For all its options, the overriding factor in selecting a plan is primarily the overall I/O cost. The Query Optimizer usually selects a query plan that results in the least amount of I/O

processing because I/O is often the most expensive aspect of a query. After the plan is selected, it's passed to the Database Engine for execution.

NOTE

As you can see in examples throughout this chapter, you can examine the query plan chosen by the Query Optimizer with the graphical execution plan feature of SSMS. You can also display a text representation of the execution plan by enabling the `SHOWPLAN_TEXT`, `SHOWPLAN_ALL`, `SHOWPLAN_XML`, `STATISTICS PROFILE`, or `STATISTICS XML` option in a user session. How to interpret the output from these tools is covered in Chapter 36, “Query Analysis,” along with a discussion of other tools available for examining the query plan selection process.

You also have the capability to influence or override the query plan selection process, using methods discussed later in this chapter, in the section “Managing the Optimizer.”

The Query Optimizer can choose from many possible execution plans, especially when a large number of tables are involved in the query—and an even greater number of permutations of join strategies and index usage is possible. The number of permutations grows exponentially as the number of tables involved in the query grows. Some complex queries could potentially have millions of possible execution plans. In these cases, the Query Optimizer does not analyze all possible plan combinations. Instead, it tries to find an execution plan that has a cost reasonably close to the theoretical minimum.

Initially, SQL Server tries to determine whether only one viable plan for a query exists. This is called *trivial plan optimization*. For simple queries, this can save the Query Optimizer a lot of work. The idea behind trivial plan optimization is that cost-based optimization can be expensive to initialize and run. The Query Optimizer can try many possible variations in looking for the cheapest plan and the time required to find the optimal query plan could potentially be longer than the time required to execute the query itself. If the Query Optimizer can determine by investigating the query and the relevant metadata that there is only one viable plan for a query, it can avoid a lot of the work required to initialize and perform cost-based optimization.

An example of a trivial query plan is a single table `SELECT` statement with a SARG on a unique key or a `SELECT` on a table with no indexes or `GROUP BY` clause. Another example is an `INSERT` statement using a `VALUES` clause into a table that doesn't participate in indexed views: There is only one way to insert this record. For each of these examples, the query plans are fairly obvious plans that are typically very inexpensive, so the Query Optimizer generates the plan without trying to find something better. If the Query Optimizer tried to consider every possible plan, the optimization cost could actually exceed the query processing time, outweighing any benefit provided by well-optimized queries.

If a trivial plan is not available, the Query Optimizer next performs some query simplifications, usually syntactic transformations of the query itself, such as commutative properties and operations that can be rearranged. An example of simplification is evaluation of simple single-table SARG filters before processing the joins. While the filters are logically

evaluated after the joins, evaluating the filters before the joins still produces the correct result and is more efficient because it removes unqualified rows before the join operation is performed, resulting in fewer iterations and, subsequently, fewer I/Os.

After any attempts at query simplification, the Query Optimizer begins a more thorough optimization process. To avoid just running through all the possibilities that would cause the optimization process to take a long time, it breaks up the optimization into three phases. After each phase, the Query Optimizer applies a set of rules to evaluate the cost of any resulting plan. If, according to these rules, the plan is cheap enough, it chooses and submits that plan for execution. If, according to the rules, no plan is cheap enough, the Query Optimizer continues on to the next phase, with its own set of (usually more complex) rules to apply. In the vast majority of cases, the Query Optimizer finds a viable execution plan in the preliminary phases.

The first phase of optimization, Phase 0, contains a limited set of rules and is applied to queries with at least four tables. As you've seen previously, join reordering alone generates many potential plan candidates, so the Query Optimizer uses a limited number of join orders in Phase 0 and considers using only the hash or nested-loop join strategies. If, at the end of this phase, the Query Optimizer finds a plan with an estimated cost below the threshold for Phase 0, the optimization ends. Phase 0 is also referred to as the *transaction processing phase* because the final query plans produced by Phase 0 are typically found in transaction processing applications.

The next phase is Phase 1, or quick plan optimization. This phase applies additional transformation rules and examines different possible join orders than were considered in Phase 0. If, at the end of Phase 1, the Query Optimizer finds a best plan with a cost less than the threshold for Phase 1, optimization ends and the best plan identified is returned.

Up to this point, the Query Optimizer has considered only nonparallel query plans. If more than one CPU is available to SQL Server and the cost of the least expensive plan produced by Phase 1 is greater than the Cost Threshold for Parallelism configuration setting, the Query Optimizer runs the Phase 1 optimization again, this time looking for the best parallel query plan. The costs of the nonparallel and parallel plans generated by Phase 1 are then compared and the Query Optimizer enters the last phase of optimization, Phase 2, for the cheaper of the two.

Phase 2 is also referred to as the full optimization phase. If the cost of the best nonparallel plan found so far is still below the parallelism threshold, or there is only a single CPU available, the full optimization phase continues using a brute-force method to find the best serial plan, checking additional combinations of indexes and processing strategies such as outer join reordering and automatic indexed view substitution for multitable views. In this phase, the Query Optimizer examines every possible execution plan and eventually chooses the cheapest one. The number of execution plans it considers during Phase 2 is restricted by a time limit. When the designated time limit for Phase 2 is reached, the Query Optimizer returns the cheapest plan found thus far.

Eventually, an execution plan is determined to be the most efficient. After this is determined, the execution plan is passed on to the SQL Server query processor to be executed.

Query Plan Caching

SQL Server 2008 has a pool of memory used to store both execution plans and data. The amount of memory allocated to execution plans or data changes dynamically, depending on the needs of the system. The portion of memory used to store execution plans is often referred to as the *plan cache*.

The first time a cacheable query is submitted to SQL Server, the query plan is compiled and put into the plan cache. Query plans are read-only re-entrant structures shared by multiple users. At most, there are two instances of a query plan at any time in the plan cache: a serial execution plan and parallel query execution plan. The same parallel execution plan is used for all parallel executions, regardless of the degree of parallelism.

When you execute subsequent SQL statements, the Database Engine first checks to see whether an existing execution plan for the same SQL statement already resides in the plan cache. If it finds one, SQL Server attempts to reuse the matching execution plan, thereby saving the overhead of having to recompile an execution plan for each ad hoc SQL statement issued. If no matching execution plan is found, SQL Server is forced to generate a new execution plan for the query.

The ability to reuse query plans for ad hoc queries in addition to caching query plans for stored procedures can help improve the performance for complex queries that are executed frequently because SQL Server can avoid having to compile a query plan every time it's executed if a matching query plan is found in memory first.

Query Plan Reuse

Query plan reuse for stored procedures is pretty straightforward. The whole idea behind stored procedures is to promote plan reuse. For stored procedures and triggers, plan reuse is simply based on the procedure or trigger name. The first time a stored procedure is executed, the query plan is generated based on the initial parameters. On subsequent executions, SQL Server checks the plan cache to see whether a query plan exists for a procedure with the same name, and if one is found, it simply substitutes the new parameter values into the existing query plan for execution.

Another method that promotes query plan reuse is using the `sp_executesql` stored procedure for executing dynamic SQL statements. When using `sp_executesql`, typically you specify a dynamic query with explicitly identified parameters for SARGs. Here's an example:

```
sp_executesql N'select t.title, pubdate from bigpubs2008.dbo.authors a
join bigpubs2008.dbo.titleauthor ta on a.au_id = ta.au_id
join bigpubs2008.dbo.titles t on ta.title_id = t.title_id
where a.au_lname = @name', N'@name varchar(30)', 'Smith'
```

When the same query is executed again via `sp_executesql`, SQL Server reuses the existing query plan (if it is still in the plan cache) and simply substitutes the different parameter values.

Although SQL Server can also match query plans for ad hoc SQL statements, there are some limitations as to when a plan can be reused. For SQL Server to match SQL statements to existing execution plans in the plan cache for ad hoc queries, all object references in the query must be qualified with at least the schema name, and fully qualified object names (database plus schema name) provide increased likelihood of plan reuse. In addition, plan caching for ad hoc queries requires an exact text match between the queries. The text match is both case sensitive and space sensitive. For example, the following two queries are logically identical, but because they are not textually identical, they would not share the same query plan:

```
select a.au_lname, t.title, pubdate
from authors a
join titleauthor ta on a.au_id = ta.au_id
join titles t on ta.title_id = t.title_id
```

```
select a.au_lname,
       t.title,
       pubdate
from authors a
join titleauthor ta on a.au_id = ta.au_id
join titles t on ta.title_id = t.title_id
```

Another factor that can prevent query plan reuse by matching queries is differences in certain SET options, database options, or configuration options in effect for the user session when the query is invoked. For example, a query might optimize differently for one session if the ANSI_NULLS option is turned on than it would if it were turned off. The following list of SET options must match for a query plan to be reused by a session:

- ▶ ANSI_PADDING
- ▶ FORCEPLAN
- ▶ CONCAT_NULL_YIELDS_NULL
- ▶ ANSI_WARNINGS
- ▶ ANSI_NULLS
- ▶ QUOTED_IDENTIFIER
- ▶ ANSI_NULL_DFLT_ON
- ▶ ANSI_NULL_DFLT_OFF

If any one of these setting values does not match the setting options for a cached plan, the session generates a new query plan. Likewise, if the session is using a different language or DATEFORMAT setting than that used by a cached plan, it needs to generate a new execution plan. As you can see, sometimes fairly subtle differences can prevent plan reuse.

Simple Query Parameterization

For certain simple queries executed without parameters, SQL Server 2008 automatically replaces constant literal values with parameters and compiles the query plan. This simple parameterization of the query plan increases the possibility of query plan matching for subsequent queries. If a subsequent query differs in only the values of the constants, it matches with the parameterized query plan and reuses the query plan.

Consider this query:

```
SELECT * FROM AdventureWorks.Production.Product WHERE ProductSubcategoryID = 1
```

The search value 1 at the end of the statement can be treated like a parameter. When the query plan is generated for this query, the Query Optimizer replaces the search value with a placeholder parameter, such as @p1. This process is called *simple parameterization*. Using the method of simple parameterization, SQL Server 2008 recognizes that following statement is identical to the first except for the search value of 9 and would generate essentially the same execution plan:

```
SELECT * FROM AdventureWorks.Production.Product WHERE ProductSubcategoryID = 9
```

This query will reuse the query plan generated by the first query.

NOTE

You can determine whether simple parameterization has been used for a query by examining the query plan information for the query. If the query plan information contains such placeholders as @p1 and @p2 in the search predicates when literal values were specified in the actual query, you know simple parameterization has been applied for the query. You can see an example of this in Figure 35.13 where parameters were substituted in the query plan for the search arguments against qty and ord_date.

Query Plan Aging

A query plan is saved in cache along with a cost factor that reflects the cost of actually creating the plan when compiling the query. For ad hoc query plans, SQL Server sets its cost to 0, which indicates that the plan can be removed from the plan cache immediately if space is needed for other plans. For other query plans, such as for a stored procedure, the query plan cost is a measure of the amount of resources required to produce it. This cost is calculated in “number of ticks.” The maximum plan cost is 31. The plan cost is determined as follows:

Every 2 I/Os required by the plan = 1 tick (with a maximum of 19 ticks)

Every 2 context switches in the plan = 1 tick (with a maximum of 8 ticks)

Every 16 pages (128KB) of memory required for the plan = 1 tick (with a maximum of 4 ticks)

All reusable query plans remain in cache until space is needed in the plan cache for a new plan. When space is needed, SQL Server removes the oldest unused execution plan from the plan cache that has the lowest plan cost.

As plans age in cache, the plan cost is not decremented until the size of the plan cache reaches 50% of the buffer pool size. When this occurs, the next access of the plan cache results in the plan cost for all query plans being decremented by 1. As plans reside in the plan cache over a period of time and are not reused, they eventually reach a plan cache cost of 0 and thus become eligible to be removed from cache the next time plan cache space is needed. However, when a query plan is reused, its plan cost is reset back to its initial value. This helps ensure that frequently accessed query plans remain in the plan cache.

Recompiling Query Plans

Certain changes in a database over time can cause existing execution plans to become either inefficient or invalid, based on the new state of the database. SQL Server detects the changes that invalidate an execution plan and marks the plan as not valid. A new plan is then automatically recompiled the next time the query that uses that query plan is invoked. Most query plan recompilations are required either for statement correctness or to obtain potentially faster query execution plans. The types of conditions that can invalidate a query plan include the following:

- ▶ Modifications made to the definition of a table or view referenced by the query using `ALTER TABLE` and `ALTER VIEW`
- ▶ Changes made to any indexes used by the execution plan
- ▶ Updates to the statistics used by the execution plan via either the `UPDATE STATISTICS` command or automatically
- ▶ Dropping of an index or indexed view used by the execution plan
- ▶ Execution of `sp_recompile` on a table referenced by the query plan
- ▶ Large numbers of changes to keys (generated by `INSERT` or `DELETE` statements from other users that modify a table referenced by the query)
- ▶ Adding or dropping a trigger on a table
- ▶ When the number of rows in the inserted or deleted tables grows significantly within a trigger defined on a table referenced in the query plan
- ▶ Execution of a stored procedure with the `WITH RECOMPILE` option specified

To avoid the unnecessary recompilation of statements that do not require it, SQL Server 2008 performs statement-level recompilation: only the statement inside the batch or stored procedure that requires recompilation is recompiled. Statement-level recompilation

helps improve query performance because, in most cases, only a small number of statements within a batch or stored procedure cause recompilations and their associated penalties, in terms of CPU time and locks. These penalties are therefore avoided for the other statements in the batch that do not have to be recompiled.

Forcing Query Plan Recompiles

If you suspect that a query plan that is being reused is not appropriate for the current execution of a query, you can also manually force the query plan to be recompiled for the query. This capability can be especially useful for parameterized queries. Query parameterization provides a performance benefit by minimizing compilation overhead, but a parameterized query often provides less specific costing information to the Query Optimizer and can result in the creation of a more general plan, which can be less efficient than a more specific plan created for a specific set of literal values.

If the initial parameterized query plan generated for the query was not based on a representative set of parameters, or if you are invoking an instance of the query with a nonrepresentative set of search values, you might find it necessary to force the Query Optimizer to generate a new query plan. You can force query recompilation for a specific execution of a query by specifying the `RECOMPILE` query hint. For more information on specifying the `RECOMPILE` query hint, see the “Managing the Optimizer” section, later in this chapter.

Monitoring the Plan Cache

You can view and get information about the query plans currently in plan cache memory by using some of the DMVs available in SQL Server 2008. Following are some of the useful ones related to monitoring the plan cache:

- ▶ **sys.dm_exec_cached_plans**—Returns general information about the query execution plans currently in the plan cache.
- ▶ **sys.dm_exec_query_stats**—Returns aggregate performance statistics for cached query plans.
- ▶ **sys.dm_exec_sql_text**—Returns the text of the SQL statement for a specified plan handle.
- ▶ **sys.dm_exec_cached_plan_dependent_objects**—Returns one row for every dependent object of a compiled plan.
- ▶ **sys.dm_exec_plan_attributes**—Returns one row per attribute associated with the plan for a specified plan handle.

sys.dm_exec_cached_plans

The `sys.dm_exec_cached_plans` DMV provides information on all the execution plans currently in the plan cache. Because the cache can have a large number of plans, you usually want to limit the results returned from `sys.dm_exec_cached_plans` by using a filter on the `cacheobjtype` column and also using the `TOP` clause. For example, the query shown in Listing 35.1 returns the top 10 compiled plans currently in the plan cache, sorted in descending order by the number of times the plan has been reused (`usecounts`).

The type of object or query for which a plan is cached is stored in the `objtype` column. This column can contain one of the following values:

- ▶ **Proc**—The cached plan is for a stored procedure or inline function.
- ▶ **Prepared**—The cached plan is for queries submitted using `sp_executesql` or for queries using the `prepare` and `execute` method.
- ▶ **Adhoc**—The cached plan is for queries that don't fall into any other category.
- ▶ **ReplProc**—The cached plan is for replication agents.
- ▶ **Trigger**—The cached plan is for a trigger.
- ▶ **View**—The cached plan is for a view or a noninline function. You typically see a parse tree only for a view or noninline function, not a compiled plan. The view or function typically does not have its own separate plan because it is expanded as part of another query.
- ▶ **UsrTab** or **SysTab**—The cached plan is for a user or system table that has computed columns. This is typically associated with a parse tree.
- ▶ **Default, Check, or Rule**—The cached plan is simply a parse tree for these types of objects because they are expanded as part of another query in which they are applied.

To determine how often a plan is being reused, you can examine the value in the `usecounts` columns. The `usecounts` value is incremented each time the cached plan is looked up and reused.

sys.dm_exec_sql_text

Overall, the information returned by `sys.dm_exec_cached_plans` is not overly useful unless you know what queries or stored procedures these plans refer to. You can view the SQL text of these query plans by writing a query that joins `sys.dm_exec_cached_plans` with the `sys.dm_exec_sql_text` DMV. For example, you can use the query shown in Listing 35.2 to return the SQL text for the top 10 largest ad hoc query plans currently in the plan cache.

LISTING 35.2 Returning the Top 10 Largest Ad Hoc Query Plans

```
select top 10 objtype, usecounts, size_in_bytes, plan_handle,
    -- the following removes newline and carriage return from the sql text
    replace(replace( text, char(13), ' '), char(10), ' ') as sqltext
from sys.dm_exec_cached_plans as p
cross apply sys.dm_exec_sql_text (p.plan_handle)
where cacheobjtype = 'Compiled Plan'
    and objtype = 'Adhoc'
order by size_in_bytes desc, usecounts desc
```

sys.dm_exec_query_stats

The plan cache also keeps track of useful statistics about each cached plan, such as the amount of CPU or the number of reads and writes performed by the query plan since it was placed into the plan cache. This information can be examined using the `sys.dm_exec_query_stats` DMV, which returns statistics for each statement in a stored procedure or a SQL batch. To provide statistics for the procedure or batch as a whole, you need to summarize the data. Listing 35.3 provides a sample query that returns the I/O, CPU, and elapsed time statistics for the 10 most recently executed stored procedures.

LISTING 35.3 Returning Query Plan Stats for the 10 Most Recently Executed Procedures

```
select TOP 10 usecounts, size_in_bytes,
    max(last_execution_time) as last_execution_time,
    sum(total_logical_reads) as total_logical_reads,
    sum(total_physical_reads) as total_physical_reads,
    sum(total_worker_time/1000) as total_CPU_time,
    sum(total_elapsed_time/1000) as total_elapsed_time,
    replace(substring (text,
        patindex('%create procedure%', text),
        datalength(text)),
        'create procedure', '') as procname
from sys.dm_exec_query_stats s
join sys.dm_exec_cached_plans p on s.plan_handle = p.plan_handle
CROSS APPLY sys.dm_exec_sql_text(p.plan_handle) as st
where p.objtype = 'Proc' and p.cacheobjtype = 'Compiled Plan'
group by usecounts, size_in_bytes, text
order by max(last_execution_time) desc
```

Table 35.1 describes some of the most useful columns returned by the `sys.dm_exec_query_stats` DMV.

TABLE 35.1 Description of Columns for **sys.dm_exec_query_stats**

Column Name	Description
<code>statement_start_offset</code>	The starting position of the query that the row describes within the text of its batch or stored procedure, indicated in bytes, beginning with 0.
<code>statement_end_offset</code>	The ending position of the query that the row describes within the text of its batch or stored proc. A value of -1 indicates the end of the batch.
<code>plan_generation_num</code>	The number of times the plan has been recompiled while it has remained in the cache.

TABLE 35.1 Description of Columns for **sys.dm_exec_query_stats**

Column Name	Description
<code>plan_handle</code>	A pointer to the plan. This value can be passed to the <code>dm_exec_query_plan</code> dynamic management function.
<code>creation_time</code>	The time the plan was compiled.
<code>last_execution_time</code>	The last time the plan was executed.
<code>execution_count</code>	The number of times the plan has been executed since it was last compiled.
<code>total_worker_time</code>	The total amount of CPU time, in microseconds, consumed by executions of this plan for the statement.
<code>last_worker_time</code>	The CPU time, in microseconds, consumed the last time the plan was executed.
<code>min_worker_time</code>	The minimum CPU time, in microseconds, this plan has ever consumed during a single execution.
<code>max_worker_time</code>	The maximum CPU time, in microseconds, this plan has ever consumed during a single execution.
<code>total_physical_reads</code>	The total number of physical reads performed by executions of this plan since it was compiled.
<code>last_physical_reads</code>	The number of physical reads performed the last time the plan was executed.
<code>min_physical_reads</code>	The minimum number of physical reads this plan has ever performed during a single execution.
<code>max_physical_reads</code>	The maximum number of physical reads this plan has ever performed during a single execution.
<code>total_logical_writes</code>	The total number of logical writes performed by executions of this plan since it was compiled.
<code>last_logical_writes</code>	The number of logical writes performed the last time the plan was executed.
<code>min_logical_writes</code>	The minimum number of logical writes this plan has ever performed during a single execution.
<code>max_logical_writes</code>	The maximum number of logical writes this plan has ever performed during a single execution.
<code>total_logical_reads</code>	The total number of logical reads performed by executions of this plan since it was compiled.
<code>last_logical_reads</code>	The number of logical reads performed the last time the plan was executed.

TABLE 35.1 Description of Columns for `sys.dm_exec_query_stats`

Column Name	Description
<code>min_logical_reads</code>	The minimum number of logical reads this plan has ever performed during a single execution.
<code>max_logical_reads</code>	The maximum number of logical reads this plan has ever performed during a single execution.
<code>total_elapsed_time</code>	The total elapsed time, in microseconds, for completed executions of this plan.
<code>last_elapsed_time</code>	The elapsed time, in microseconds, for the most recently completed execution of this plan.
<code>min_elapsed_time</code>	The minimum elapsed time, in microseconds, for any completed execution of this plan.
<code>max_elapsed_time</code>	The maximum elapsed time, in microseconds, for any completed execution of this plan.
<code>query_hash</code>	The binary hash value calculated on the query and used to identify queries with similar logic.
<code>query_plan_hash</code>	The binary hash value calculated on the query execution plan and used to identify similar query execution plans.

The `query_hash` and `query_plan_hash` values are new for SQL Server 2008. You can use these values to determine the aggregate resource usage for queries that differ only by literal values or with similar execution plans. You can use these values to write queries that you can use to help determine the aggregate resource usage for similar queries and similar query execution plans. For example, Listing 35.4 provides a query to find the `query_hash` and `query_plan_hash` values for queries that select from the `titles` table searching by `ytd_sales`. Looking at the results, you can see that even with different search arguments, each of the matching queries generates the same query hash value, but they have different query plan hash values for queries that use different query plans.

LISTING 35.4 Returning Query and Query Plan Hash Values for a Query

```
SELECT convert(varchar(41), substring(st.text, 1, 42)) AS 'Query Text',
       qs.query_hash AS 'Query Hash',
       qs.query_plan_hash as 'Query Plan Hash'
FROM sys.dm_exec_query_stats qs
CROSS APPLY sys.dm_exec_sql_text (qs.sql_handle) st
WHERE st.text like 'SELECT * from titles where ytd_sales%'
go
```

Query Text	Query Hash	Query Plan Hash
select * from titles where ytd_sales = 0	0x9AB21AC5889FE2D0	0x8D6DE6D258BABB2B
select * from titles where ytd_sales = 0	0x9AB21AC5889FE2D0	0x8D6DE6D258BABB2B
select * from titles where ytd_sales = 99	0x9AB21AC5889FE2D0	0xE889B5D23D917DFD
select * from titles where ytd_sales = 10	0x9AB21AC5889FE2D0	0xE889B5D23D917DFD
select * from titles where ytd_sales = 0	0x9AB21AC5889FE2D0	0x8D6DE6D258BABB2B
select * from titles where ytd_sales = 0	0x9AB21AC5889FE2D0	0xE889B5D23D917DFD

This query hash or query plan hash value can be used in a query to aggregate performance statistics for like queries. For example, the following query returns the average processing time and logical reads for the same queries that were returned in Listing 35.2:

```
SELECT
    SUM(total_worker_time) / SUM(execution_count)/1000. AS "Avg CPU Time(ms)",
    SUM(total_logical_reads) / SUM(execution_count) AS "Avg Reads"
FROM
    sys.dm_exec_query_stats
where query_hash = 0x9AB21AC5889FE2D0
go
```

Avg CPU Time(ms)	Avg Reads
164.092000	7

Listing 35.5 provides a sample query using the query hash value to return information about the top 25 queries ranked by average processing time.

LISTING 35.5 Returning Top 25 Queries Using Query Hash

```
SELECT TOP 25 query_stats.query_hash AS "Query Hash",
    SUM(query_stats.total_worker_time) / SUM(query_stats.execution_count) AS
    "Avg CPU Time",
    MIN(query_stats.statement_text) AS "Statement Text"
FROM
    (SELECT QS.*,
    SUBSTRING(ST.text, (QS.statement_start_offset/2) + 1,
    ((CASE statement_end_offset
        WHEN -1 THEN DATALENGTH(ST.text)
        ELSE QS.statement_end_offset END
        - QS.statement_start_offset)/2) + 1) AS statement_text
    FROM sys.dm_exec_query_stats AS QS
    CROSS APPLY sys.dm_exec_sql_text(QS.sql_handle) as ST) as query_stats
GROUP BY query_stats.query_hash
```

```
ORDER BY 2 DESC;
GO
```

sys.dm_exec_plan_attributes

If you want to get information about specific attributes of a specific query plan, you use `sys.dm_exec_plan_attributes`. This DMV takes a `plan_handle` as an input parameter (see Listing 35.1 for an example of a query that you can use to retrieve a query's plan handle) and returns one row for each attribute associated with the query plan. These attributes include information such as the ID of the database context the query plan was generated in, the ID of the user who generated the query plan, session SET options in effect at the time the plan was generated, and so on. Many of these attributes are used as part of the cache lookup key for the plan (indicated by the value 1 in the `is_cache_key_column`). Following is an example of the output for `sys.dm_exec_plan_attributes`:

```
select convert(varchar(30), attribute) as attribute,
        convert(varchar(12), value) as value,
        is_cache_key
FROM
sys.dm_exec_plan_attributes (0x06000400EBC44D2AB880A00600000000000000000000000000000)
where is_cache_key = 1
go
```

attribute	value	is_cache_key
-----	-----	-----
set_options	187	1
objectid	709739755	1
dbid	4	1
dbid_execute	0	1
user_id	-2	1
language_id	0	1
date_format	1	1
date_first	7	1
compat_level	100	1
status	0	1
required_cursor_options	0	1
acceptable_cursor_options	0	1
merge_action_type	0	1
is_replication_specific	0	1
optional_spid	0	1
optional_clr_trigger_dbid	0	1
optional_clr_trigger_objid	0	1

Note the attributes flagged as cache keys for the plan. If one of these properties does not match the state of the current user session, the plan cannot be reused for that session, and a new plan must be compiled and stored in the plan cache. If you see multiple plans in cache for what appears to be the same query, you can determine the key differences between them by comparing the columns associated with the plan's cache keys to see where the differences lie.

TIP

If SQL Server has been running for a while, with a lot of activity, the number of plans in the plan cache can become quite large, resulting in a large number of rows being returned by the plan cache DMVs. To run your own tests to determine which query plans get cached and when specific query plans are reused, you should clear out the cache occasionally. You can use the DBCC FREEPROCCACHE command to clear all cached plans from memory. If you want to clear only the cached plans for objects or queries in a specific database, you execute the following command:

```
DBCC FLUSHPROCINDB (dbid)
```

Keep in mind that you should run these commands only in a test environment. Running these commands in production servers could impact the performance of the currently running applications.

Other Query Processing Strategies

In addition to the optimization strategies covered so far, SQL Server also has some additional strategies it can apply for special types of queries. These strategies are used to help further reduce the cost of executing various types of queries.

Predicate Transitivity

You might be familiar with the transitive property from algebra. The transitive property simply states that if $A=B$ and $B=C$, then $A=C$. SQL Server supports the transitive property in its query predicates. Predicate transitivity enables SQL Server to infer a join equality from two given equalities. Consider the following example:

```
SELECT *
  FROM table1 t1
  join table2 t2 on t1.column1 = t2.column1
  join table3 t3 on t2.column1 = t3.column1
```

Using the principle of predicate transitivity, SQL Server is able to infer that $t1.column1$ is equal to $t3.column1$. This capability provides the Query Optimizer with another join

strategy to consider when optimizing this query. This might result in a much cheaper execution plan.

The transitive property can also be applied to SARGs used on join columns. Consider the following query:

```
select *
  from sales s
  join stores st on s.stor_id = st.stor_id
 and s.stor_id = 'B199'
```

Again, using transitive closure, it follows that `st.stor_id` is also equal to `'B199'`. SQL Server recognizes this and can compare the search value against the statistics on both tables to more accurately estimate the number of matching rows from each table.

Group by Optimization

One way SQL Server can process `GROUP BY` results is to retrieve the matching detailed data rows into a worktable and then sort the rows and calculate the aggregates on the groups formed. In SQL Server 2008, the Query Optimizer also may choose to use hashing to organize the data into groups and then compute the aggregates.

The hash aggregation strategy uses the same basic method for grouping and calculating aggregates as for a hash join. At the point where the probe input row is checked to determine whether it already exists in the hash bucket, the aggregate is computed if a hash match is found. The following pseudocode summarizes the hash aggregation strategy:

```
create a hash table
for each row in the input table
  read the row
  hash the key value
  search the hash table for matches
  if match found
    aggregate the value into the old record
  else
    insert the hashed key into the hash bucket
scan and output the hash table contents
drop the hash table
```

For some join queries that contain `GROUP BY` clauses, SQL Server might perform the grouping operation before processing the join. This could reduce the size of the input table to the join and lower the overall cost of executing the query.

NOTE

One important point to keep in mind is that regardless of the `GROUP BY` strategy employed, the rows are not guaranteed to be returned in sorted order by the grouping column(s) as they were in earlier releases. If the results must be returned in a specific sort order, you need to use the `ORDER BY` clause with `GROUP BY` to ensure ordered results. You might want to get into the habit of doing this regularly.

Queries with `DISTINCT`

When the `DISTINCT` clause is specified in a query, SQL Server can eliminate duplicate rows by the sorting the result set in a worktable to identify and remove the duplicates, similar to how a worktable is used for `GROUP BY` queries. In SQL Server 2008, the Query Optimizer can also employ a hashing strategy similar to that used for `GROUP BY` to return only the distinct rows before the final result set is determined.

In addition, if the Query Optimizer can determine at compile time that there will be no possibility of duplicate rows in the result set (for example, each row contains the table's primary key), the strategies for removing duplicate rows are skipped altogether.

Queries with `UNION`

When you specify `UNION` in a query, SQL Server merges the result sets, applying one of the merge or concatenation operators with sorting strategies to remove any duplicate rows. Figure 35.25 shows an example similar to the `OR` strategy where the rows are concatenated and then sorted to remove any duplicates.

If you specify `UNION ALL` in a query, SQL Server simply appends the result sets together. No intermediate sorting or merge step is needed to remove duplicates. Figure 35.26 shows the same query as in Figure 35.25, except that a `UNION ALL` is specified.

When you know that you do not need to worry about duplicate rows in a `UNION` result set, always specify `UNION ALL` to eliminate the extra overhead required for sorting.

When a `UNION` is used to merge large result sets together, SQL Server 2008 may opt to use a merge join or hash match operation to remove any duplicate rows. Figure 35.27 shows an example of a `UNION` query where the rows are concatenated, and then a hash match operation is used to remove any duplicates.

Parallel Query Processing

The query processor in SQL Server 2008 includes parallel query processing—an execution strategy that can improve the performance of complex queries on computers with more than one processor.

SQL Server inserts exchange operators into each parallel query to build and manage the query execution plan. The exchange operator is responsible for providing process management, data redistribution, and flow control. The exchange operators are displayed in the

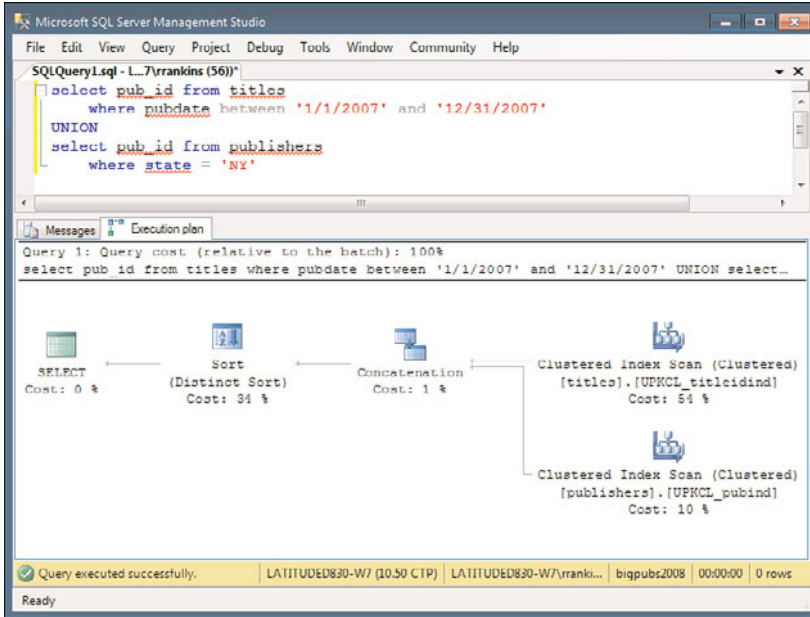

FIGURE 35.25 An execution plan for a **UNION** query.

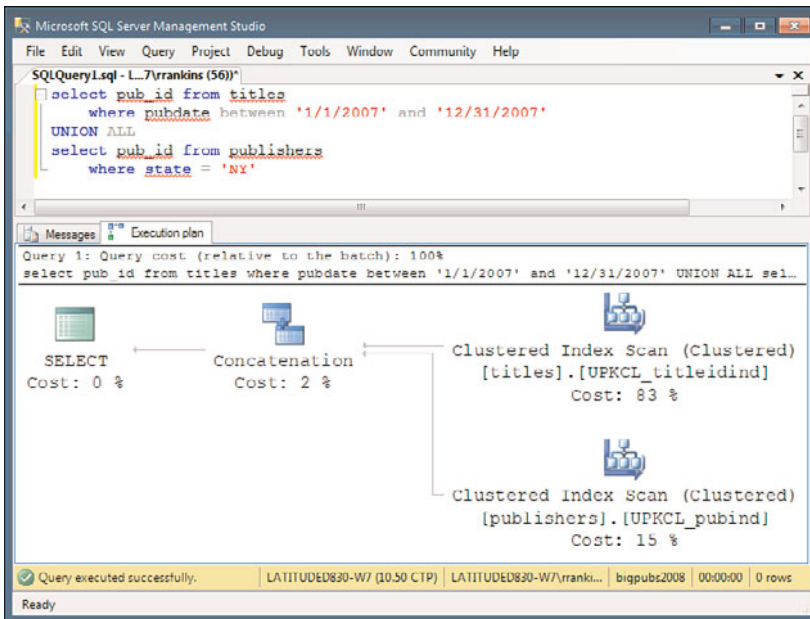

FIGURE 35.26 An execution plan for a **UNION ALL** query.

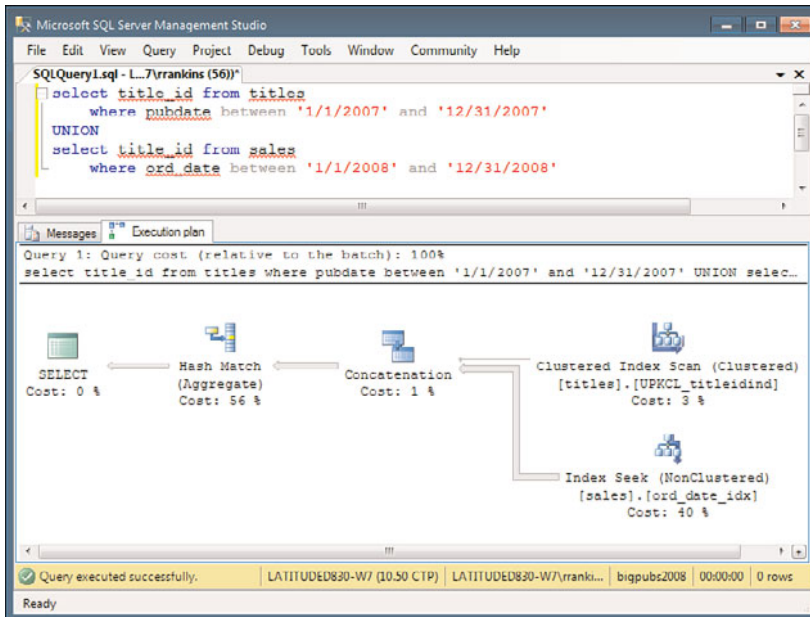

FIGURE 35.27 An execution plan for a **UNION** query, using a hash match to eliminate duplicate rows.

query plans as the Distribute Streams, Repartition Streams, and Gather Streams logical operators. One or more of these operators can appear in the execution plan output of a query plan for a parallel query.

Whereas a parallel query execution plan can use more than one thread, a serial execution plan, used by a nonparallel query, uses only a single thread for its execution. Prior to query execution time, SQL Server determines whether the current system state and configuration allow for parallel query execution. If parallel query execution is justified, SQL Server determines the optimal number of threads, called the degree of parallelism, and distributes the query workload execution across those threads. The parallel query uses the same number of threads until the query completes. SQL Server reexamines the optimal degree of parallelism each time a query execution plan is retrieved from the procedure cache. Individual instances of the same query could be assigned a different degree of parallelism.

SQL Server calculates the degree of parallelism for each instance of a parallel query execution by using the following criteria:

- ▶ How many processors does the computer running SQL Server have, and how many are allocated to SQL Server?
 - If two or more processors are allocated to SQL Server, it can use parallel queries.
- ▶ What is the number of concurrent active users?

The degree of parallelism is inversely related to CPU usage. The Query Optimizer assigns a lower degree of parallelism if the CPUs are already busy.

- ▶ Is sufficient memory available for parallel query execution?

Queries, like other processes, require resources to execute, particularly memory. Obviously, a parallel query demands more memory than a serial query. More importantly, as the degree of parallelism increases, so does the amount of memory required. The Query Optimizer carefully considers this in developing a query execution plan. The Query Optimizer could either adjust the degree of parallelism or use a serial plan to complete the query.

- ▶ What is the type of query being executed?

Queries that use several CPU cycles justify using a parallel execution plan. Some examples are joins of large tables, substantial aggregations, and sorting of large result sets. The Query Optimizer determines whether to use a parallel or serial plan by checking the value of the cost threshold for parallelism.

- ▶ Are a sufficient number of rows processed in the given stream?

If the Query Optimizer determines that the number of rows in a stream is too low, it does not execute a parallel plan. This prevents scenarios where the parallel execution costs exceed the benefits of executing a parallel plan.

Regardless of the answers to the previous questions, the Query Optimizer does not use a parallel execution plan for a query if any one of the following conditions is true:

- ▶ The serial execution cost of the query is not high enough to consider an alternative parallel execution plan.
- ▶ A serial execution plan exists that is estimated to be faster than any possible parallel execution plan for the particular query.
- ▶ The query contains scalar or relational operators that cannot be run in parallel.

Parallel Query Configuration Options

Two server configuration options—maximum degree of parallelism and cost threshold for parallelism—affect the consideration for a parallel query. Although doing so is not recommended, you can change the default settings for each. For single processor machines, these settings are ignored.

The maximum degree of parallelism option limits the number of threads to use in a parallel plan execution. The range of possible values is 0 to 32. This value is configured to 0 by default, which allows the Query Optimizer to use up to the actual number of CPUs allocated to SQL Server. If you want to suppress parallel processing completely, set the value to 1.

The cost threshold for parallelism option establishes a ceiling value the Query Optimizer uses to consider parallel query execution plans. If the calculated value to execute a serial plan is greater than the value set for the cost threshold for parallelism, a parallel plan is generated. This value is defined by the estimated time, in seconds, to execute the serial plan. The range of values for this setting is 0 to 32767. The default value is 5. If the maximum degree of parallelism is set to 1, or if the computer has a single processor, the cost threshold for parallelism value is ignored.

You can modify the settings for the maximum degree of parallelism and the cost threshold for parallelism server configuration options either by using the `sp_configure` system stored procedure or through SSMS. To set the values for these options, use the `sp_configure` system stored procedure via SSMS or via `SQLCMD`, as follows:

```
USE master
go
exec sp_configure 'show advanced options', 1
GO
RECONFIGURE
GO
exec sp_configure 'max degree of parallelism', 2
exec sp_configure 'cost threshold for parallelism', 15
RECONFIGURE
GO
```

To set these configuration options via SSMS, right-click the SQL Server instance in the Object Explorer and then click Properties. In the Server Properties dialog, select the Advanced page. The parallelism options are near the bottom, as shown in Figure 35.28.

Identifying Parallel Queries

You can identify when a parallel execution plan is being chosen by displaying the graphical execution plan in SSMS. The graphical execution plan uses icons to represent the execution of specific statements and queries in SQL Server. The execution plan output for every parallel query has at least one of these three logical operators:

- ▶ **Distribute Streams**—Receives a single input stream of records and distributes multiple output streams. The contents and form of the record are unchanged. All records enter through the same single input stream and appear in one of the output streams, preserving the relative order.
- ▶ **Gather Streams**—Assembles multiple input streams of records and yields a single output stream. The relative order of the records, contents, and form is maintained.
- ▶ **Repartition Streams**—Accepts multiple input streams and produces multiple streams of records. The record contents and format are unchanged.

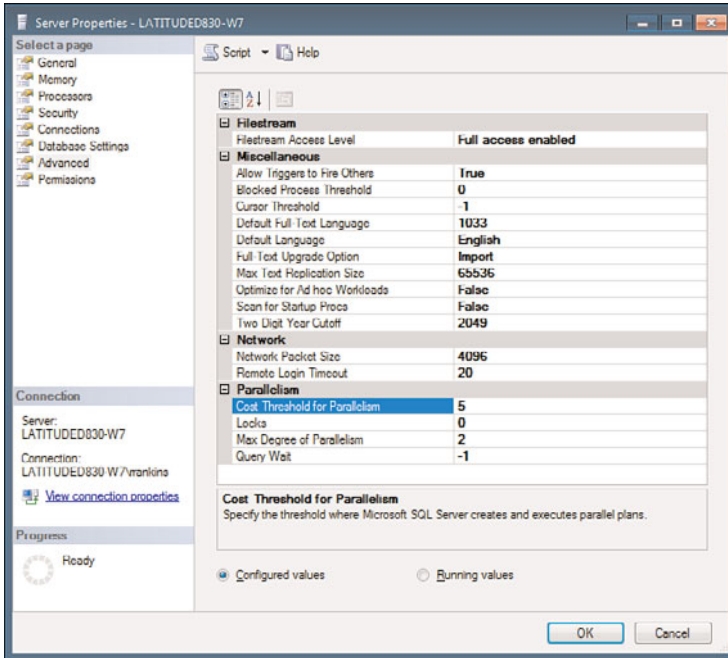

FIGURE 35.28 Setting SQL Server parallelism options.

Figure 35.29 shows a portion of a sample query plan that uses parallel query techniques—both repartition streams and gather streams.

Parallel Queries on Partitioned Objects

SQL Server 2008 provides improved query processing performance for partitioned objects when running parallel plans including changes in the way parallel and serial plans are represented, and enhancements to the partitioning information provided in both compile-time and runtime execution plans. SQL Server 2008 also automates and improves the thread partitioning strategy for parallel query execution plans on partitioned objects.

In addition to the performance improvements, query plan information has been improved as well in SQL Server 2008, now providing the following information related to partitioned objects:

- ▶ The partitions accessed by the query, available in runtime execution plans.
- ▶ An optional Partitioned attribute indicating that an operation, such as a seek, scan, insert, update, merge, or delete, is performed on a partitioned table.
- ▶ Summary information that provides a total count of the partitions accessed. This information is available only in runtime plans.

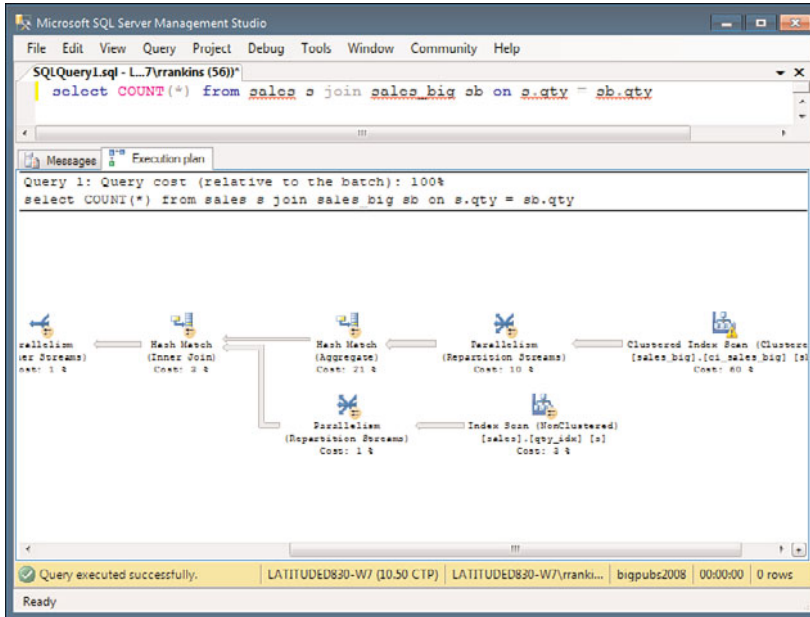

FIGURE 35.29 A graphical execution plan of a query using parallel query techniques.

Common Query Optimization Problems

So you've written a query and examined the query plan, and performance isn't what you expected. It might appear that SQL Server isn't choosing the appropriate query plan that you expect. Is something wrong with the query or with the Query Optimizer? Before delving into a detailed discussion about how to debug and analyze query plans (covered in detail in Chapter 36), the following sections look at some of the most common problems and SQL coding issues that can lead to poor query plan selection.

Out-of-Date or Insufficient Statistics

Admittedly, having out-of-date or unavailable statistics is not as big a problem as it was in SQL Server releases prior to 7.0. Back in those days, the first question asked when someone was complaining of poor performance was, "When did you last update statistics?" If the answer was "Huh?" we usually found the culprit.

With the Auto-Update Statistics and Auto-Crete Statistics features in SQL Server 2008, this problem is not as prevalent as it used to be. If a query detects that statistics are out of date or missing, it causes them to be updated or created and then optimizes the query plan based on the new statistics.

NOTE

If statistics are missing or out of date, the first running query that detects this condition might run a bit more slowly as it updates or creates the statistics first, especially if the table is relatively large, and also if it has been configured for FULLSCAN when indexes are updated.

However, SQL Server 2008 provides the `AUTO_UPDATE_STATISTICS_ASYNC` database option. When this option is set to ON, queries do not wait for the statistics to be updated before compiling. Instead, the out-of-date statistics are put on a queue for updating by a worker thread in a background process, and the query and any other concurrent queries compile immediately, using the existing out-of-date statistics. Although there is no delay for updated statistics, the out-of-date statistics may cause the Query Optimizer to choose a less efficient query plan, but the response times are more predictable. Any queries invoked after the updated statistics are ready will use the updated statistics in generating a query plan. This may cause the recompilation of any cached plans that depend on the older statistics.

You should consider setting the `AUTO_UPDATE_STATISTICS_ASYNC` option to ON when any of your applications have experienced client request timeouts caused by queries waiting for updated statistics or when it is acceptable for your application to run queries with less efficient query plans due to outdated statistics so that you can maintain predictable query response times.

You could have insufficient statistics to properly optimize a query if the sample size used when the statistics were generated wasn't large enough. Depending on the nature of your data and size of the table, the statistics might not accurately reflect the actual data distribution and cardinality. If you suspect that this is the case, you can update statistics by specifying the `FULLSCAN` option or a larger sample size, so SQL Server examines more records to derive the statistics.

For more information on understanding and managing index statistics, see Chapter 34.

Poor Index Design

Poor index design is another reason—often a primary reason—why queries might not optimize as you expect them to. If no supporting indexes exist for a query, or if a query contains SARGs that cannot be optimized effectively to use the available indexes, SQL Server ends up performing either a table scan, an index scan, or another hash or merge join strategy that is less efficient. If this appears to be the problem, you need to reevaluate your indexing decisions or rewrite the query so it can take advantage of an available index. For more information on designing useful indexes, see Chapter 34.

Search Argument Problems

It's the curse of SQL that there are a number of ways to write a query and get the same result set. Some queries, however, might not be as efficient as others. A good understanding of the Query Optimizer can help you avoid writing search arguments that SQL Server can't optimize effectively. The following sections highlight some of the common "gotchas" encountered in SQL Server SARGs that can lead to poor or unexpected query performance.

Using Optimizable SARGs

As mentioned previously, in the section "Identifying Search Arguments," the Query Optimizer uses search arguments to help it narrow down the set of rows to evaluate. The search argument is in the form of a WHERE clause that equates a column to a constant. The SARGs that optimize most effectively are those that compare a column with a constant value that is not an expression or a variable, and with no operation performed against the column itself. The following is an example:

```
SELECT column1
   FROM table1
  WHERE column1 = 123
```

You should try to avoid using any negative logic in your SARGs (for example, !=, <>, not in) or performing operations on, or applying functions to, the columns in the SARG.

No SARGs

You need to watch out for queries in which the SARG might have been left out inadvertently, such as this:

```
select title_id from titles
```

A SQL query with no search argument (that is, no WHERE clause) always performs a table or clustered index scan unless a nonclustered index can be used to cover the query. (See Chapter 34 for a discussion of index covering.) If you don't want the query to affect the entire table, you need to be sure to specify a valid SARG that matches an index on the table to avoid table scans.

Unknown Values in WHERE Clauses

You need to watch out for expressions in which the search value in the SARG cannot be evaluated until runtime. In these expressions, often the search value is a local variable or subquery that can be materialized to a single value.

SQL Server treats these expressions as SARGs but can't use the statistics histogram to estimate the number of matching rows because it doesn't have a value to compare against the histogram values during query optimization. The values for the expressions aren't known until the query is actually executed. In this situation, the Query Optimizer uses the index density information. The Query Optimizer is generally able to better estimate the number of rows affected by a query when it can compare a known value against the statistics

histogram than when it has to use the index density to estimate the average number of rows that match an unknown value. This is especially true if the data in a table isn't distributed evenly. When you can, you should try to avoid using constant expressions that can't be evaluated until runtime so that the statistics histogram can be used rather than the density value.

To avoid using constant expressions in `WHERE` clauses that can't be evaluated until runtime, you should consider putting the queries into stored procedures and passing in the constant expression as a parameter. Because the Query Optimizer evaluates the value of a parameter prior to optimization, SQL Server evaluates the expression prior to optimizing the stored procedure.

For best results when writing queries inside stored procedures, you should use stored procedure parameters rather than local variables in your SARGs whenever possible. This strategy allows the Query Optimizer to optimize the query by using the statistics histogram, comparing the parameter value against the statistics histogram to estimate the number of matching rows. If you use local variables as SARGs in stored procedures, the Query Optimizer is restricted to using index density, even if the local variable is assigned the value of a parameter.

Other types of constructs for which it is difficult for the Query Optimizer to accurately estimate the number of qualifying rows or the data distribution using the statistics histogram include aggregations in subqueries, scalar expressions, user-defined functions, and nonlinear table-valued functions.

Data Type Mismatches

Another common problem is data type mismatches. If you attempt to join tables on columns of different data types, the Query Optimizer might not be able to effectively use indexes to evaluate the join. This can result in a less efficient join strategy because SQL Server has to convert all values first before it can process the query. You should avoid this situation by maintaining data type consistency across the join key columns in your database.

Large Complex Queries

For complex queries with a large number of tables and join conditions, the number of possible execution plans can be enormous. The full optimization phase of the Query Optimizer has a time limit to restrict how long it spends analyzing all the possible query plans. There is no known general and effective shortcut to arrive at the optimal plan. To deal with such a large selection of plans, SQL Server 2008 implements a number of heuristics to deal with very large queries and attempt to come up with an efficient query plan within the time available. When it is not possible to analyze the entire set of plan alternatives and the heuristics are applied, it is not uncommon to encounter suboptimal query plans being chosen.

When is your query large enough to be a concern? Answering this question is difficult because the answer depends on the number of tables involved, the form of filter and join predicates, and the operations performed. If a query involves more than 12 tables, it is likely that the Query Optimizer is having to rely on heuristics and shortcuts to generate a query plan and may miss some optimal strategies.

In general, you get more optimal query plans if you can simplify your queries as much as possible.

Triggers

If you are using triggers on `INSERT`, `UPDATE`, or `DELETE`, it is possible that your triggers can cause performance problems. You might think that `INSERT`, `UPDATE`, or `DELETE` is performing poorly when actually it is the trigger that needs to be tuned. In addition, you might have triggers that fire other triggers. If you suspect that you are having performance problems with the triggers, you can monitor the SQL they are executing and the response time, as well as execution plans generated for statements within triggers using SQL Server Profiler. For more information on monitoring performance with SQL Server Profiler, see Chapter 6, “SQL Server Profiler.” You can also see the query plans for statements executed in triggers by using SSMS if you enable the Include Actual Execution Plan option. For more information on using SSMS to view and analyze query plans, see Chapter 36.

Managing the Optimizer

Because the Query Optimizer might sometimes make poor decisions as to how to best process a query, you need to know how and when you may need to override the Query Optimizer and force SQL Server to process a query in a specific manner.

How often does SQL Server require manual intervention to execute a query optimally? Considering the overwhelming number of query types and circumstances in which those queries are run, SQL Server does a surprisingly effective job of query optimization in most instances. For all but the most grueling, complex query operations, experience has shown that SQL Server’s Query Optimizer is quite clever—and very, very good at wringing the best performance out of any hardware platform. For this reason, you should treat the material covered in this chapter as a collection of techniques to be used only where other methods of getting optimal query performance have already failed.

Before indiscriminately applying the techniques discussed in this section, remember one very important point: use of these features can effectively hide serious fundamental design or coding flaws in your database, application, or queries. In fact, if you’re tempted to use these features (with a few moderate exceptions), it should serve as an indicator that the problems might lie elsewhere in the application or queries.

If you are satisfied that no such flaws exist and that SQL Server is choosing the wrong plan to optimize your query, you can use the methods discussed in this section to override two of the three most important decisions the Query Optimizer makes:

- ▶ Choosing which index, if any, to resolve the query
- ▶ Choosing the join strategy to apply in a multitable query

The other decision made by the Query Optimizer is the locking strategy to apply. Using table hints to override locking strategies is discussed in Chapter 37, “Locking and Performance.”

Throughout this and following sections, one point must remain clear in your mind: these options should be used only in *exception cases* to cope with specific optimization problems in specific queries in specific applications. There are therefore no standard or global rules to follow because the application of these features, by definition, means that normal SQL Server behavior isn’t taking place.

The practical result of this idea is that you should test every option in *your* environment, with *your* data and *your* queries, and use the techniques and methods discussed in this chapter and the other performance-related chapters to optimize and fine-tune the performance of your queries. The fastest-performing query wins, so you shouldn’t be afraid to experiment with different alternatives—but you shouldn’t think that these statements and features are globally applicable or fit general categories of problems, either! There are, in fact, only three rules: *Test, test, and test!*

TIP

As a general rule, Query Optimizer and table hints should be used only as a last resort, when all other methods to get the Query Optimizer to generate a more efficient query plan have failed. Always try to find other ways to rewrite the queries to encourage the Query Optimizer to choose a better plan. This includes adding additional SARGs, substituting unknown values for known values in SARGs or trying to replace unknown values with known values, breaking up queries, converting subqueries to joins or joins to subqueries, and so on. Essentially, you should try other coding variations on the query itself to get the same result in a different way and try to see if one of the variations ends up using the more efficient query plan that you expect it to.

In reality, about the only time you should use these hints is when you’re testing the performance of a query and want to see if the Query Optimizer is actually choosing the best execution plan. You can enable the various query analysis options, such as `STATISTICS PROFILE` and `STATISTICS IO`, and then see how the query plan and statistics change as you apply various hints to the query. You can examine the output to determine whether the I/O cost and/or runtime improves or gets worse if you force one index over another or if you force a specific join strategy or join order.

The problem with hard-coding table and Query Optimizer hints into application queries is that the hints prevent the Query Optimizer from modifying the query plan as the data in the tables changes over time. Also, if subsequent service packs or releases of SQL Server incorporate improved optimization algorithms or strategies, the queries with hard-coded hints will not be able to take advantage of them.

If you find that you must incorporate any of these hints to solve query performance problems, you should be sure to document which queries and stored procedures contain Query Optimizer and table hints. It's a good idea to periodically go back and test the queries to determine whether the hints are still appropriate. You might find that, over time, as the data values in the table change, the forced query plan generated because of the hints is no longer the most efficient query plan, and the Query Optimizer now generates a more efficient query plan on its own.

Optimizer Hints

You can specify three types of hints in a query to override the decisions made by the Query Optimizer:

- ▶ Table hints
- ▶ Join hints
- ▶ Query hints

The following sections examine and describe each type of table hint.

Forcing Index Selection with Table Hints

In addition to locking hints that can be specified for each table in a query, SQL Server 2008 allows you to provide table-level hints that enable you to specify the index SQL Server should use for accessing the table. The syntax for specifying an index hint is as follows:

```
SELECT column_list FROM tablename WITH (INDEX (indid | index_name [, ...]) )
```

This syntax allows you to specify multiple indexes. You can specify an index by name or by ID. It is recommended that you specify indexes by name as the IDs for nonclustered indexes can change if they are dropped and re-created in a different order than that in which they were created originally. You can specify an index ID of 0, or the table name itself, to force a table scan.

When you specify multiple indexes in the hint list, all the indexes listed are used to retrieve the rows from the table, forcing an index intersection or index covering via an index join. If the collection of indexes listed does not cover the query, a regular row fetch is performed after all the indexed columns are retrieved.

To get a list of indexes on a table, you can use `sp_helpindex`. However, the stored procedure doesn't display the index ID. To get a list of all user-defined tables and the names of the indexes defined on them, you can execute a query against the `sys.indexes` catalog view similar to the one shown in Listing 35.6, which was run against the `bigpubs2008` database.

LISTING 35.6 Query Against **sys.indexes** Catalog View to Get Index Names and IDs

```
select 'Table name' = convert(char(20), object_name(object_id)),
      'Index name' = convert(char(30), name),
      'Index ID' = index_id,
      'Index Type' = convert(char(15), type_desc)
```

```

from sys.indexes where object_id > 99 --only system tables have id less than 99
and index_id between 1 and 254 /* do not include rows for text columns
                                or tables without a clustered index*/
/* do not include auto statistics */
and is_hypothetical = 0
and objectproperty(object_id, 'IsUserTable') = 1
order by 1, 3
go

```

SQL Server 2008 introduces the new FORCESEEK table hint, which provides an additional query optimization option. This hint specifies that the query optimizer use only an index seek operation as the access path to the data in the table or view referenced in the query rather than a index or table scan. If a query plan contains table or index scan operators, forcing an index seek operation may yield better query performance. This is especially true

when inaccurate cardinality or cost estimations cause the optimizer to favor scan operations at plan compilation time.

Before using the `FORCESEEK` table hint, you should make sure that statistics on the table are current and accurate. Also, you should evaluate the query for items that can cause poor cardinality or cost estimates and remove these items if possible. For example, replace local variables with parameters or literals and limit the use of multistatement table-valued functions and table variables in the query.

Also, be aware that if you specify the `FORCESEEK` hint in addition to an index hint, the `FORCESEEK` hint can cause the optimizer to use an index other than one specified in the index hint.

Forcing Join Strategies with Join Hints

Join hints let you force the type of join that should be used between two tables. The join hints correspond with the three types of join strategies:

- ▶ LOOP
- ▶ MERGE
- ▶ HASH

You can specify join hints only when you use the ANSI-style join syntax—that is, when you actually use the keyword `JOIN` in the query. The hint is specified between the type of join and the keyword `JOIN`, which means you can't leave out the keyword `INNER` for an inner join. Thus, the syntax for the `FROM` clause when using join hints is as follows:

```
FROM table1 {INNER | OUTER} [LOOP | MERGE | HASH} JOIN table2
```

The following example forces SQL Server to use a hash join:

```
select st.stor_name, ord_date, qty
  from stores st INNER HASH JOIN sales s on st.stor_id = s.stor_id
 where st.stor_id between 'B100' and 'B599'
```

You can also specify a global join hint for all joins in a query by using a query processing hint.

Specifying Query Processing Hints

SQL Server 2008 enables you to specify additional query hints to control how your queries are optimized and processed. You specify query hints at the end of a query by using the `OPTION` keyword. There can be only one `OPTION` clause per query, but you can specify multiple hints in an `OPTION` clause, as shown in the following syntax:

```
OPTION (hint1 [, ...hintn])
```

Query hints are grouped into four categories: `GROUP BY`, `UNION`, join, and miscellaneous.

GROUP BY Hints GROUP BY hints specify how GROUP BY or COMPUTE operations should be performed. The following GROUP BY hints can be specified:

- ▶ **HASH GROUP**—This option forces the Query Optimizer to use a hashing function to perform the GROUP BY operation.
- ▶ **ORDER GROUP**—This option forces the Query Optimizer to use a sorting operation to perform the GROUP BY operation.

Only one GROUP BY hint can be specified at a time.

UNION Hints The UNION hints specify how UNION operations should be performed. The following UNION hints can be specified:

- ▶ **MERGE UNION**—This option forces the Query Optimizer to use a merge operation to perform the UNION operation.
- ▶ **HASH UNION**—This option forces the Query Optimizer to use a hash operation to perform the UNION operation.
- ▶ **CONCAT UNION**—This option forces the Query Optimizer to use the concatenation method to perform the UNION operation.

Only one UNION hint can be specified at a time, and it must come after the last query in the UNION. The following is an example of forcing concatenation for a UNION:

```
select stor_id from sales where stor_id like 'B19%'
UNION
select title_id from titles where title_id like 'C19%'
OPTION (CONCAT UNION)
```

Join Hints The join hint specified in the OPTION clause specifies that all join operations in the query are performed as the type of join specified in the hint. The join hints that can be specified in the query hints are the same as the table hints:

- ▶ LOOP JOIN
- ▶ MERGE JOIN
- ▶ HASH JOIN

If you also specify a join hint for a specific pair of tables, the table-level hints specified must be compatible with the query-level join hint.

Miscellaneous Hints The following miscellaneous hints can be used to override various query operations:

- ▶ **FORCE ORDER**—This option tells the Query Optimizer to join the tables in the order in which they are listed in the FROM clause and not to determine the optimal join order.

- ▶ **FAST *n***—This hint instructs SQL Server to optimize the query to return the first *n* rows as quickly as possible, even if the overall throughput is reduced. In other words, it improves response time at the expense of total query execution time. This option generally influences the Query Optimizer to retrieve data using a nonclustered index that matches the `ORDER BY` clause of a query instead of using a different access method that would require a sort operation first to return rows in the specified order. After *n* number of rows have been returned, the query continues execution normally to produce its full result set.
- ▶ **ROBUST PLAN**—This option forces the Query Optimizer to attempt a plan that works for the maximum potential row size, even if it means degrading performance. If you have very wide `VARCHAR` columns, some types of query plans might create intermediate tables, and if any of the internal operations need to store and process rows in these intermediate tables, some rows might exceed SQL Server's row size limit. If this happens, SQL Server generates an error during query execution. When the `ROBUST PLAN` hint is specified, the Query Optimizer does not consider any plans that might encounter this problem.
- ▶ **MAXDOP *number***—This hint overrides the server-level configuration setting for `max degree of parallelism` for the current query in which the hint is specified.
- ▶ **KEEP PLAN**—When this hint is specified, it forces the Query Optimizer to relax the estimated recompile threshold for a query. The estimated recompile threshold is the point at which a query is automatically recompiled when the estimated number of indexed column changes have been made to a table by updates, inserts, or deletes. Specifying `KEEP PLAN` ensures that the query is not recompiled as frequently when there are multiple updates to a table. This option is useful primarily for queries whose execution plan stays in memory, such as for stored procedures. You might want to specify this option for a stored procedure that does a lot of work with temporary tables, which can lead to frequent recompilations of the execution plan for the stored procedure.
- ▶ **KEEPFIXED PLAN**—This query hint tells the Query Optimizer not to recompile the query plan when there are changes in statistics or modifications to indexed columns used by the query via updates, deletes, or inserts. When this option is specified, the query is recompiled only if the schema of the underlying tables is changed or `sp_recompile` is executed against those tables.
- ▶ **EXPAND VIEWS**—This hint tells the Query Optimizer not to consider any indexed view as a substitute for any part of the query and to force the view to be expanded into its underlying query. This hint essentially prevents direct use of indexed views in the query plan.
- ▶ **MAXRECURSION *number***—This hint specifies the maximum number of recursions allowed for the common table expression query, where *number* is an integer between 0 and 32767. When 0 is specified, no limit is applied. If this option is not specified, the default limit for the server is 100. For more information on common table

expressions and recursive queries, see Chapter 43, “Transact-SQL Programming Guidelines, Tips, and Tricks.”

- ▶ **RECOMPILE**—This hint forces SQL Server not to keep the execution plan generated for the query in the plan cache after it executes. This forces a new plan to be generated the next time the same or a similar query plan is executed. **RECOMPILE** is useful for queries with variable values that vary widely each time they are compiled and executed. This hint can be used for individual statements within a stored procedure in place of the global **WITH RECOMPILE** option when you want only a subset of queries inside the stored procedure to be recompiled rather than all of them.
- ▶ **OPTIMIZE FOR (@variable_name = literal_constant [, ...n])**—This hint instructs SQL Server to use a specified value to optimize the SARGs for a local variable that is otherwise unknown when the query is compiled and optimized. The value is used only during query optimization and not during query execution. **OPTIMIZE FOR** can help improve optimization by allowing the Query Optimizer to use the statistics histogram rather than index densities to estimate the rows that match the local variable, or can be used when you create plan guides.
- ▶ **OPTIMIZE FOR UNKNOWN**—This hint instructs the query optimizer to use statistical data instead of the initial values for local variables when the query is compiled and optimized, including parameters created with forced parameterization.
- ▶ **TABLE HINT (object_name [, table_hint [[,]...n]])**—New in SQL Server 2008, you can now specify table hints in the Query Hint **OPTION** clause. It is recommended that the **TABLE HINT** clause be used only in the context of a plan guide. For all other ad hoc queries, it is recommended that normal table hints be used.
- ▶ **USE PLAN N'xml_plan'**—This hint instructs SQL Server to use an existing query plan for a query as specified by the designated *xml_plan*. The **USE PLAN** query hint can be used for queries whose plans result in slow execution times but for which you know better plans exist.

NOTE

Optimizer hints are not always executed. For example, the Query Optimizer is likely to ignore a **HASH UNION** hint for a query using the **UNION ALL** statement. Because **UNION ALL** means to return all rows whether or not there are duplicates, you don't need to hash these values to determine uniqueness and remove duplicates, so the normal concatenation is likely to still take place.

Forced Parameterization

In SQL Server 2008, if a SQL statement is executed without parameters, the Query Optimizer parameterizes the statement internally to increase the possibility of matching it against an existing execution plan. This process is called *simple parameterization*, sometimes referred to as auto-parameterization. Simple parameterization is somewhat limited in that it can parameterize only a relatively small number of queries that match a small

number of very simple and strictly defined query templates. For example, simple parameterization is not possible for queries that contain any of the following query elements:

- ▶ References to more than one table
- ▶ IN clauses or OR expressions
- ▶ UNION
- ▶ Any query hints
- ▶ DISTINCT
- ▶ TOP
- ▶ Subqueries
- ▶ GROUP BY
- ▶ Not equal (<> or !=) comparisons
- ▶ References to functions

SQL Server 2008 enables you to override the default simple parameterization behavior of SQL Server and provide parameterization for more complex queries by specifying that all SELECT, INSERT, UPDATE, and DELETE statements in a database be implicitly parameterized when they are compiled by the Query Optimizer. You enable this by setting the PARAMETERIZATION option to FORCED in the ALTER DATABASE statement:

```
ALTER DATABASE dbname SET PARAMETERIZATION {FORCED | SIMPLE}
```

Setting the PARAMETERIZATION option is an online operation that can be issued at any time and requires no database-level exclusive locks.

Forced parameterization may improve the performance of queries for certain databases by reducing the frequency of query compilations and recompilations. Essentially, forced parameterization provides the query plan reuse benefits of parameterized queries without requiring you to rewrite a single line of application code. The databases that may benefit from forced parameterization generally support OLTP-type applications that experience high volumes of concurrent queries, such as point-of-sale applications.

When the PARAMETERIZATION FORCED option is enabled, any literal value that appears in a SELECT, INSERT, UPDATE, or DELETE statement, submitted in any form, is converted to a parameter during query compilation. The exceptions are literals that appear in the following query constructs:

- ▶ INSERT...EXECUTE statements
- ▶ Statements inside the bodies of stored procedures, triggers, or user-defined functions. SQL Server already reuses query plans for these routines.
- ▶ Prepared statements that have already been parameterized by the client-side application.
- ▶ Statements inside a T-SQL cursor.

- ▶ Any statement run in a context where `ANSI_PADDING` or `ANSI_NULLS` is set to `OFF`.
- ▶ Statements that contain more than 2,097 literals eligible for parameterization.
- ▶ Statements that reference variables, such as `WHERE st.state = @state`.
- ▶ Statements that contain the `RECOMPILE` or `OPTIMIZE FOR` query hints.
- ▶ Statements that contain a `COMPUTE` clause.
- ▶ Statements that contain a `WHERE CURRENT OF` clause.

If an execution plan for a query is cached, you can determine whether the query is parameterized by referencing the `sql` column of the `sys.syscacheobjects` DMV. If a query is parameterized, the names and data types of parameters are listed in this column before the text of the submitted SQL (for example, `@1 tinyint`).

Guidelines for Using Forced Parameterization

Consider the following guidelines when determining whether to enable forced parameterization for a database:

- ▶ Forced parameterization, in effect, changes the literal constants in a query to parameters when the query is compiled, and thus, the Query Optimizer might choose suboptimal plans for queries. For example, the Query Optimizer may be less likely to match the query to an indexed view or an index on a computed column. It may also choose suboptimal plans for queries posed on partitioned tables and distributed partitioned views. Forced parameterization should not be used for environments that rely heavily on indexed views and indexes on computed columns.
- ▶ Enabling the `PARAMETERIZATION FORCED` option causes all query plans for the database to be flushed from the plan cache.
- ▶ Generally, the `PARAMETERIZATION FORCED` option should be used only by experienced database administrators after determining that doing this does not adversely affect performance.

If forced parameterization is enabled and you want to override this behavior and have simple parameterization used for a single query and any others that are syntactically equivalent but differ only in their parameter values, you can use plan guides and specify `PARAMETERIZATION SIMPLE` when creating the plan guides. Conversely, rather than enabling `PARAMETERIZATION FORCED` for an entire database, you can use plan guides and specify the `PARAMETERIZATION FORCED` query option only for a specific set of syntactically equivalent queries that you have determined would benefit from forced parameterization.

Using the `USE PLAN` Query Hint

The `USE PLAN` query hint in SQL Server 2008 can be used to encourage the Query Optimizer to use the specified XML query plan for processing the query. This option provides more control over influencing the execution of a query than is possible with the other available query hints, such as `FORCE ORDER`, `LOOP JOIN`, and `KEEP PLAN`. None of these options individually are powerful enough to influence the Query Optimizer to

consistently choose a particular query plan, especially when the referenced table row counts, statistics, indexes, and other attributes of the environment change.

The `USE PLAN` query hint is specified in the `OPTION` clause, and you provide it with a query plan in XML format. Listing 35.7 provides an example of the `USE PLAN` hint being specified for a merge join for a simple query that consists of a join between two tables. (Note: For the sake of space, the full XML plan has been truncated.)

LISTING 35.7 Specifying the **USE PLAN** Query Option

```
select st.stor_name, s.ord_date
  from sales s join stores st on s.stor_id = st.stor_id
 WHERE st.state = 'NY'
OPTION (USE PLAN N'
<?xml version="1.0" encoding="utf-16"?>
<ShowPlanXML xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"

</RelOp>
</QueryPlan>
</StmtSimple>
</Statements>
</Batch>
</BatchSequence>
</ShowPlanXML>

```

To obtain an XML-formatted query plan, which you can provide to the `USE PLAN` query hint, SQL Server 2008 provides the following methods:

- ▶ Using the `SET SHOWPLAN_XML` and `SET STATISTICS XML` session options
- ▶ Querying the plan column of the `sys.dm_exec_query_plan` dynamic management view for a cached query plan
- ▶ Using SQL Server Profiler and capturing either the `Showplan XML`, `Showplan XML Statistics Profile`, or `Showplan XML For Query Compile` event classes

NOTE

When the XML query plan contains a character string in single quotation marks (`'`), the quotation marks must be escaped by a second quotation mark before using the plan with the `USE PLAN` query hint. For example, a plan that contains `WHERE A.varchar = 'This is a string'` must be escaped by modifying the code to `WHERE A.varchar = ''This is a string''`; otherwise, it will generate a syntax error when submitted for execution.

You may choose to use the `USE PLAN` hint for queries where the execution plan chosen leads to slow execution times but for which you know a better plan exists. This scenario may commonly occur for queries that might have executed well in an earlier version of SQL Server but that perform poorly under an upgraded version. Another scenario could be a complex query that involves multiple tables where the compiled or recompiled query plan generated is occasionally not optimal, possibly as a result of out-of-date or missing statistics in any of the underlying tables or because of complex constructs in the query

that cause the Query Optimizer to inaccurately estimate the size of the intermediate query results.

The `USE PLAN` query hint can be specified only for `SELECT` and `SELECT INTO` statements. Also, you can force only query plans that can be produced by the Query Optimizer's normal optimization strategy.

Because the `USE PLAN` option requires that the XML execution plan be hard-coded in the SQL statement itself, it is not a viable solution for deployed or third-party applications where it may not be possible or feasible to modify the queries directly. It's really useful only as a tool for troubleshooting poorly running queries. To force query plans to apply query hints to queries when you cannot or do not want to directly change the application or SQL code, you might consider using plan guides.

Using Plan Guides

At times, you might find it necessary to use query hints to improve the performance of queries for a particular query or a small set of queries. Although this may be easy to do when you have access to the application code, often the particular queries to be modified are embedded within a third-party application, and alteration of the queries themselves is virtually impossible. Also, if you start hard-coding query hints in your application code, changing them as necessary when data volumes change or when upgrading to a new version of SQL Server can be a difficult undertaking.

The plan guides feature in SQL Server 2008 provides an ideal solution for such scenarios by offering another mechanism for injecting query hints into the original query without having to modify the query itself. The plan guides mechanism uses an internal lookup system table, based on information in the `sys.plan_guides` catalog view, to map the original query to a substitute query or query template.

As described earlier in this chapter, when a SQL statement is submitted, it is first compared against the cached plans to check for a match. If a match exists, the cached query plan is used to execute the query. If no cached plan exists for the query, the Query Optimizer next looks for a match against the set of existing plan guides, if any, stored in the current database for a match. If an active plan guide that matches the SQL statement is found, the original matching statement is substituted with the one from the plan guide, the query plan is compiled and cached, and the query is executed using the plan generated from the plan guide.

Queries that can benefit from plan guides are generally those that are parameter based and those that are likely performing poorly because they use cached query plans whose parameter values do not represent a more representative scenario.

The plan guides feature essentially consists of two stored procedures to create, drop, enable, and disable plan guides and the `sys.plan_guides` metadata view that describes the stored plan guides. Plan guides are created and administered by using the two system stored procedures:

- ▶ `sp_create_plan_guide`

► `sp_control_plan_guide`

The syntax for these procedures is as follows:

```
sp_create_plan_guide [ @name = ] N'plan_guide_name'
    , [ @stmt = ] N'statement_text'
    , [ @type = ] N'{ OBJECT | SQL | TEMPLATE }'
    , [ @module_or_batch = ]
        {
            N'[ schema_name. ] object_name'
            | N'batch_text'
            | NULL
        }
    , [ @params = ] { N'@parameter_name data_type [ ,...n ]' | NULL }
    , [ @hints = ] { N'OPTION ( query_hint [ ,...n ] )'
        | N'XML_execution plan'
        | NULL }
```

```
sp_control_plan_guide [ @operation = ] N'<control_option>'
    [ , [ @name = ] N'plan_guide_name' ]
```

```
<control_option>::=
{
    DROP
    | DROP ALL
    | DISABLE
    | DISABLE ALL
    | ENABLE
    | ENABLE ALL
}
```

Note that in SQL Server 2008, the `sp_create_plan_guide` stored procedure enables you to pass an XML execution plan directly in the `@hints` parameter instead of embedding the output in a `USE PLAN` hint. This capability simplifies the process of applying a fixed query plan as a plan guide hint.

In addition, a new stored procedure, `sp_create_plan_guide_from_handle`, allows you to create one or more plan guides from a query plan in the plan cache. The syntax for `sp_create_plan_guide_from_handle` is as follows:

```
sp_create_plan_guide_from_handle [ @name = ] N'plan_guide_name'
    , [ @plan_handle = ] plan_handle
    , [ [ @statement_start_offset = ] { statement_start_offset | NULL } ]
```

Instead of specifying an actual XML execution plan, you pass the handle for a query plan currently in the plan cache to the `@plan_handle` parameter. As shown previously in this chapter, a `plan_handle` can be obtained from the `sys.dm_exec_query_stats` DMV. If the

cached plan contains multiple queries in a SQL batch, you can specify the starting position of the statement within the batch via the `@statement_start_offset` parameter. The statement offset corresponds to the `statement_start_offset` column in the `sys.dm_exec_query_stats` dynamic management view. If no statement offset is specified, a plan guide is created for each statement in the batch using the query plan for the specified plan handle. The resulting plan guides are equivalent to plan guides that use the `USE PLAN` query hint to force the use of a specific plan.

Creating Plan Guides

Plan guides can be created to match queries executed in the following contexts:

- ▶ An `OBJECT` plan guide matches queries that execute in the context of T-SQL stored procedures, scalar functions, or multistatement table-valued functions.
- ▶ A `SQL` plan guide matches queries that execute in the context of ad hoc T-SQL statements and batches that are not part of a stored procedure or other compiled database object.
- ▶ A `TEMPLATE` plan guide matches ad hoc queries that parameterize to a specified form. These plan guides are used to override the current `SET PARAMETERIZATION` database option.

In the `sp_create_plan_guide` statement, you specify the query that you want optimized and provide the `OPTION` clause with the query hints necessary to optimize the query in the manner desired, or an `XML` execution plan for the query plan you want the query to use. When the query executes, SQL Server matches the query to the plan guide and applies the forced query plan to the query at runtime.

The plan guide can specify any of the following query hints individually or combined with others, when applicable:

- ▶ `{HASH | ORDER} GROUP`
- ▶ `{CONCAT | HASH | MERGE} UNION`
- ▶ `{LOOP | MERGE | HASH} JOIN`
- ▶ `FAST n`
- ▶ `FORCE ORDER`
- ▶ `MAXDOP number_of_processors`
- ▶ `OPTIMIZE FOR (@variable_name = literal_constant) [,...n]`
- ▶ `OPTIMIZE FOR UNKNOWN`
- ▶ `RECOMPILE`
- ▶ `ROBUST PLAN`
- ▶ `KEEP PLAN`
- ▶ `KEEPFIXED PLAN`

- ▶ EXPAND VIEWS
- ▶ MAXRECURSION *number*
- ▶ TABLE HINT (*object_name* [, *table_hint* [[,]...*n*]])
- ▶ USE PLAN <*xmlplan*>
- ▶ PARAMETERIZATION { SIMPLE | FORCED }

The PARAMETERIZATION { SIMPLE | FORCED } query hint can be used only within a plan guide, and it specifies whether a query is parameterized as part of compiling a query plan. This option overrides the current setting of the PARAMETERIZATION option set at the database level.

Listing 35.8 provides a sample plan guide created for a simple SQL statement.

LISTING 35.8 Creating a Plan Guide for a Simple SQL Statement

```
sp_create_plan_guide @name = N'PlanGuide1',
@stmt = N'SELECT COUNT(*) AS Total
FROM dbo.sales s, dbo.titles t
WHERE s.title_id = t.title_id
and t.pubdate BETWEEN ''1/1/2004'' AND ''1/1/2006''
',
@type = N'SQL',
@module_or_batch = NULL,
@params = NULL,
@hints = N'OPTION (HASH JOIN)'
```

For plan guides of type 'SQL' or 'TEMPLATE' to match a query successfully, the values for *batch_text* and *@parameter_name data_type [,...n]* must be provided in exactly the same format as their counterparts submitted by the application. Specifically, they must match character for character, including comments and whitespaces.

TIP

When you are creating plan guides, be careful to specify the query in the @stmt parameter and any parameter names and values in the @params parameter exactly as they are received from the application. The best way to ensure this is to capture the batch or statement text from SQL Server Profiler. (See Chapter 6 for more information on using SQL Server Profiler to capture SQL queries.) Also, as with the XML query plans passed to the USE PLAN query hint, single-quoted literal values, such as '1/1/2000', need to be delimited with single quotation marks escaped by additional single quotation marks, as shown in Listing 35.6.

Managing Plan Guides

You use the sp_control_plan_guide stored procedure to enable, disable, or drop a plan guide. The following example drops the plan guide created in Listing 35.8:

```
sp_control_plan_guide N'DROP', N'PlanGuide1'
```

To execute `sp_control_plan_guide` on a plan guide of type `OBJECT` (for example, a plan guide created for a stored procedure), you must have at least `ALTER` permission on the object that is referenced by the plan guide. For all other plan guides, you must have at least `ALTER DATABASE` permission. Attempting to drop or alter a function or stored procedure that is referenced by a plan guide results in an error.

In SQL Server 2008, it is possible to define multiple plan guides for the same query. However, only one plan guide can be active at a time. You can use `sp_control_plan_guide` to enable and disable plan guides.

Validating Plan Guides

The new system function `sys.fn_validate_plan_guide` can be used to validate a plan guide. Plan guides can become invalid after changes such as dropping an index are made to the physical design of the database. By validating a plan guide, you can determine whether the plan guide can be used unmodified by the query optimizer. The `sys.fn_validate_plan_guide` function returns the first error message encountered when the plan guide is applied to its query. If the plan guide is valid, an empty rowset is returned.

The `sys.plan_guides` Catalog View

All plan guides are stored in the `sys.plan_guides` database system catalog view. You can get information about the plan guides defined in a database by running a query against the `sys.plan_guides` catalog view, as in the following example:

```
select name, is_disabled, scope_type_desc, scope_object_id,
       parameters, hints, query_text from sys.plan_guides
```

Table 35.2 describes the columns in the `sys.plan_guides` catalog view.

TABLE 35.2 **sys.plan_guides** Columns

Column Name	Description
<code>plan_guide_id</code>	Unique identifier of the plan guide.
<code>Name</code>	Name of the plan guide.
<code>create_date</code>	Date and time the plan guide was created.
<code>modify_date</code>	Date the plan guide was last modified.
<code>is_disabled</code>	1 = disabled and 0 = enabled.
<code>query_text</code>	Text of the query on which the plan guide is created.
<code>scope_type</code>	Scope of the plan guide: 1 = <code>OBJECT</code> , 2 = <code>SQL</code> , and 3 = <code>TEMPLATE</code> .
<code>scope_type_desc</code>	Description of scope of the plan guide: <code>OBJECT</code> , <code>SQL</code> , or <code>TEMPLATE</code> .

<code>scope_object_id</code>	If <code>scope_type</code> is <code>OBJECT</code> , the <code>object_id</code> of the object defining the scope of the plan guide; otherwise, <code>NULL</code> .
<code>scope_batch</code>	If <code>scope_type</code> is <code>SQL</code> , the text of the SQL batch. If <code>NULL</code> , either the batch type is not <code>SQL</code> or <code>scope_type</code> is <code>SQL</code> , and the value of <code>query_text</code> applies.
<code>parameters</code>	The string defining the list of parameters associated with the plan guide. If <code>NULL</code> , no parameter list is associated with the plan guide.
<code>hints</code>	The query <code>OPTION</code> hints associated with the plan guide.

Plan Guide Best Practices

Following are some of the recommended best practices for using the `USE PLAN` query hint and the plan guides feature:

- ▶ The `USE PLAN` query hint and plan guides should be used only when other standard query tuning options, such as tuning indexes and ensuring the table has current statistics, have been extensively tried and have failed to produce the necessary results. When a query plan is forced by using either the `USE PLAN` query hint or a plan guide, it prevents the Query Optimizer from adapting to changing data distributions, new indexes, or improved query execution algorithms in successive SQL Server releases or service packs.
- ▶ You need to be sure to have a full understanding of query optimization and of the implications and long-term ramifications of forcing query plans.
- ▶ You should try to force only a small fraction of the workload. If you find you are forcing more than a few dozen queries, you should check whether other issues with the configuration could be limiting performance, including insufficient system resources, incorrect database configuration settings, missing indexes, poorly written queries, and other factors.
- ▶ It is not advisable to attempt to code by hand or modify the XML execution plan that is specified in the `USE PLAN` query hint. You should capture and use a plan produced by SQL Server itself. The XML execution plan is a lengthy and complex listing, and improper changes could prevent it from identically matching one of the Query Optimizer-generated plans, which would result in the `USE PLAN` hint being ignored.
- ▶ The `USE PLAN` query hint should not be directly embedded into the application code because that would make the maintenance of the application across query plan and SQL Server version changes difficult to manage. Also, embedding `USE PLAN` directly into the query generally prevents the plan for the query from being cacheable. The `USE PLAN` hint is intended primarily for ad hoc performance tuning and test purposes, and for use with the plan guides feature.
- ▶ The plan guides created for an application should be well documented and regularly backed up because they constitute an integral part of the application's performance

tuning. You should also retain the scripts that you used to create plan guides and treat them as you would other source code for an application.

- ▶ After creating a plan guide, you should test to make sure that it is being applied to the intended queries.

Verifying That a Plan Guide Is Being Applied

When you have a plan guide defined, you might want to verify that the application query is making use of the plan guide. You can follow these steps to confirm whether a plan guide is being used:

1. After creating the plan guide, run SQL Server Profiler and configure it to capture the query text and XML execution plan for the application and the query in question and start the Profiler trace.
2. Run your application and cause it to invoke the query in question.
3. Stop the profiler trace and collect the query plan by right-clicking the Showplan XML Statistics Profile event that corresponds to the query and then selecting the Extract Event Data option.
4. Save the event data to a file.
5. Open the Showplan.xml file in any text file viewer or Internet Explorer to examine the XML code.
6. If the plan guide was used to generate the query plan, the XML execution plan output contains the PlanGuideDB and PlanGuideName tags, as shown in the following example:

```
<ShowPlanXML xmlns=
"http://schemas.microsoft.com/sqlserver/2004/07/showplan"
Version="1.0" Build="9.00.1282.00">
  <BatchSequence>
    <Batch>
      <Statements>
        <StmtSimple PlanGuideDB="bigpubs2008"
PlanGuideName="PlanGuide1">
...
      </StmtSimple>
    </Statements>
  </Batch>
</BatchSequence>
</ShowPlanXML>
```

As another option to help determine whether or not plan guides are being used, you can use two new event classes available in the SQL Server 2008 Profiler: Plan Guide Successful and Plan Guide Unsuccessful. These new event classes make it easier to verify whether plan guides are being used by the Query Optimizer. For example, if SQL Server cannot produce an execution plan for a query that contains a plan guide when the initial plan guide compilation is performed, the query is automatically compiled without using the

plan guide, and the Plan Guide Unsuccessful event is raised. For more information on monitoring SQL Server using SQL Profiler, see Chapter 6.

NOTE

Note that the plan guide events are raised only during the initial compilation of a query that contains a plan guide when the query plan gets loaded into the plan cache. If you do not see either of these events, you may need to flush the plan cache using DBCC FREEPROCCACHE.

In addition, there are two new Performance Monitor counters: Guided Plan Executions/sec and Misguided Plan Executions/sec. These counters are available in the SQL Server, SQL Statistics Object. They report the number of plan executions in which the query plan has been successfully or unsuccessfully generated using a plan guide. For more information on monitoring SQL Server performance using Performance Monitor, see Chapter 39, “Monitoring SQL Server Performance.”

Creating and Managing Plan Guides in SSMS

SQL Server 2008 enables you to create, delete, enable, disable, or script plan guides within SSMS. The plan guides options are available in the Programmability folder in Object Explorer. To create a new plan guide in SSMS, right-click on Plan Guides and select the New Plan Guide option. This brings up the dialog shown in Figure 35.30.

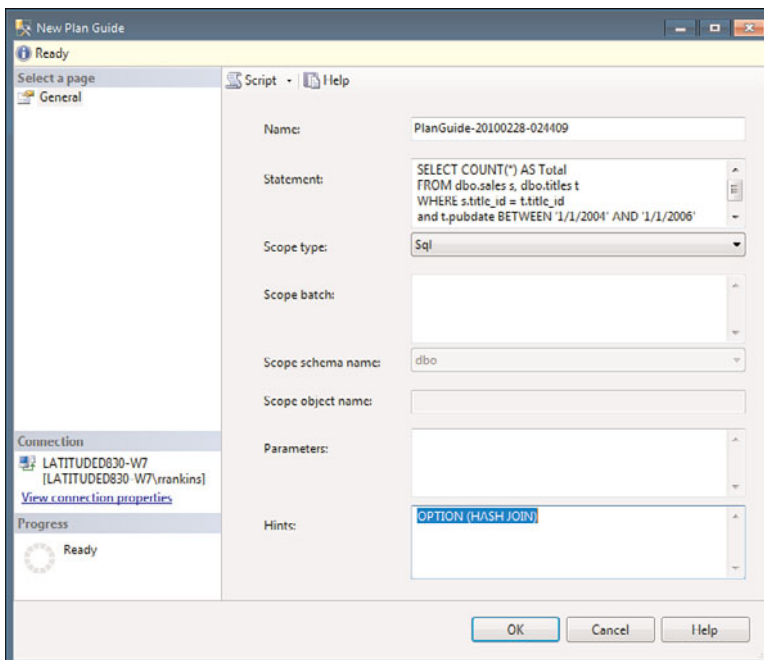

FIGURE 35.30 Creating a plan guide in SSMS.

To manage existing plan guides in SSMS, you can right-click on the plan guide name to bring up the context menu that allows you to enable, disable, delete, script, or view the properties of the plan guide, as shown in Figure 35.31.

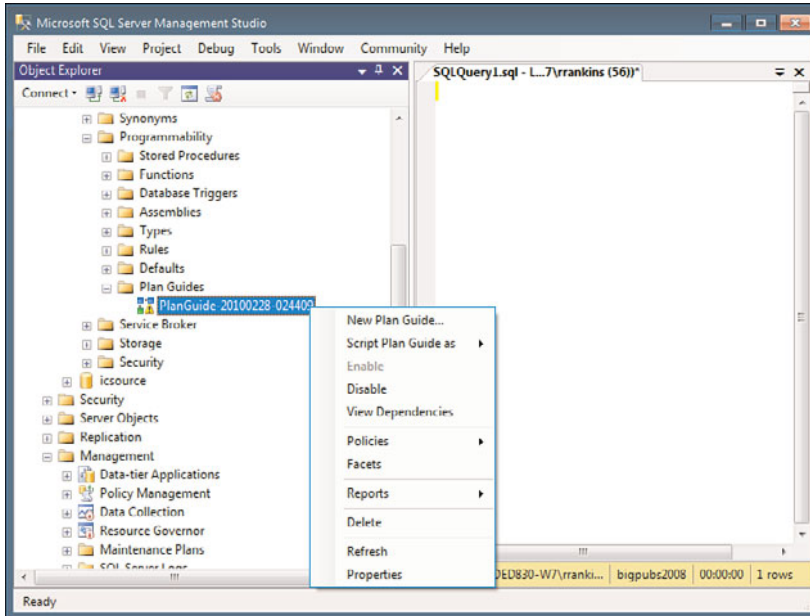

FIGURE 35.31 Managing a plan guide in SSMS.

Limiting Query Plan Execution with the Query Governor

Another tool for managing query plans in SQL Server 2008 is the query governor. Because SQL Server uses a cost-based Query Optimizer, the cost of executing a given query is always estimated before the query is actually executed. The query governor enables you to set a cost threshold to prevent certain long-running queries from being executed. This is not so much an optimization tuning tool as it is a performance problem prevention tool.

For example, if you have an application with an ad hoc reporting front end, you have no way of controlling what the user is going to request from the database and the type of query generated. The query governor allows you to prevent a runaway query from executing and using up valuable CPU and memory resources by processing a poorly formed query. You can set the query governor cost limit for the current user session by setting the session-level property `QUERY_GVERNOR_COST_LIMIT`:

```
SET QUERY_GVERNOR_COST_LIMIT value
```

The value specified is the maximum length of time, in seconds, a query is allowed to run. If the Query Optimizer estimates the query would take longer than the specified value, SQL Server does not execute it.

Although the option is specified in seconds, it is a relative value that corresponds to the estimated subtree cost, as calculated by the Query Optimizer. In other words, if you set the query governor cost limit to `100`, it prevents the execution of any queries whose estimated subtree cost is greater than 100 seconds. The estimated subtree cost time is based on the query cost algorithm in SQL Server and might not map exactly to how long the query actually takes to run on your own system. The actual runtime depends on a number of factors: CPU speed, I/O speed, network speed, the number of rows returned over the network, and so on. You need to correlate the Query Optimizer runtime estimate to how long the query actually takes to run on your system to set the query governor cost limit to a value related to actual query runtime.

The best way to figure out how to set the query governor is to run your queries with the `STATISTICS PROFILE` and `STATISTICS TIME` session settings enabled. (These settings are discussed in more detail in Chapter 36.) You then compare the values in the `TotalSubtree Cost` column for the first row of the `STATISTICS PROFILE` output with the `elapsed time` displayed by `STATISTICS TIME` for your query. If you do this for a number of your queries, you might be able to come up with an average correlation of the actual runtimes with the Query Optimizer's estimated query cost. For example, if the average cost estimate is 30 seconds and the actual runtimes are 15 seconds, you may need to double the setting for query governor cost limit to correspond to the actual execution time threshold; in other words, if you want the threshold to be 60 seconds for this example, you would want to set the query governor threshold to `120`.

To configure a query governor threshold for all user connections, you can also set it at the server level. In SSMS, right-click the server in the Object Browser and choose `Properties` from the menu. In the `Server Properties` dialog, select the `Connections` page. Enable the `Use Query Governor to Prevent Long-Running Queries` check box and specify the desired cost threshold (see Figure 35.32). The cost threshold is specified in the same units as specified for the `QUERY_GOVERNOR_COST_LIMIT` session setting.

Alternatively, you can configure the server-wide query governor setting by using `sp_configure`:

```
sp_configure query governor cost limit, 100
```

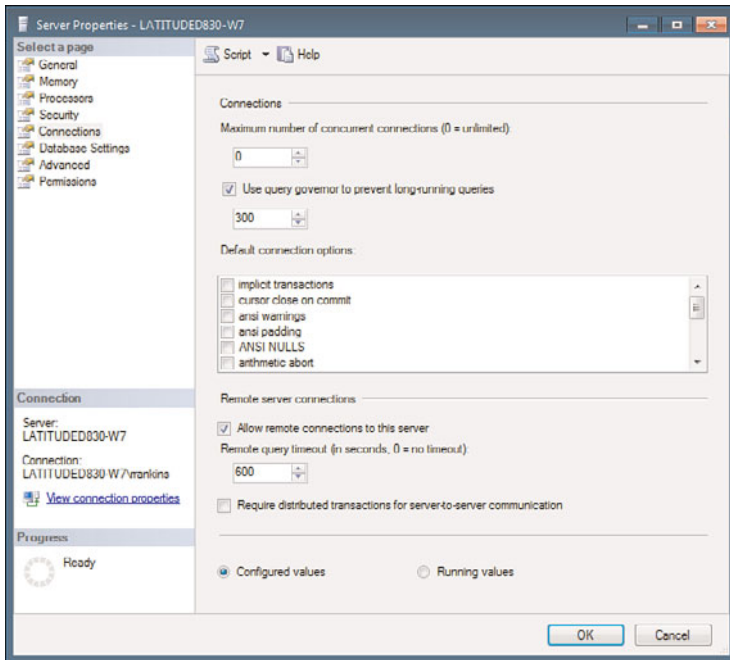

FIGURE 35.32 Configuring the query governor settings in the SQL Server Properties dialog.

Summary

The SQL Server Query Optimizer has improved over the years, taking advantage of new techniques and algorithms to improve its capability to find the most efficient execution plan. Understanding how queries are optimized and what information the Query Optimizer uses to generate and select an execution plan will help you write more efficient queries and choose better indexes. To help the Query Optimizer, you should at least try to write queries that can be optimized effectively by avoiding the common query optimization problems discussed in this chapter.

Most of the time, the Query Optimizer chooses the most efficient query plan. When it doesn't, the reason might be problems with the way the query itself is written, out-of-date or unavailable statistics, poor index design, or other common query performance problems, as discussed in this chapter. Still, on occasion, the Query Optimizer may make the wrong choice for an execution plan. When you suspect that the Query Optimizer is making the wrong decision, you can use SQL Server's table and Query Optimizer hints and the plan guide feature to override the Query Optimizer's decisions. However, before arbitrarily applying these hints, you should analyze the queries fully to try to determine why the Query Optimizer is choosing a particular plan. To aid you in this effort, SQL Server provides a number of tools to analyze the query plans generated and determine the source of the problem. These tools are described in Chapter 36.

CHAPTER 36

Query Analysis

SQL Server's cost-based Query Optimizer typically does a good job of determining the best query plan for processing a query. At times, however, you might be a little bit skeptical about the plan the Query Optimizer generates or want to understand why it is choosing a specific plan. At the least, you will want to know the specifics about the query plans the Query Optimizer is generating, such as the following:

- ▶ Is the Query Optimizer using the indexes you have defined, or is it performing table or index scans?
- ▶ Are work tables being used to process the query?
- ▶ What join strategy is being applied?
- ▶ What join order is the Query Optimizer using?
- ▶ What statistics and cost estimates is the Query Optimizer using to make its decisions?
- ▶ How do the Query Optimizer's estimates compare to actual I/O costs and row counts?

Fortunately, SQL Server provides some tools to help you answer these questions. The primary tool is SQL Server Management Studio (SSMS). SSMS provides a number of features for monitoring the estimated or actual execution plan as well as viewing the actual runtime statistics for your queries. This chapter describes how to display the graphical execution plan as well as client statistics within SSMS.

Although SSMS is a powerful and useful tool for query analysis, SQL Server still provides some text-based query

IN THIS CHAPTER

analysis utilities as well. These tools are also described in this chapter, along with tips on how to use them most effectively.

NOTE

The examples presented in this chapter use the `bigpubs2008` database because most examples require sufficient data to demonstrate many of the more interesting query plans. A copy of the `bigpubs2008` database is available on the CD included with this book. Instructions on how to obtain and install the database are presented in the Introduction.

What's New in Query Analysis

There are not many significant changes or new features related to Query Analysis provided in SQL Server 2008. The tools and commands are mostly unchanged from what was introduced in SQL Server 2005. One new useful enhancement, however, is the Missing Index Hints feature available when displaying the Execution Plan of a query in SSMS.

Query Analysis in SSMS

The main tool for query analysis in SQL Server 2008 is the Query Editor available in SSMS. The SSMS Query Editor can produce a graphical execution plan that provides analysis information in an intuitive and easy-to-view manner. You can display the execution plan in one of two ways: the estimated execution plan or the actual execution plan.

You can display an estimated execution plan for the entire contents of the query window, or for any highlighted SQL code in the query window, by choosing Display Estimated Execution Plan from the Query menu. You can also invoke it by using the Ctrl+L keyboard shortcut. This feature is useful for displaying and analyzing execution plans for long-running queries or queries with large result sets without having to actually run the query and wait for the results to be returned.

You can also display the actual execution plans for queries as they are executed by selecting the Include Actual Execution Plan option from the Query menu or by using the Ctrl+M keyboard shortcut. This option is a toggle that remains on until you select it again to disable it. When this option is enabled, your query results are displayed, along with an Execution Plan tab in the Results panel. Click the Execution Plan tab to display the execution plan for the query or queries that are executed. This option is especially useful when you want to execute commands and compare the actual runtime and I/O statistics with the execution plan estimates. (These statistics can be displayed with the `SET STATISTICS` options described in the “Query Statistics” section, later in this chapter.)

The graphical execution plans display a series of nodes connected by lines. Each node is represented by an icon, which indicates the logical and physical operator executed for that node. The execution plan flows from right to left and top to bottom, eventually ending at a statement icon, which indicates the type of query that generated the execution plan.

This query might be a SELECT, INSERT, UPDATE, TABCREATE, and so on. The arrows between the icons indicate the movement of rows between operators. If the query window contains multiple statements, multiple query execution plans are displayed in the Execution Plan tab. For each query in the batch that is analyzed and displayed, the relative cost of the query is displayed as a percentage of the total cost of the batch.

To interpret and analyze the execution plan output, you start with the farthest icon on the right and read each ToolTip as you move left and down through the tree. Each icon in the query tree is called a *node*, and icons displayed under each other participate in the same level of the execution tree.

NOTE

The displayed width of each of the arrowhead lines in the graphical execution plan can indicate the relative cost, in estimated number of rows, and the row and data size of the data moving through the query. The smaller the width of the arrow, the smaller the estimated row count or row size. Moving the cursor over the line displays a ToolTip that indicates the estimated row count and row and data size.

Figure 36.1 shows a sample SSMS graphical execution plan window.

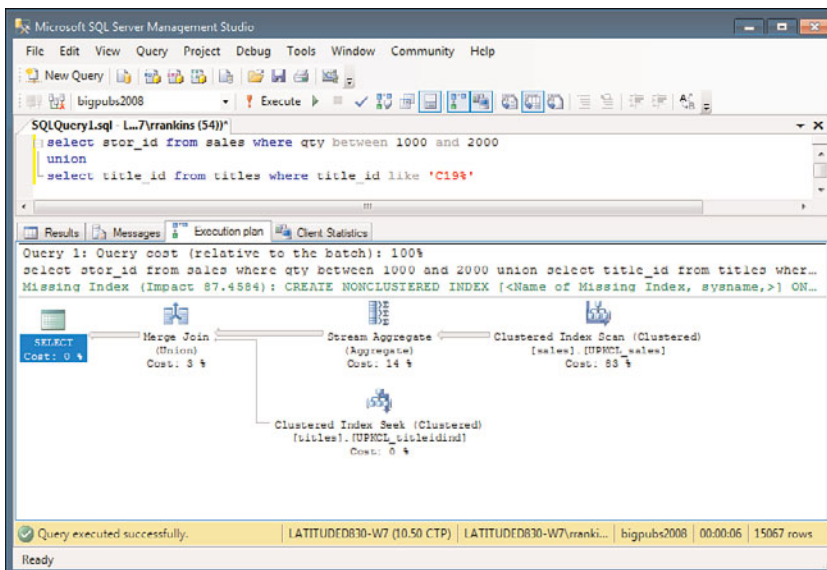

FIGURE 36.1 SSMS graphical execution plan.

The following sections describe the icons and information provided in the graphical execution plan.

Execution Plan ToolTips

When a graphical execution plan is presented in the Query Analyzer, you can get more information about each node in the execution plan by moving the mouse cursor over one of the icons. ToolTips for estimated execution plans are slightly different from the ToolTips displayed for an execution plan that is generated when a query is actually executed. The ToolTip displayed for an estimated execution plan provides the following information:

- ▶ **Physical Operation**—Lists the physical operation being performed for the node, such as a Clustered Index Scan, Index Seek, Aggregate, Hash or Nested Loop Join, and so on.
- ▶ **Logical Operation**—Lists the logical operation that corresponds with the physical operation, such as the logical operation of a union being physically performed as a merge join. The logical operator, if different from the physical operator, is listed in parentheses below the physical operator in the icon text in the graphical execution plan. Essentially, the logical operators describe the relational operation used to process a statement, while the physical operation describes how it is being performed.
- ▶ **Estimated I/O Cost**—Indicates the estimated relative I/O cost for the operation. Preferably, this value should be as low as possible.
- ▶ **Estimated CPU Cost**—Lists the estimated relative CPU cost for the operation.
- ▶ **Estimated Number of Executions**—Lists the estimated number of times this operation will be executed.
- ▶ **Estimated Operator Cost**—Indicates the estimated cost to execute the physical operation. For best performance, you want this value as low as possible.
- ▶ **Estimated Number of Rows**—Lists the estimated number of rows to be output by the operation and passed on to the parent operation.
- ▶ **Estimated Row Size**—Indicates the estimated average row size of the rows being passed through the operator.
- ▶ **Estimated Subtree Cost**—Lists the estimated cumulative total cost of this operation and all child operations preceding it in the same subtree.
- ▶ **Object**—Indicates which database object is being accessed by the operation being performed by the current node.
- ▶ **Predicate**—Indicates the search predicate specified for the object in the original query.
- ▶ **Seek Predicates**—Indicates the search predicate being used in the seek against the index when an index seek is being performed.
- ▶ **Output List**—Indicates which columns of data are being returned by the operation.

- ▶ **Ordered**—Indicates whether the rows are being retrieved via an index in sorted order.
- ▶ **Node ID**—Lists a unique identifier of the node within the execution plan.

Some operators may also include the Actual Rebinds and Actual Rewinds counts. When an operator is on the outer side of a loop join, Actual Rebinds equals 1 and Actual Rewinds equals 0. If an operator is on the inner side of a loop join, the sum of the number of rebinds and rewinds should equal the number of rows returned by the table on the outer side of the join. A rebind means that one or more of the correlated parameters of the join changed and the inner side must be reevaluated. A rewind means that none of the correlated parameters changed and the prior inner result set may be reused.

NOTE

Depending on the type of operator and other query characteristics, not all the preceding items are displayed in the Tooltip.

The ToolTips for an execution plan generated when the query is actually executed display the same information as the estimated execution plan, but the Tooltip also displays the actual number of rows returned by the operation and the actual number of executions. This information is useful in determining the effectiveness of the statistics on the column or index because it helps you compare how closely the estimated row count matches the actual row count. If a significant difference exists (significant being a relative term), you might need to update the statistics and possibly increase the sample size used when the statistics are updated to generate more accurate statistics.

Figure 36.2 displays a sample Tooltip. Notice the difference between the Estimated Number of Rows value (8325.01) and the Actual Number of Rows value (160). This indicates an obvious issue with missing or out-of-date statistics.

NOTE

To achieve the large difference between the actual row count and estimated row count shown in Figure 36.2, we disabled the `AUTO-CREATE STATISTICS` option for the database. If this option is not disabled, SQL Server automatically generates the missing statistics on the `ord_date` column before generating the execution plan. With the column statistics generated, it would likely come up with a better row estimate.

In this example, the Tooltip displays the information for a Table Scan physical operation. The Estimated I/O Cost and Estimated CPU Cost provide critical information about the relative performance of this query. You want these numbers to be as low as possible.

The Estimated Subtree Cost displays cumulated costs for this node and any previous nodes that feed into it. This number increases as you move from right to left in the execution plan diagram. For the next-to-last icon for a query execution path (the icon leading into the statement icon), the Tooltip displays the Total Estimated Subtree Cost for the entire query.

Table Scan	
Scan rows from a table.	
Physical Operation	Table Scan
Logical Operation	Table Scan
Actual Number of Rows	160
Estimated I/O Cost	1.14172
Estimated CPU Cost	0.185676
Estimated Number of Executions	1
Number of Executions	1
Estimated Operator Cost	1.3274 (100%)
Estimated Subtree Cost	1.3274
Estimated Number of Rows	8325.01
Estimated Row Size	48 B
Actual Rebinds	0
Actual Rewinds	0
Ordered	False
Node ID	0
Predicate	
[bigpubs2008].[dbo].[new_sales].[ord_date] =CONVERT_IMPLICIT(datetime,[@1],0)	
Object	
[bigpubs2008].[dbo].[new_sales]	
Output List	
[bigpubs2008].[dbo].[new_sales].stor_id, [bigpubs2008].[dbo].[new_sales].ord_num, [bigpubs2008].[dbo].[new_sales].ord_date, [bigpubs2008].[dbo].[new_sales].qty, [bigpubs2008]. [dbo].[new_sales].payterms, [bigpubs2008].[dbo]. [new_sales].title_id	
Warnings	
Columns With No Statistics: [bigpubs2008].[dbo]. [new_sales].ord_date	

FIGURE 36.2 A ToolTip example.

NOTE

The total Estimated Subtree Cost displayed for the statement icon is the cost compared against the query governor cost limit setting, if enabled, to determine whether the query will be allowed to run. For more information on configuring and setting the query governor cost limit, see Chapter 35, “Understanding Query Optimization.”

The Predicate section outlines the predicates and parameters the query uses. This information is useful in determining how the Query Optimizer is interpreting your search arguments (SARGs) and if they are being interpreted as SARGs that can be optimized effectively.

Putting all the ToolTip information together provides the key to understanding each operation and its potential cost. You can use this information to compare various incarnations of a query to determine whether changes to the query result in improved query plans and whether the estimated values are consistent with actual values.

NOTE

If the Query Optimizer has issued a warning about one of the execution plan operators, such as missing column statistics or missing join predicates, the icon is displayed with a yellow warning triangle (see Figure 36.3). These warnings indicate a condition that can cause the Query Optimizer to choose a less efficient query plan than otherwise expected. The ToolTip for the operation with the warning icon includes a Warnings item that indicates why the warning was generated.

The screenshot shows the Microsoft SQL Server Management Studio interface. The query window contains the following SQL code:

```
SQLQuery1.sql - L:\7\rrankins (54)*
select title from new_sales s
join titles t
on t.title_id = s.title_id
where ord_date = '2008-01-01 00:00:00.000'
```

The Execution Plan tab is active, showing a graphical execution plan. A yellow warning triangle is visible on the 'Table Scan' operator. The tooltip for this operator is displayed, showing the following details:

Table Scan	
Scan rows from a table.	
Physical Operation	Table Scan
Logical Operation	Table Scan
Actual Number of Rows	160
Estimated I/O Cost	1.14164
Estimated CPU Cost	0.185754
Estimated Number of Executions	1
Number of Executions	1
Estimated Operator Cost	1.3274 (88%)
Estimated Subtree Cost	1.3274
Estimated Number of Rows	8325.01
Estimated Row Size	22 B
Actual Rebinds	0
Actual Rewinds	0
Ordered	False
Node ID	2
Predicate	
[bigpubs2008].[dbo].[new_sales].[ord_date] as [s].	
[ord_date]= '2008-01-01 00:00:00.000'	
Object	
[bigpubs2008].[dbo].[new_sales] [s]	
Output List	
[bigpubs2008].[dbo].[new_sales].title_id	
Warnings	
Columns With No Statistics: [bigpubs2008].[dbo].[new_sales].title_id	

The status bar at the bottom indicates 'Query executed successfully.' and 'LATITUDE0830-W7 (10.50 CT)'. The bottom right corner of the tooltip shows '0 | 160 rows'.

FIGURE 36.3 An example of an execution plan with warnings.

If you prefer to view the information about a node in an execution tree in more detail and with something more stable than a ToolTip, you can right-click the node and select Properties. This brings up the Properties window, as shown in Figure 36.4.

The Properties window provides all the same information available in the ToolTip and also provides some more detailed information, along with descriptions of the types of information provided.

NOTE

For more examples of graphical execution plans, see Chapter 35. The sections that discuss the different query strategies contain examples of the graphical showplans that correspond to the strategies. Many of these showplans provide various examples of the operator icons discussed in this section.

The screenshot displays the Microsoft SQL Server Management Studio interface. The query editor shows the following SQL query:

```
select title from new_sales s
join titles t
on t.title_id = s.title_id
where ord_date = '2008-01-01 00:00:00.000'
```

The execution plan shows a Hash Match (Inner Join) node with a cost of 12, which is connected to an Index Scan (NonClustered) node with a cost of 0 and a Table Scan (new_sales) [s] node with a cost of 88. The Properties window for the Table Scan node is open, showing details such as Actual Number of Rows (160), Estimated CPU Cost (0.185754), and Estimated I/O Cost (1.14164).

FIGURE 36.4 The query execution plan node properties.

Logical and Physical Operator Icons

If you want to better understand the graphical execution plans displayed in SSMS, it helps to be able to recognize what each of the displayed icons represents. Recognizing them is especially valuable when you need to quickly locate operations that appear out of place for the type of query being executed. The following sections cover the more common logical and physical operators displayed in the Query Analyzer execution plans.

Assert

Assert is used to verify a condition, such as referential integrity (RI) or check constraint, or to ensure that a scalar subquery returns only a single row. It acts as sort of a roadblock, allowing a result stream to continue only if the check being performed is satisfied. The argument displayed in the Assert ToolTip spells out each check being performed.

For example, a deletion from the titles table in the bigpubs2008 database has to be verified to ensure that it doesn't violate referential integrity with the sales and titleauthors table. The reference constraints need to check that the title_id being deleted does not exist in either the sales or titleauthors tables. If the result of the Assert returns a NULL, the stream continues through the query. Figure 36.5 shows the estimated execution plan and ToolTip of the Assert that appears for a delete on titles. The Predicate indicates that the reference constraint rejects any case in which the matching foreign key expression that returns from both child tables is NOT NULL. Notice that it returns a different value (0

or 1), depending on the table on which the foreign key violation occurs so that the appropriate error message can be displayed.

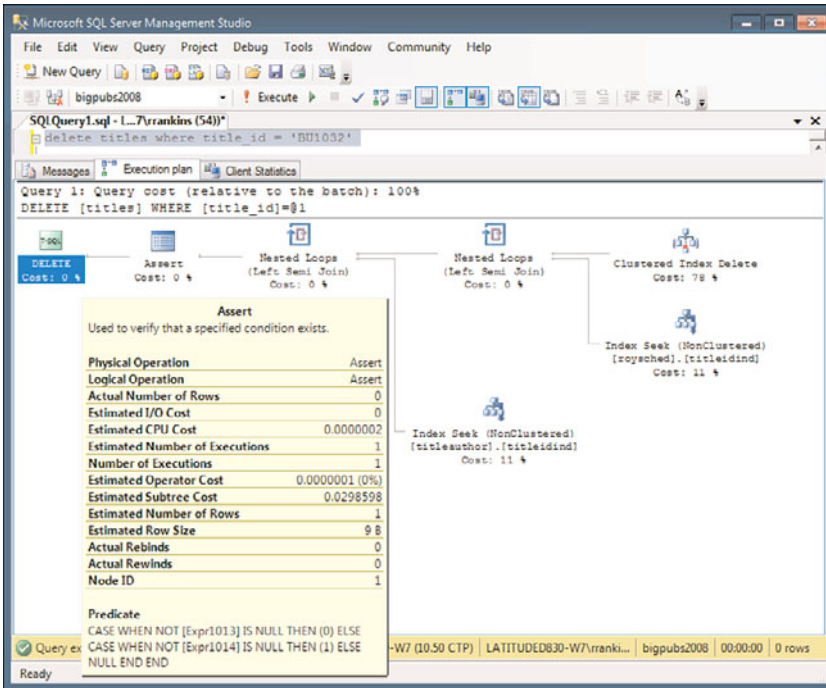

FIGURE 36.5 An Assert example.

Clustered Index Delete  , **Insert**  , and **Update** 

The Clustered Index physical operators Delete, Insert, and Update indicate that one or more rows in the specified clustered index are being deleted, inserted, or updated. The index or indexes affected by the operation are specified in the Object item of the ToolTip. The Predicate indicates which rows are being deleted or which columns are being updated.

Nonclustered Index Delete  , **Insert**  , and **Update** 

Similar to the Clustered Index physical operators Delete, Insert, and Update, the Nonclustered Index physical operators Delete, Insert, and Update indicate that one or more rows in the specified nonclustered index are being deleted, inserted, or updated.

Clustered Index Scan  and **Seek** 

A Clustered Index Seek is a logical and physical operator that indicates the Query Optimizer is using the clustered index to find the data rows via the index pointers. A Clustered Index Scan (also a logical and physical operator) indicates whether the Query

Optimizer is scanning all or a subset of the table or index rows. Note that a table scan against a table with a clustered index displays as a Clustered Index Scan; the Query Optimizer is performing a full scan against all data rows in the table, which are in clustered key order.

Figure 36.6 shows a Clustered Index Seek ToolTip. The ToolTip indicates that the seek is being performed against the UPK_Storeid index on the stores table. The Seek Predicates item indicates the search predicate being used for the lookup against the clustered index, and the Query Optimizer determines that the results will be output in clustered index order, as indicated by the Ordered item indicating true.

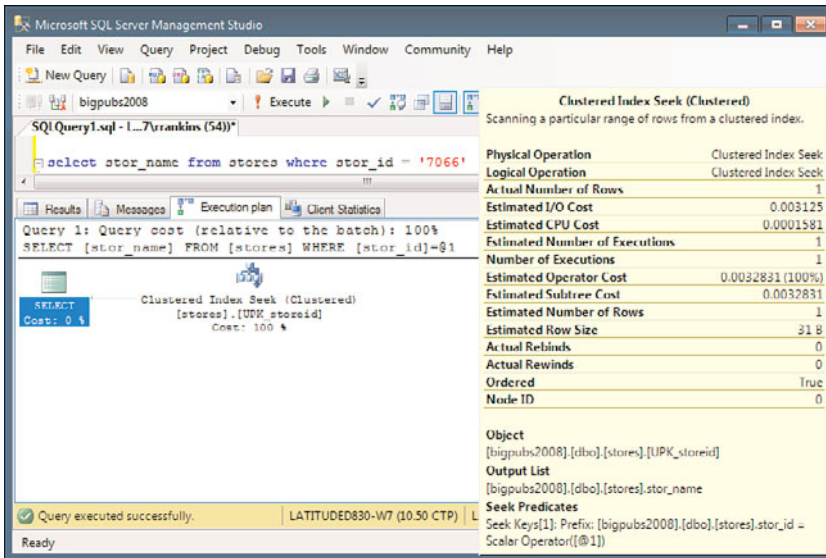

FIGURE 36.6 Clustered Index Seek ToolTip example.

Nonclustered Index Scan  and Seek 

A Nonclustered Index Seek is a logical and physical operator that indicates the Query Optimizer is using the nonclustered index to find the data rows via the index pointers. A Nonclustered Index Scan (also a logical and physical operator) indicates whether the Query Optimizer is scanning all or a subset of the nonclustered index rows. The Seek Predicates item in a Nonclustered Index Seek operator identifies the search predicate being used for the lookup against the nonclustered index. The Ordered item in the ToolTip indicates true if the rows will be returned in nonclustered index key order.

Collapse  and Split 

A Split physical and logical operator indicates that the Query Optimizer has decided to break the rows' input from the previous update optimization step into a separate delete and insert operation. The Estimated Number of Rows in the Split icon ToolTips is normally double the input row count, reflecting this two-step operation. If possible, the

Query Optimizer might choose later in the plan to collapse those rows, grouping by a key value. The collapse typically occurs if the query processor encounters adjacent rows that delete and insert the same key values.

Compute Scalar

The Query Optimizer uses the Compute Scalar operator to output a computed scalar value. This value might be returned in the result set or used as input to another operation in the query, such as a Filter operator. You might see this operator when data values that are feeding an input need to be converted to a different data type first.

Concatenation [

The Concatenation operator indicates that the result sets from two or more input sources are being concatenated into a single output. You often see this when a UNION ALL is being used. You can force a concatenation union strategy by using the OPTION clause in the query and specifying a CONCAT UNION. Optimization of UNION queries, with examples of the execution plan outputs, is covered in Chapter 35.

Constant Scan

The Constant Scan operator introduces one or more constant rows into a query. A Compute Scalar operation sometimes is used to provide input to the Constant Scan operator. A Compute Scalar operator often follows a Constant Scan operator to add columns to any rows produced by the Constant Scan operator.

Deleted Scan and Inserted Scan

The Deleted Scan and Inserted Scan icons in the execution plan indicate that a trigger is being fired and that within that trigger, the Query Optimizer needs to scan either the deleted or inserted tables.

Filter

The Filter icon indicates that the input rows are being filtered according to the predicate indicated in the ToolTip. This operator is used primarily for intermediate operations that the Query Optimizer needs to perform.

Hash Match

Hash joins are covered in more detail in Chapter 35, but to understand the Hash Match physical operator, you must understand the basic concept of hash joins to some degree.

In a hash join, the keys common between the two tables are hashed into a hash bucket, using the same hash function. This bucket usually starts out in memory and then moves to disk as needed. The type of hashing that occurs depends on the amount of memory required. Hashing is commonly used for inner and outer joins, intersections, unions, and differences. The Query Optimizer often uses hashing for intermediate processing.

A hash join requires at least one equality clause in the predicate, which includes the clauses used to relate a primary key to a foreign key. Usually, the Query Optimizer selects a hash join when the input tables are unsorted or are different in size, when no appro-

appropriate indexes exist, or when specific ordering of the result is not required. Hash joins help provide better query performance for large databases, complex queries, and distributed tables.

A hash match operator uses the hash join strategy and might also include other criteria to be considered a match. The other criteria are indicated in the Probe Residual clause shown in the Hash Match ToolTip.

Nonclustered Index Spool , Row Count Spool , and Table Spool

An Index Spool, Row Count Spool, or Table Spool icon indicates that the rows are being stored in a hidden spool table in the tempdb database, which exists only for the duration of the query. Generally, this spool is created to support a nested iteration operation because the Query Optimizer might need to use the rows again. If the operator is rewound (for example, by a Nested Loops operator) but no rebinding is needed, the spooled data is used instead of rescanning the input data.

Often, you see a Spool icon under a Nested Loops icon in the execution plan. A Table Spool ToolTip does not show a predicate because no index is used. An Index Spool ToolTip shows a SEEK predicate. A temporary work table is created for an index spool, and then a temporary index is created on that table. These temporary work tables are local to the connection and live only as long as the query.

The Row Count Spool operator counts how many rows are present in the input and returns just the number of rows. This operator is used when checking for the existence of rows, rather than the actual data contained in the rows (for example, an existence subquery or an outer join when the actual data from the inner side is not needed).

Eager Spool or Lazy Spool

The Query Optimizer selects to use either an Eager or Lazy method of filling the spool, depending on the query. The Eager method means that the spool table is built all at once upon the first request for a row from the parent operator. The Lazy method builds the spool table as a row is requested by its parent operator.

Log Row Scan

The Log Row Scan icon indicates that the transaction log is being scanned.

Merge Join

The merge join is a strategy requiring that both the inputs be sorted on the common columns, defined by the predicate. The Merge Join operator may be preceded by an explicit sort operation in the query plan. A merge join performs one pass through each input table, matching the columns defined in the WHERE or JOIN clause as it steps through each input. A merge join looks similar to a simple nested loop but uses only a single pass of each table. Occasionally, you might see an additional sort operation prior to the merge join operation when the initial inputs are not sorted properly. Merge joins are often used to perform inner joins, left outer joins, left semi-joins, left anti-semi-joins, right outer joins, right semi-joins, right anti-semi-joins, and union logical operations.

Nested Loops

Nested loop joins are also known as nested iteration. Basically, in a nested iteration, every qualifying row in the outer table is compared to every qualifying row in the inner table. This is why you may at times see a Spool icon of some sort providing input to a Nested Loop icon. This allows the inner table rows to be reused (that is, rewound). When every row in each table is being compared, it is called a naïve nested loops join. If an index is used to find the qualifying rows, it is referred to as an index nested loops join. Nested loops can be used to perform inner joins, left outer joins, left semi-joins, and left anti-semi-joins.

The number of comparisons performed for a nested loop join is the calculation of the number of outer rows times the estimated number of matching inner rows for each lookup. This can become expensive. Generally, a nested loop join is considered to be most effective when both input tables are relatively small.

Parameter Table Scan

The Parameter Table Scan icon indicates that a table is acting as a parameter in the current query. Typically, this icon is displayed when INSERT queries exist in a stored procedure.

Remote Delete , Remote Insert , Remote Query , Remote Scan , and Remote Update

The Remote Delete, Remote Insert, Remote Query, Remote Scan, and Remote Update operators indicate that the operation is being performed against a remote object such as a linked table.

RID Lookup

The RID Lookup operator indicates that a bookmark lookup is being performed on a heap table using a row identifier (RID). The ToolTip indicates the bookmark label used to look up the row and the name of the table in which the row is being looked up. The RID Lookup operator is always accompanied by a Nested Loop Join operator.

Sequence

The Sequence operator executes each operation in its child node, moving from top to bottom in sequence, and returns only the end result from the bottom operator. You see this most often in the updates of multiple objects.

Sort

The Sort operator indicates that the input is being sorted. The sort order is displayed in the ToolTip's Order By item.

Stream Aggregate

You most often see the Stream Aggregate operation when you are aggregating a single input, such as a `DISTINCT` clause or a `SUM`, `COUNT`, `MAX`, `MIN`, or `AVG` operator. The output of this operator may be referenced by later operators in the query, returned to the client, or both.

Because the Stream Aggregate operator requires input ordered by the columns within its groups, a Sort operator often precedes the Stream Aggregate operator unless the data is already sorted due to a prior Sort operator or due to an ordered index seek or scan.

Table Delete , Table Insert , Table Scan , and Table Update

You see the Table Delete, Table Insert, Table Scan, and Table Update operators when the indicated operation is being performed against that table as a whole. The presence of these operators does not always mean a problem exists, although a table scan can be an indicator that you might need some indexes to support the query. A table scan may be performed on small tables even if appropriate indexes exist, especially when the table is only a single page or two in size.

Table-valued Function

The Table-valued Function operator is displayed for queries with calls to table-valued functions. The Table-valued Function operator evaluates the table-valued function, and the resulting rows are stored in the `tempdb` database. When the parent operators request the rows, the Table-valued Function operator returns the rows from `tempdb`.

Top

The Top operator indicates a limit that is set, either by number of rows or a percentage, on the number of results to be returned from the input. The ToolTip may also contain a list of the columns being checked for ties if the `WITH TIES` option has been specified.

Parallelism Operators

The Parallelism operators indicate that parallel query processing is being performed. The associated logical operator displayed is one of the Distribute Streams, Gather Streams, or Repartition Streams logical operators.

Distribute Streams  The Distribute Streams operator takes a single input stream of records and produces multiple output streams. Each record from the input stream appears in one of the output streams. Hashing is typically used to decide to which output stream a particular input record belongs.

Gather Streams  The Gather Streams operator consumes several input streams and produces a single output stream of records by combining the input streams. If the output is ordered, the ToolTip will contain an `Order By` item indicating the columns being ordered.

Repartition Streams  The Repartition Streams operator consumes multiple streams and produces multiple streams of records. Each record from an input stream is placed into one output stream. If the output is ordered, the ToolTip contains an `Order By` item indicating the columns being ordered.

NOTE

Parallel query processing strategies are covered in more detail in Chapter 35.

Analyzing Stored Procedures

When displaying the estimated execution plan for a stored procedure, you see multiple statement operators as inputs to the Stored Procedure operator, especially if you have any conditional branching in the stored procedure. One operator exists for each statement defined in the stored procedure. When conditional branching occurs in the stored procedure, SQL Server does not know at query optimization time which statements in the stored procedure will actually be executed, so it has to estimate a query plan for each individual statement. An example is shown in Figure 36.7.

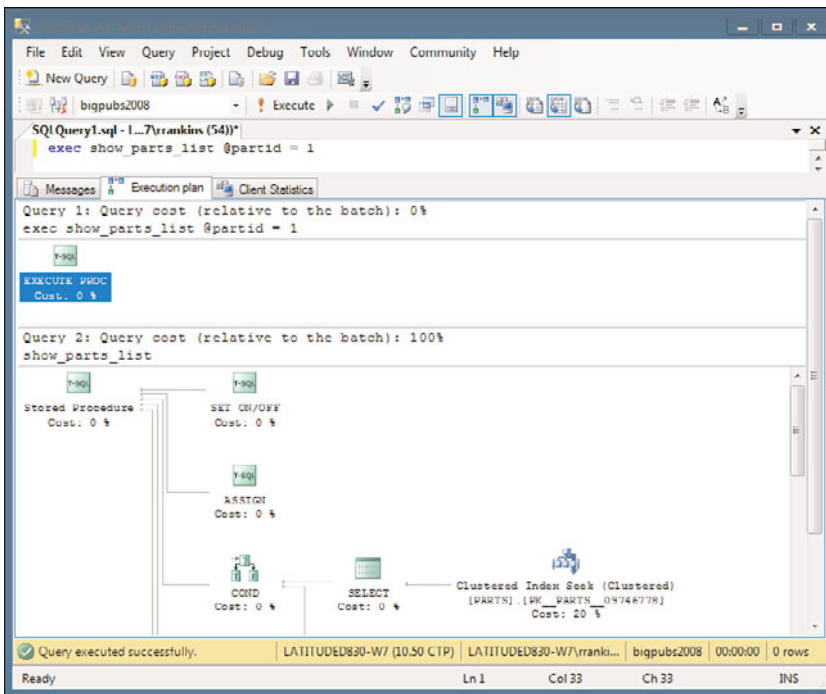

FIGURE 36.7 Estimated execution plan for a stored procedure.

When you execute the stored procedure with the Show Execution Plan option enabled, SSMS displays only the execution plans for the path or statements that are actually executed, as shown in Figure 36.8.

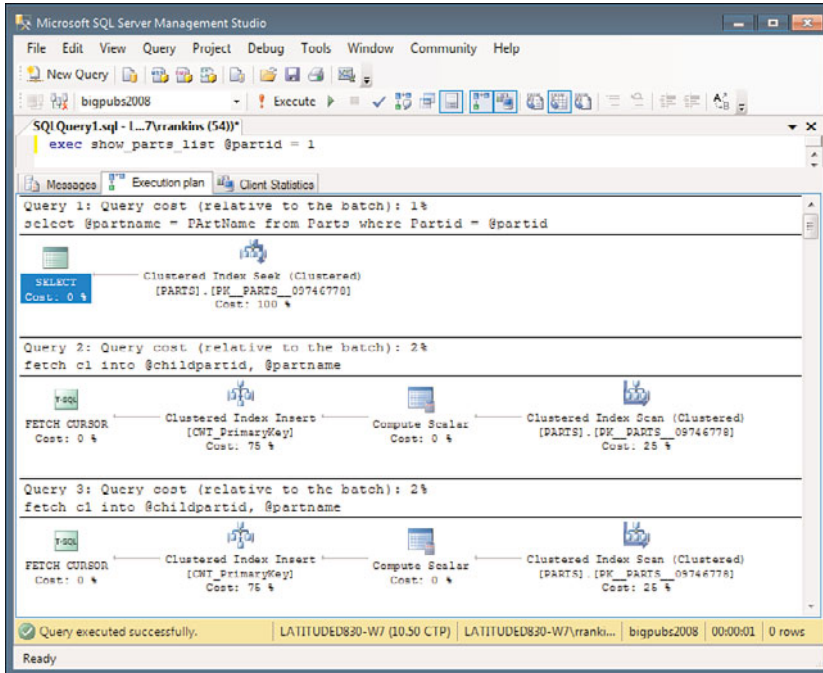

FIGURE 36.8 Actual execution plan used for a stored procedure.

In addition, because stored procedures can become quite complex, with multiple SQL statements, seeing the graphical execution plan in the SSMS Execution Plan window can be difficult. You might find it easier to break up the stored procedure into smaller batches or individual queries and analyze it a bit at a time.

Saving and Viewing Graphical Execution Plans

SQL Server Management Studio 2008 enables you to save an execution plan as an XML file. To save a graphical execution plan in SSMS, you right-click anywhere on the graphical execution plan and choose **Save Execution Plan As** to bring up the **Save As** dialog (alternatively, you can choose the **Save Execution Plan As** option from the **File** menu).

When you save the execution plan to a file, the graphical execution plan is saved as an XML file with the **.sqlplan** file extension. To view a saved execution plan, click on the **File** menu; select **Open** and then **File**. In the **Open File** dialog, select **Execution Plan files** in the **Files of Type** drop-down to limit the files displayed to just **Execution Plan Files** (see Figure 36.9). After you identify the file you want to load, click the **Open** button, and SSMS opens a new window with the selected execution plan displayed. Just as when the execu-

tion plan was originally generated, you can mouse over the operators and display the detailed information contained in the ToolTips.

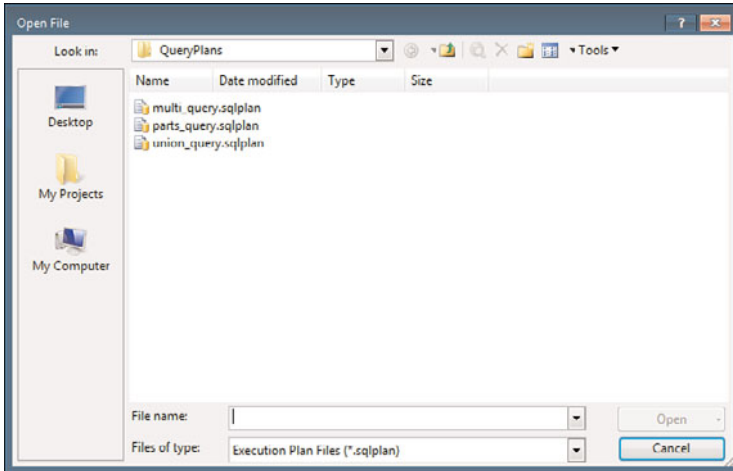

FIGURE 36.9 Loading an execution plan into SSMS.

Displaying Execution Plan XML

In addition to viewing the graphical execution plan in SSMS, you can also display the XML generated by the Query Optimizer that is used to create the graphical execution plan. Right-click on the execution plan and select the Show Execution Plan XML option (see Figure 36.10).

Selecting this option opens a new XML editor window with the `SHOWPLAN_XML` output generated by the query optimizer.

Missing Index Hints

One new feature in SQL Server Management Studio 2008 is Missing Index Hints when displaying the execution plan of a query. You can use the Missing Index Hints feature to help identify columns on which adding an index might help the query execute faster and more efficiently. Missing Index Hints is a lightweight, server-side, always-on feature using dynamic management objects and execution plans to provide information about missing indexes that could enhance query performance.

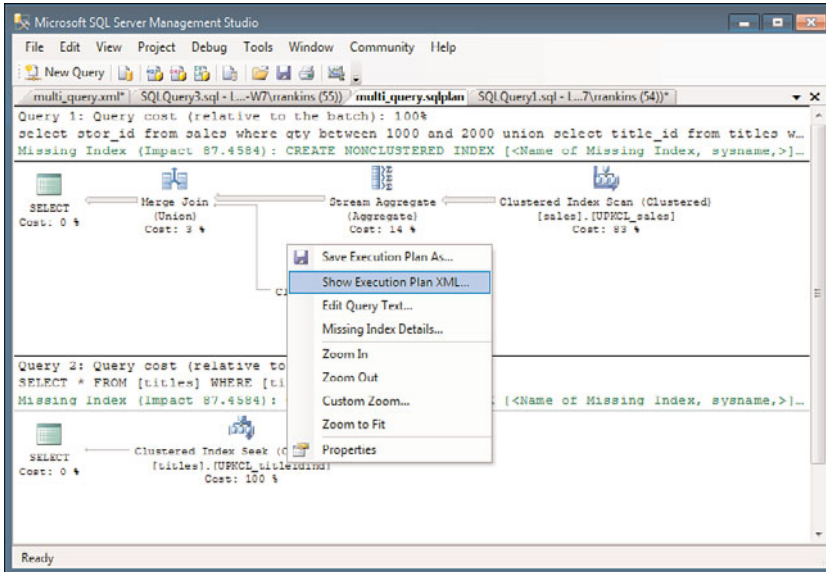

FIGURE 36.10 Generating execution plan XML in SSMS.

NOTE

The Missing Index Hints feature is separate from the Database Engine Tuning Advisor available in SQL Server 2008. The Database Engine Tuning Advisor is a more comprehensive tool that assesses the physical database design and recommends new physical design structures for performance improvement. In addition to index recommendations, it also considers whether indexed views or partitioning could be used to improve query performance.

When the query optimizer generates an execution plan, it analyzes what are the best available indexes for a the specified search and join conditions. If a useful index is not found, the query optimizer generates a suboptimal query plan but still stores information about the missing indexes. The Missing Index Hints feature enables you to view information about these indexes so you can decide whether they should be implemented.

If any missing indexes are identified by the Query Optimizer, the Execution Plan tab in SSMS displays information related to all the missing indexes. If you put the mouse pointer over the missing index text, it displays a ToolTip showing the T-SQL code required to create the suggested missing index as suggested, as shown in Figure 36.11.

In addition to displaying a ToolTip with the T-SQL code, you can also generate the SQL code to create the recommended index by right-clicking on the missing index text and then selecting the Missing Index Details option from the drop-down list (see Figure 36.12). SSMS generates the T-SQL code in a new query window. An example of the T-SQL code generated is shown in Listing 36.1.

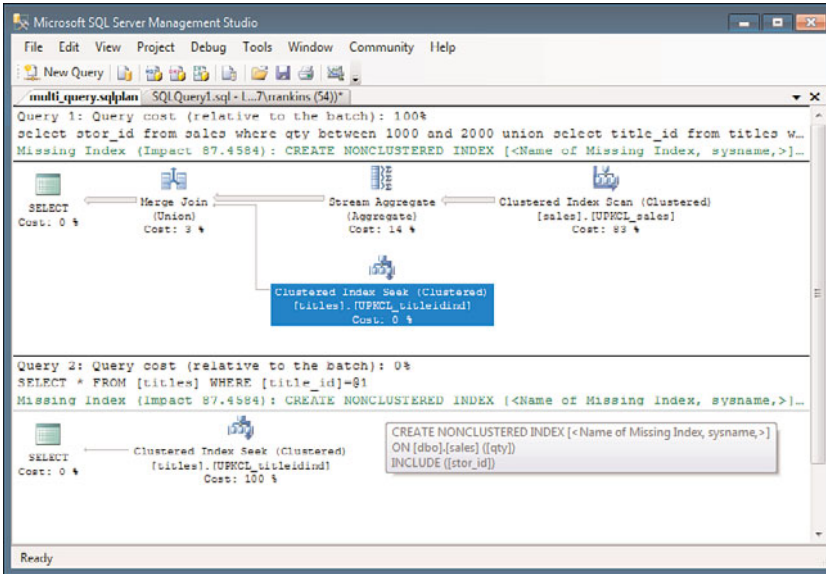

FIGURE 36.11 Displaying missing indexes in SSMS.

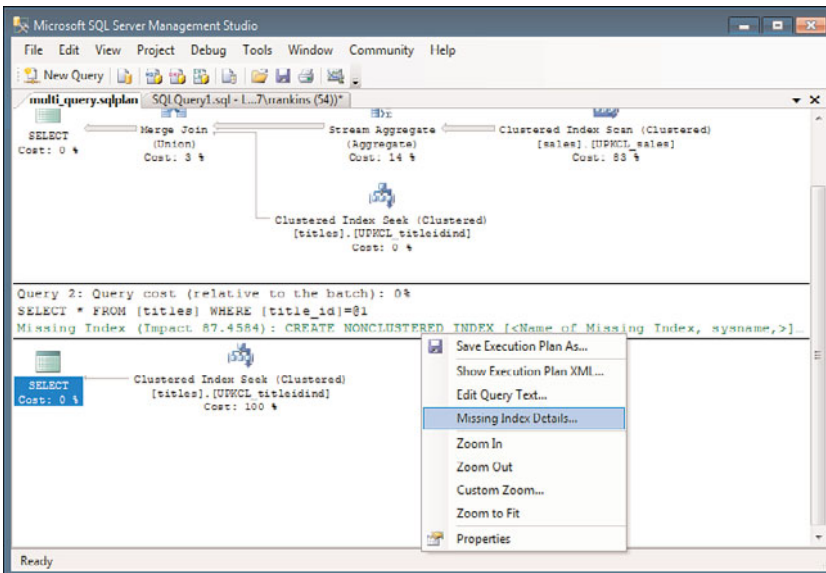

FIGURE 36.12 Generating T-SQL code to create a missing index.

LISTING 36.1 SQL Generated by SSMS Missing Index Hints Feature

```

/*
Missing Index Details from multi_query.sqlplan
The Query Processor estimates that implementing the following index could improve
the query cost by 87.4584%.
*/

/*
USE [bigpubs2008]
GO
CREATE NONCLUSTERED INDEX [<Name of Missing Index, sysname,>]
ON [dbo].[sales] ([qty])
INCLUDE ([stor_id])
GO
*/

```

If you examine the SQL generated by SSMS, notice that it displays the estimated associated cost benefit expected by adding the recommended index. Also note that the script does not include an index name. You need to specify an index name based on your naming standards.

NOTE

If you decide to create a recommended index, be sure to review the subsequent query plan to determine if the query is using the index and that it provides the expected performance benefit.

Missing Index Dynamic Management Objects

The Missing Index Hints feature in SSMS draws information regarding missing indexes from a set of new dynamic management objects introduced in SQL Server 2008:

- ▶ **sys.dm_db_missing_index_group_stats**—Returns summary information about missing index groups, such as the performance improvements that could be gained by implementing a specific group of missing indexes.
- ▶ **sys.dm_db_missing_index_groups**—Returns information about a specific group of missing indexes, such as the group identifier and the identifiers of all missing indexes contained in that group.
- ▶ **sys.dm_db_missing_index_columns**—Returns detailed information about a missing index; for example, it returns the name and identifier of the table where the index is missing, and the columns and column types that should make up the missing index.
- ▶ **sys.dm_db_missing_index_details**—Returns information about the database table columns that are missing an index.

Although the missing indexes feature in SSMS is useful when analyzing individual queries, it's not convenient for analyzing missing indexes for a large set of SQL queries, like the set of queries executed by an application. This is where the dynamic management objects

come in handy. After running a typical workload on SQL Server, you can retrieve information about missing indexes by querying the dynamic management functions directly. You can use the information returned by these dynamic management objects in scripts and use the information to generate `CREATE INDEX` statements to create the missing indexes. Listing 36.2 provides a sample query that displays the missing index information for a query on the sales table that was run between 10:30 and 10:40 p.m. on February 21, 2010.

LISTING 36.2 Querying the Missing Index Dynamic Management Objects

```

SELECT
    mig.index_group_handle as handle,
    convert(varchar(30), statement) AS table_name,
    convert(varchar(12), column_name) AS Column_name,
    convert(varchar(10), column_usage) as ColumnUsage,
    avg_user_impact as avg_impact
FROM sys.dm_db_missing_index_details AS mid
CROSS APPLY sys.dm_db_missing_index_columns (mid.index_handle)
INNER JOIN sys.dm_db_missing_index_groups AS mig
    ON mig.index_handle = mid.index_handle
inner join sys.dm_db_missing_index_group_stats AS migs
    ON migs.group_handle = mig.index_group_handle
where mid.object_id = object_id('sales')
and last_user_seek between '2010-02-21 22:30' and '2010-02-21 22:40'
ORDER BY mig.index_group_handle, mig.index_handle, column_id;
GO

```

handle	table_name	Column_name	ColumnUsage	avg_impact
2	[bigpubs2008].[dbo].[sales]	stor_id	INCLUDE	87.46
2	[bigpubs2008].[dbo].[sales]	qty	INEQUALITY	87.46

If you view the output of this query, you see that the optimizer is recommending an index on the qty column to support an inequality operator. It is also recommended that the stor_id column be specified as an included column in the index. This index is estimated to improve performance by 87.46%. When you use this information, the `CREATE INDEX` statement for the recommended index would be the following:

```
CREATE INDEX qty_idx on [bigpubs2008].[dbo].[sales] (qty) INCLUDE (stor_id)
```

Missing Index Hints Features Limitations

The Missing Index Hints feature provides some helpful information for identifying potentially missing indexes in your database, but it does have a few limitations:

- ▶ It is not intended to fine-tune the existing indexes, only to recommend additional indexes when no useful index is found that can be used to satisfy a search or join condition.
- ▶ It does not specify the order for columns to be specified in the index.
- ▶ For queries involving only inequality predicates, the cost information returned is less accurate than for equality operators.
- ▶ It only recommends adding included columns to indexes for some queries instead of creating composite indexes. You need to determine whether the included columns should be specified as additional index key columns instead.
- ▶ It returns only raw information about columns on which indexes might be missing.
- ▶ It may return different costs for the same missing index group for different executions.
- ▶ It does not suggest filtered indexes.
- ▶ The dynamic management objects can store information from a maximum of 500 missing indexes.
- ▶ It is unable to provide recommendations for clustered indexes, indexed views, or table partitioning. (Use the Database Engine Tuning Advisor instead for these recommendations.)
- ▶ After the SQL Server is restarted, all the information related to missing indexes is lost. To keep the information for later use, the DBA needs to back up all the data available within all the missing index dynamic management objects prior to restarting SQL Server.

NOTE

Although the Missing Index Hints feature is helpful for identifying indexes that may be useful for you to define, it's not a substitute for a well-thought-out index design. For more information on index design, see Chapter 34, "Data Structures, Indexes, and Performance."

SSMS Client Statistics

You can use SSMS to get some additional information related to the client-side performance of the query by toggling the Include Client Statistics option in the Query menu. When turned on, the Client Statistics tab is added to the Results panel. This tab displays useful performance statistics in a tabular format that is related to how much work the client had to do to submit the query and process the results, including statistics about the network packets and elapsed time of the query.

SSMS keeps track of the statistics for previous executions within a session so that you can compare the statistics between different query executions. It also keeps track of the overall

average statistics across all executions. Figure 36.13 shows an example of the client statistics displayed after three separate query executions.

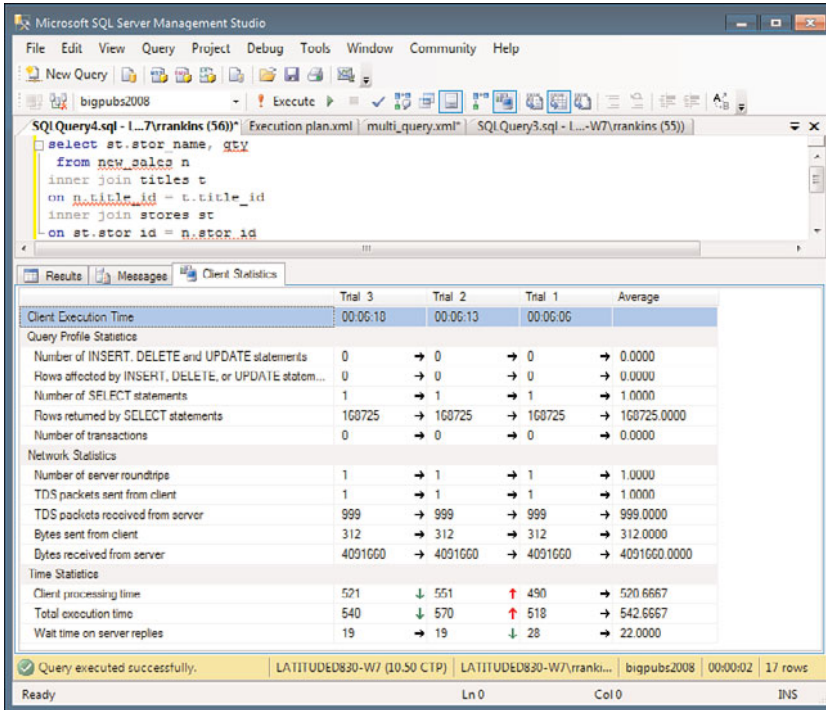

FIGURE 36.13 SSMS client statistics.

The first line in the Client Statistics tab displays the actual time the query was executed. The Time Statistics values are specified in number of milliseconds. Some of the most useful pieces of information include the number of rows returned by SELECT statements, total client processing time, total execution time, and number of bytes sent and received across the network.

The Average column contains the cumulative average since the Include Client Statistics option was enabled. Turning the option off and back on clears out all the historical statistics and resets the averages. Alternatively, you can also reset the client statistics by selecting the Reset Client Statistics option from the Query menu.

One of the most helpful features of the client statistics is the arrow indicators provided for the different executions, which makes it easy to identify which values increased, decreased, or stayed this same. This feature makes it easy to compare the runtime statistics between different queries or different executions of the same query.

TIP

Unlike the graphical execution plans, SSMS does not provide a way to save the client statistics. Fortunately, the statistics are displayed using a standard grid control. You can right-click the client statistics and choose **Select All**. Then you right-click and select **Copy**. You can then paste the information into a spreadsheet program such as Excel, which allows you to save the information or perform further statistical analysis on it.

Using the SET SHOWPLAN Options

In addition to the graphical execution plans available in SSMS, SQL Server 2008 provides three SET SHOWPLAN options to display the execution plan information in a text or XML format. These options are SET SHOWPLAN_TEXT, SET SHOWPLAN_ALL, and SET SHOWPLAN_XML. When one of these options is enabled, SQL Server returns the execution plan generated for the query, but no results are returned because the query is not executed. It's similar to the **Display Estimated Execution Plan** option in SSMS.

You can turn on the textual execution plan output in a couple of ways. One way is to issue the SET SHOWPLAN_TEXT ON, SET SHOWPLAN_ALL ON, or SET SHOWPLAN_XML ON command directly in the SSMS query window. These commands must be executed in a separate batch by themselves before running a query.

TIP

Before enabling SHOWPLAN_TEXT or SHOWPLAN_ALL options in a Query Editor session in SSMS, be sure to disable the **Include Actual Execution Plan** option; otherwise, the SHOWPLAN options will have no effect.

SHOWPLAN_TEXT

Typing the following command in an SSMS query window turns on the SHOWPLAN_TEXT option:

```
SET SHOWPLAN_TEXT ON
GO
```

Setting this option causes the textual showplan output to be displayed in the results panel but does not execute the query. You can also enable the SHOWPLAN_TEXT option by choosing the **Query Options** item from the **Query** menu. In the **Query Options** dialog, you click the **Advanced** item and check the SET SHOWPLAN_TEXT option.

The SHOWPLAN_TEXT option displays a textual representation of the execution plan. Listing 36.3 shows an example for a simple inner join query.

TIP

When you are displaying the SHOWPLAN_TEXT information in SSMS, it is usually easiest to view if you configure SSMS to return results to text rather than as a grid.

LISTING 36.3 An Example of **SHOWPLAN_TEXT** Output

```

set showplan_text on
go
select st.stor_name, ord_date, qty
from stores st join sales_noclust s on st.stor_id = s.stor_id
where st.stor_id between 'B100' and 'B199'
go
StmtText
-----
select st.stor_name, ord_date, qty
from stores st join sales_noclust s on st.stor_id = s.stor_id
where st.stor_id between 'B100' and 'B199'

(1 row(s) affected)

StmtText
-----
-----
-----
-----
-----
|--Nested Loops(Inner Join, OUTER REFERENCES:([Bmk1002], [Expr1006]) WITH
UNORDERED PREFETCH)
    |--Nested Loops(Inner Join, OUTER REFERENCES:([st].[stor_id]))
    |   |--Clustered Index
Seek(OBJECT:([bigpubs2008].[dbo].[stores].[UPK_storeid]
AS [st]), SEEK:([st].[stor_id] >= 'B100' AND [st].[stor_id] <= 'B199')
ORDERED FORWARD)
    |   |--Index Seek(OBJECT:([bigpubs2008].[dbo].[sales_noclust].[idx1] AS
[s]), SEEK:([s].[stor_id]=[bigpubs2008].[dbo].[stores].[stor_id] as
[st].[stor_id]), WHERE:([bigpubs2008].[dbo].[sales_noclust].[stor_id] as
[s].[stor_id]>='B100' AND [bigpubs
    |--RID Lookup(OBJECT:([bigpubs2008].[dbo].[sales_noclust] AS [s]),
SEEK:([Bmk1002]=[Bmk1002]) LOOKUP ORDERED FORWARD)

(5 row(s) affected)

```

The output is read from right to left, similarly to the graphical execution plan. Each line represents a physical/logical operator. The text displayed matches the logical and physical operator names displayed in the graphical execution plan. If you can read the graphical query plan, you should have no trouble reading the **SHOWPLAN_TEXT** output.

In the example in Listing 36.3, SQL Server performs a clustered index seek on the `stores` table, using the `UPK_storeid` index, and a nonclustered index seek on `sales_noclust`, using index `idx1`. The inputs are combined using a nested loop join. Finally, a RID lookup is performed to retrieve the `ord_date` and `qty` information from the `sales_noclust` table.

When the `SHOWPLAN_TEXT` option is set to `ON`, execution plan information about all subsequent SQL Server 2008 statements is returned until the option is set to `OFF`. Also, all subsequent commands are optimized but not executed. To turn off the textual showplan output and allow execution of commands again, type the following command:

```
SET SHOWPLAN_TEXT OFF
GO
```

TIP

To switch from one `SET SHOWPLAN` option to another, remember that no commands are executed until the `SET SHOWPLAN` option is turned off. This includes setting the `SET SHOWPLAN` options. For example, to switch from `SHOWPLAN_TEXT` to either `SHOWPLAN_ALL` or `SHOWPLAN_XML`, you have to turn off `SHOWPLAN_TEXT` first with the `SET SHOWPLAN_TEXT OFF` command.

SHOWPLAN_ALL

The `SHOWPLAN_ALL` option displays the same textual execution plan information as the `SHOWPLAN_TEXT` option, and it also provides additional columns of output for each row of textual showplan output. These columns provide much of the same information available in the graphical execution ToolTips, and the column headings correspond to the ToolTip items listed in the “Execution Plan ToolTips” section, earlier in this chapter. Table 36.1 describes the information provided in the data columns returned by the `SHOWPLAN_ALL` option.

TABLE 36.1 Data Columns Returned by **SHOWPLAN_ALL**

Column Name	Description
StmtText	The text of the T-SQL statement and also each of the physical operators in the execution plan. (It may optionally also contain the logical operators.)
StmtId	The number of the statement in the current batch.
NodeId	The ID of the node in the current query.
Parent	The node ID of the parent operator for the current operator.
PhysicalOp	Physical operator description for the current node.
LogicalOp	Logical operator description for the current node.
Argument	Supplemental information about the operation being performed.
DefinedValues	A comma-separated list of values introduced by this operator. These may be either computed expressions present in the current query or internal values introduced by the query processor to be able to process this query.

TABLE 36.1 Data Columns Returned by **SHOWPLAN_ALL**

Column Name	Description
EstimateRows	Estimated number of rows of output produced by the operator.
EstimateIO	Estimated I/O cost for the operator.
EstimateCPU	Estimated CPU cost for the operator.
AvgRowSize	Estimated average row size (in bytes) of the row being passed through the operator.
TotalSubtreeCost	Estimated (cumulative) cost of this operation and all child operations.
OutputList	A comma-separated list of columns being projected by the current operation.
Warnings	A comma-separated list of warning messages relating to the current operation (for example, missing statistics).
Type	The type of node (either PLAN_ROW or the type of T-SQL statement).
Parallel	Whether the operator is running in parallel (1) or not (0).
EstimateExecutions	Estimated number of times this operator will be executed while running the current query.

TIP

When you are displaying the SHOWPLAN_ALL information in SSMS, it is usually easiest to view if you configure SSMS to return results to grid rather than as text.

SHOWPLAN_XML

When SET SHOWPLAN_XML is set to ON, SQL Server does not execute the query but returns execution information for each T-SQL batch as an XML document. The execution plan information for each T-SQL batch is contained in a single XML document. Each XML document contains the text of the statements in the batch, followed by the details of the execution steps and operators. The document includes the estimated costs, numbers of rows, indexes used, join order, and types of operators performed.

The SHOWPLAN_XML option generates the same XML output as the Show Estimated Execution Plan option in SSMS. In essence, you are looking at the same information, just without the pretty pictures. As a matter of fact, you can save the output from the SHOWPLAN_XML option to a file and open it back into SSMS as a SQL plan file. The recommended approach is to configure the query window to return results to a grid. If you return the results as text or to a file, the maximum output size for a character column in

SSMS is 8,192 bytes. If the XML document exceeds this length, it is truncated and does not load correctly. In the grid results, the maximum size of XML data is 2MB.

After you run the query and generate the grid results, you can right-click on the result row and choose the Save Results As option to specify the file to save the results to. If all goes well, you end up with a .sqlplan file that you can then load back into SSMS for further analysis at a later date.

NOTE

The document containing the XML schema for the SET SHOWPLAN_XML output is available in the same directory as the SQL Server installation, which by default is C:\Program Files\Microsoft SQL Server\100\Tools\Binn\schemas\sqlserver\2004\07\showplan\showplanxml.xsd.

Using sys.dm_exec_query_plan

Dynamic management views (DMVs) can return server state information that can be used to monitor and diagnose database engine issues and help tune performance. The sys.dm_exec_query_plan DMV returns the showplan information for a T-SQL batch whose query execution plan resides in the plan cache. This can be any SQL batch, not just the batch executed by the current user session. The sys.dm_exec_query_plan DMV also provides the capability to retrieve the execution plan for currently long-running processes to help diagnose why they may be running slowly.

The showplan information provided by sys.dm_exec_query_plan is returned in a column called query_plan, which is of the xml data type. This column provides the same information as SET SHOWPLAN XML. The syntax of sys.dm_exec_query_plan is

```
sys.dm_exec_query_plan ( plan_handle )
```

In SQL Server 2008, the query plans for various types of T-SQL batches are cached in an area of memory called the *plan cache*. Each cached query plan is identified by a unique identifier called a *plan handle*. To view the showplan for one of these batches, you need to provide the plan handle for the batch to the sys.dm_exec_query_plan DMV.

The tricky part about using sys.dm_exec_query_plan is determining the plan handle to use. First, you need to determine the SPID for the process with the long-running query. This is usually accomplished using sp_who2 or via the SSMS Activity Monitor.

When you have the SPID, you can use the sys.dm_exec_requests DMV to obtain the plan handle (assume in this case that the SPID is 58):

```
select plan_handle from sys.dm_exec_requests where session_id = 58
go
```

plan_handle

```
-----
0x06000A00E96E6D2CB8A1F50500000000000000000000000000000
```

When you have the plan handle, you can pass it on to the `sys.dm_exec_query_plan` DMV to return the query plan:

```
SELECT query_plan
FROM sys.dm_exec_query_plan (0x06000A00E96E6D2CB8A1F50500000000000000000000000000000)
```

Alternatively, to prevent having to copy and paste the plan handle from the `sys.dm_exec_requests` query into the query against `sys.dm_exec_query_plan`, you can use the `CROSS APPLY` clause, as in the following query:

```
SELECT query_plan FROM sys.dm_exec_requests cp
      CROSS APPLY sys.dm_exec_query_plan(cp.plan_handle)
      where cp.session_id = 58
```

If you return the results to grid, you can right-click the data in the `query_plan` column and save it to a file, which can then be loaded into SSMS to view the graphical execution plan, just like the output from the `SET SHOWPLAN_XML` option.

To return the query plan for all currently running T-SQL batches, you can run the following:

```
SELECT query_plan FROM sys.dm_exec_requests cp
      CROSS APPLY sys.dm_exec_query_plan(cp.plan_handle)
```

In addition to returning the query plans for the currently running T-SQL batches, SQL Server 2008 also provides the `sys.dm_exec_query_stats` and `sys.dm_exec_cached_plans` DMVs. The `sys.dm_exec_cached_plans` DMV can be used to return information about all query plans currently residing in the plan cache. For example, to retrieve a snapshot of all query plans residing in the plan cache, you use the `CROSS APPLY` operator to pass the plan handles from `sys.dm_exec_cached_plans` to `sys.dm_exec_query_plan`, as follows:

```
SELECT * FROM sys.dm_exec_cached_plans cp
      CROSS APPLY sys.dm_exec_query_plan(cp.plan_handle)
```

To retrieve a snapshot of all query plans that currently reside in the plan cache for which the server has gathered statistics, use the `CROSS APPLY` operator to pass the plan handles from `sys.dm_exec_query_stats` to `sys.dm_exec_query_plan` as follows:

```
SELECT * FROM sys.dm_exec_query_stats qs
      CROSS APPLY sys.dm_exec_query_plan(qs.plan_handle)
```

Because `sys.dm_exec_query_plan` provides the capability to view the query plan for any session, a user must be a member of the `sysadmin` fixed server role or have the `VIEW SERVER STATE` permission on the server to invoke it.

NOTE

The `SET SHOWPLAN_ALL` and `SET SHOWPLAN_TEXT` options are deprecated features and may be removed in a future version of SQL Server. It is recommended that you switch to using the `SET SHOWPLAN_XML` option instead.

Query Statistics

In addition to the new dynamic management objects, SQL Server 2008 still provides the `SET STATISTICS IO` and `SET STATISTICS TIME` options, which display the actual logical and physical page reads incurred by a query and the CPU and elapsed time, respectively. These two `SET` options return actual execution statistics, as opposed to the estimates returned by SSMS and the `SHOWPLAN` options discussed previously. These two tools can be invaluable for determining the actual cost of a query.

In addition to the `IO` and `TIME` statistics, SQL Server also provides the `SET STATISTICS PROFILE` and `SET STATISTICS XML` options. These options are provided to display execution plan information while still allowing the query to run.

STATISTICS IO

You can set the `STATISTICS IO` option for individual user sessions, and you can turn it on in an SSMS query window by typing the following:

```
SET STATISTICS IO ON
GO
```

You can also set this option for the query session in SSMS by choosing the `Options` item in the `Query` menu. In the `Query Options` dialog, click the `Advanced` item and check the `SET STATISTICS IO` check box, as shown in Figure 36.14.

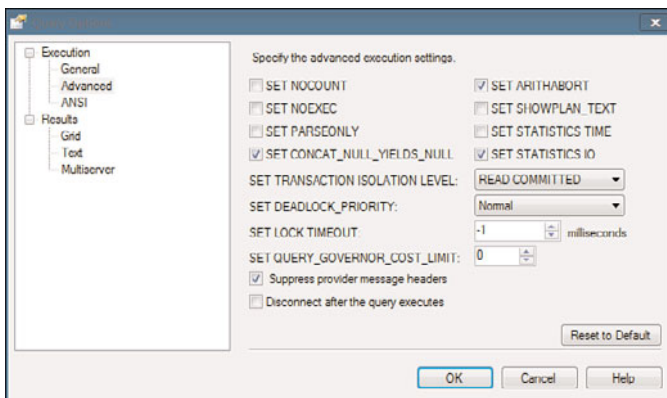

FIGURE 36.14 Enabling the **STATISTICS IO** option in SSMS.

The `STATISTICS IO` option displays the scan count (that is, the number of iterations), the logical reads (from cached data), the physical reads (from physical storage), and the read-ahead reads.

Listing 36.4 displays the `STATISTICS IO` output for the same query executed in Listing 36.3. (Note that the result set has been deleted to save space.)

LISTING 36.4 An Example of **STATISTICS IO** Output

```

set statistics io on
go
select st.stor_name, ord_date, qty
from stores st join sales_noclust s on st.stor_id = s.stor_id
where st.stor_id between 'B100' and 'B199'
go

-- output deleted

(1077 row(s) affected)
Table 'sales_noclust'. Scan count 100, logical reads 1383, physical reads 5,
read-ahead reads 8, lob logical reads 0, lob physical reads 0,
lob read-ahead reads 0.
Table 'stores'. Scan count 1, logical reads 3, physical reads 0,
read-ahead reads 0, lob logical reads 0, lob physical reads 0,
lob read-ahead reads 0.

```

Scan Count

The scan count value indicates the number of times the corresponding table was accessed during query execution. The outer table of a nested loop join typically has a scan count of 1. The scan count for the inner tables typically reflects the number of times the inner table is searched, which is usually the same as the number of qualifying rows in the outer table. The number of logical reads for the inner table is equal to the scan count multiplied by the number of pages per lookup for each scan. Note that the scan count for the inner table might sometimes be only 1 for a nested join if SQL Server copies the needed rows from the inner table into a work table in cache memory and reads from the work table for subsequent iterations (for example, if it uses the Table Spool operation). The scan count for hash joins and merge joins is typically 1 for both tables involved in the join, but the logical reads for these types of joins are usually substantially higher.

Logical Reads

The logical reads value indicates the total number of page accesses necessary to process the query. Every page is read from cache memory, even if it first has to be read from disk. Every physical read always has a corresponding logical read, so the number of physical reads will never exceed the number of logical reads. Because the same page might be

accessed multiple times, the number of logical reads for a table could exceed the total number of pages in the table.

Physical Reads

The `physical reads` value indicates the actual number of pages read from disk. The value for physical reads can vary greatly and should decrease, or drop to zero, with subsequent executions of the query because the data will be loaded into the data cache by the first execution. The number of physical reads will also be lowered by pages brought into memory by the read-ahead mechanism.

Read-Ahead Reads

The `read-ahead reads` value indicates the number of pages read into cache memory using the read-ahead mechanism while the query was processed. Pages read by the read-ahead mechanism will not necessarily be used by the query. When a page read by the read-ahead mechanism is accessed by the query, it counts as a logical read, but not as a physical read.

The read-ahead mechanism can be thought of as an optimistic form of physical I/O, reading the pages into cache memory that it expects the query will need before the query needs them. When you are scanning a table or index, the table's index allocation map pages (IAMs) are looked at to determine which extents belong to the object. An extent consists of eight data pages. The eight pages in the extent are read with a single read, and the extents are read in the order that they are stored on disk. If the table is spread across multiple files, the read-ahead mechanism attempts parallel reads from up to eight files at a time instead of sequentially reading from the files.

LOB Reads

If the query retrieves text, ntext, image, or large value type (`varchar(max)`, `nvarchar(max)`, `varbinary(max)`) data, the `lob logical reads`, `lob physical reads`, and `lob read-ahead reads` values provide the logical, physical, and read-ahead read statistics for the large object (LOB) I/Os.

Analyzing STATISTICS IO Output

The output shown in Listing 36.4 indicates that the `sales_noclust` table was scanned 100 times, with 5 physical reads (that is, 5 physical I/Os were performed). The `stores` table was scanned once, with all reads coming from cache (`physical reads = 0`).

You can use the `STATISTICS IO` option to evaluate the effectiveness of the size of the data cache and to evaluate, over time, how long a table will stay in cache. The lack of physical reads is a good sign, indicating that memory is sufficient to keep the data in cache. If you keep seeing many physical reads when you are analyzing and testing your queries, you might want to consider adding more memory to the server to improve the cache hit ratio. You can estimate the cache hit ratio for a query by using the following formula:

$$\text{Cache hit ratio} = (\text{Logical reads} - \text{Physical reads}) / \text{Logical reads}$$

The number of physical reads appears lower than it actually is if pages are preloaded by read-ahead activity. Because read-ahead reads lower the physical read count, they give the indication of a good cache hit ratio, when in actuality, the data is still being physically

read from disk. The system could still benefit from more memory so that the data remains in cache and the number of read-ahead reads is reduced. `STATISTICS IO` is generally more useful for evaluating individual query performance than for evaluating overall cache hit ratio. The pages that reside and remain in memory for subsequent executions are determined by the data pages being accessed by other queries executing at the same time and the number of data pages being accessed by the other queries. If no other activity is occurring, you are likely to see no physical reads for subsequent executions of the query if the amount of data being accessed fits in the available cache memory. Likewise, if the same data is being accessed by multiple queries, the data tends to stay in cache, and the number of physical reads for subsequent executions tends to be low. However, if other queries executing at the same time are accessing large volumes of data from different tables or ranges of values, the data needed for the query you are testing might end up being flushed from cache, and the physical I/Os will increase. Depending on the other ongoing SQL Server activity, the physical reads you see displayed by `STATISTICS IO` can be inconsistent.

When you are evaluating individual query performance, examining the logical reads value is usually more helpful because the information is consistent across all executions, regardless of other SQL Server activity. Generally speaking, the queries with the fewest logical reads are the fastest queries. If you want to monitor the overall cache hit ratio for all SQL Server activity to evaluate the SQL Server memory configuration, use the Performance Monitor, which is discussed in Chapter 39, “Monitoring SQL Server Performance.”

STATISTICS TIME

You can set the `STATISTICS TIME` option for individual user sessions. In an SSMS query window, you type the following:

```
SET STATISTICS TIME ON
```

You can also set this option for the query session in SSMS by choosing the Options item in the Query menu. In the Query Options dialog, you click the Advanced item and check the `SET STATISTICS TIME` check box.

The `STATISTICS TIME` option displays the total CPU and elapsed time that it takes to actually execute a query. The `STATISTICS TIME` output for the query in Listing 36.3 returns the output shown in Listing 36.5. (Again, the data rows returned have been deleted to save space.)

LISTING 36.5 An Example of **STATISTICS TIME** Output

```
set statistics io on
set statistics time on
go

select st.stor_name, ord_date, qty
from stores st join sales_noclust s on st.stor_id = s.stor_id
```

```
where st.stor_id between 'B100' and 'B199'
go
```

```
SQL Server parse and compile time:
  CPU time = 0 ms, elapsed time = 0 ms.
```

```
--output deleted
```

```
(1077 row(s) affected)
```

```
Table 'sales_noclust'. Scan count 100, logical reads 1383, physical reads 0,
  read-ahead reads 0, lob logical reads 0, lob physical reads 0, lob read-ahead
  reads 0.
```

```
Table 'stores'. Scan count 1, logical reads 3, physical reads 0, read-ahead
  reads 0, lob logical reads 0, lob physical reads 0, lob read-ahead reads 0.
```

```
SQL Server Execution Times:
  CPU time = 0 ms, elapsed time = 187 ms.
```

Here, you can see that the total execution time, denoted by the elapsed time, was relatively low and not significantly higher than the CPU time. This is due to the lack of any physical reads and the fact that all activity is performed in memory.

NOTE

In some situations, you might notice that the parse and compile time for a query is displayed twice. This happens when the query plan is added to the plan cache for possible reuse. The first set of information output is the actual parse and compile before placing the plan in cache, and the second set of information output appears when SQL Server retrieves the plan from cache. Subsequent executions still show the same two sets of output, but the parse and compile time is 0 when the plan is reused because a query plan is not being compiled.

If elapsed time is much higher than CPU time, the query had to wait for something, either I/O or locks. If you want to see the effect of physical versus logical I/Os on the performance of a query, you need to flush the pages accessed by the query from memory. You can use the DBCC DROPCLEANBUFFERS command to clear all clean buffer pages out of memory. Listing 36.6 shows an example of clearing the pages from cache and rerunning the query with the STATISTICS IO and STATISTICS TIME options enabled.

TIP

To ensure that none of the table is left in cache, make sure all pages are marked as clean before running the DBCC DROPCLEANBUFFERS command. A buffer is dirty if it contains a data row modification that has either not been committed yet or has not been written out to disk yet. To clear the greatest number of buffer pages from cache memory, make sure all work is committed, checkpoint the database to force all modified pages to be written out to disk, and then execute the DBCC DROPCLEANBUFFERS command.

CAUTION

The DBCC DROPCLEANBUFFERS command should be executed in a test or development environment only. Flushing all data pages from cache memory in a production environment can have a significantly adverse impact on system performance.

LISTING 36.6 An Example of Clearing the Clean Pages from Cache to Generate Physical I/Os

```
USE bigpubs2008
go
CHECKPOINT
go
DBCC DROPCLEANBUFFERS
go

SET STATISTICS IO ON
SET STATISTICS TIME ON
go
select st.stor_name, ord_date, qty
from stores st join sales_noclust s on st.stor_id = s.stor_id
where st.stor_id between 'B100' and 'B199'
go

SQL Server parse and compile time:
    CPU time = 0 ms, elapsed time = 1 ms.

--output deleted

(1077 row(s) affected)
Table 'sales_noclust'. Scan count 100, logical reads 1383, physical reads 6,
read-ahead reads 0, lob logical reads 0, lob physical reads 0, lob read-ahead
```

reads 0.

Table 'stores'. Scan count 1, logical reads 3, physical reads 2, read-ahead reads 0, lob logical reads 0, lob physical reads 0, lob read-ahead reads 0.

SQL Server Execution Times:

CPU time = 0 ms, elapsed time = 282 ms.

Notice that this time around, even though the reported CPU time was the same, the elapsed time was 282 milliseconds due to the physical I/Os that had to be performed during this execution.

You can use the `STATISTICS TIME` and `STATISTICS IO` options together in this way as a useful tool for benchmarking and comparing performance when modifying queries or indexes.

Using `datediff()` to Measure Runtime

Although the `STATISTICS TIME` option works fine for displaying the runtime of a single query, it is not as useful for displaying the total CPU time and elapsed time for a stored procedure. The `STATISTICS TIME` option generates time statistics for every command executed within the stored procedure. This makes it difficult to read the output and determine the total elapsed time for the entire stored procedure.

Another way to display runtime for a stored procedure is to capture the current system time right before it starts, capture the current system time as it completes, and display the difference between the two, specifying the appropriate-sized `datepart` parameter to the `datediff()` function, depending on how long your procedures typically run. For example, if a procedure takes minutes to complete, you probably want to display the difference in seconds or minutes, rather than milliseconds. If the time to complete is in seconds, you likely want to specify a `datepart` of seconds or milliseconds. Listing 36.7 displays an example of using this approach.

LISTING 36.7 Using `datediff()` to Determine Stored Procedure Runtime

```
set statistics time off
set statistics io off
go
declare @start datetime
select @start = getdate()
exec sp_help
select datediff(ms, @start, getdate()) as 'runtime(ms)'
go

-- output deleted
```

```
runtime(ms)
-----
          3263
```

STATISTICS PROFILE

The `SET STATISTICS PROFILE` option is similar to the `SET SHOWPLAN_ALL` option but allows the query to actually execute. It returns the same execution plan information displayed with the `SET SHOWPLAN_ALL` statement, with the addition of two columns that display actual execution information. The `Rows` column displays the actual number of rows returned in the execution step, and the `Executions` column shows the actual number of executions for the step. The `Rows` column can be compared to the `EstimatedRows` column, and the `Execution` column can be compared to the `EstimatedExecution` column to determine the accuracy of the execution plan estimates.

You can set the `STATISTICS PROFILE` option for individual query sessions. In an SSMS query window, you type the following statement:

```
SET STATISTICS PROFILE ON
GO
```

NOTE

The `SET STATISTICS PROFILE` option has been deprecated and may be removed in a future version of SQL Server. It is recommended that you switch to using the `SET STATISTICS XML` option instead.

STATISTICS XML

Similar to the `STATISTICS PROFILE` option, the `SET STATISTICS XML` option allows a query to execute while also returning the execution plan information. The execution plan information returned is similar to the XML document displayed with the `SET SHOWPLAN_XML` statement.

To set the `STATISTICS XML` option for individual query sessions in SSMS or another query tool, you type the following statement:

```
SET STATISTICS XML ON
GO
```

NOTE

With all the fancy graphical tools available, why would you want to use the text-based analysis tools? Although the graphical tools are useful for analyzing individual queries one at a time, they can be a bit tedious if you have to perform analysis on a number of queries. As an alternative, you can put all the queries you want to analyze in a script file and set the appropriate options to get the query plan and statistics output you want to see. You can then run the script through a tool such as `sqlcmd` and route the output to a file. You can then quickly scan the file or use an editor's Find utility to look for the obvious potential performance issues, such as table scans or long-running queries. Next, you can copy the individual problem queries you identify from the output file into SSMS, where you can perform a more thorough analysis on them.

You could also set up a job to run this SQL script periodically to constantly capture and save performance statistics. This gives you a means to keep a history of the query performance and execution plans over time. This information can be used to compare performance differences as the data volumes and SQL Server activity levels change over time.

Another advantage of the textual query plan output over the graphical query plans is that for very complex queries, the graphical plan tends to get very big and spread out so much that it's difficult to read and follow. The textual output is somewhat more compact and easier to see all at once.

Query Analysis with SQL Server Profiler

SQL Server Profiler serves as another powerful tool available for query analysis. When you must monitor a broad range of queries and database activity and analyze the performance, it is difficult to analyze all those queries manually. For example, if you have a number of stored procedures to analyze, how would you know which ones to focus on as problem procedures? You would have to identify sample parameters for all of them and manually execute them individually to see which ones were running too slowly and then, after they were identified, do some query analysis on them.

With SQL Server Profiler, you can simply define a trace to capture performance-related statistics on the fly while the system is being used normally. This way, you can capture a representative sample of the type of activity your database will receive and capture statistics for the stored procedures as they are being executed with real data values. Also, to avoid having to look at everything, you can set a filter on the Duration column so that it displays only items with a runtime longer than the specified threshold.

The events you want to capture to analyze query performance are listed under the Performance events. They include Showplan All, Showplan Statistics Profile, Showplan Text, Showplan Text (Unencoded), Showplan XML, Showplan XML for Query Compile,

and Showplan XML Statistics Profile. The data columns that you want to be sure to include when capturing the showplan events are TextData, CPU, StartTime, Duration, and Reads and Writes. Also, for the Showplan Statistics and Showplan All events, you must also select the BinaryData data column.

Capturing the showplan performance information with SQL Server Profiler provides you with all the same information you can capture with all the other individual tools discussed in this chapter. You can easily save the trace information to a file or table for replaying the sequence to test index or configuration changes, or simply for historical analysis. If you choose any of the Showplan XML options, you have the option of saving the XML Showplan events separately from the overall trace file. You can choose to save all XML Showplan events in a single file or separate file for each event (see Figure 36.15). You can then load the Showplan XML file into SSMS to view the graphical execution plans and perform your query analysis.

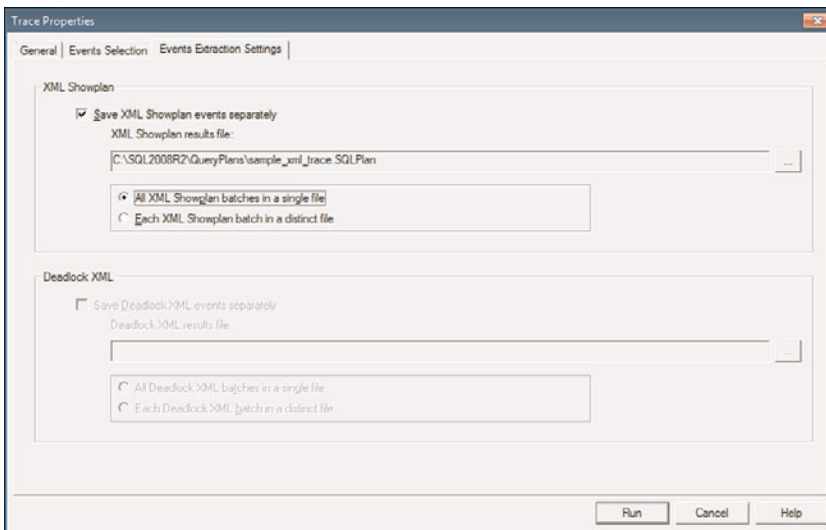

FIGURE 36.15 Saving XML Showplan events to a single file.

When you run a SQL Server Profiler trace with the Showplan XML event enabled, SQL Server Profiler displays the graphical execution plans captured in the bottom display panel of the Profiler window when you select a record with a Showplan XML EventClass. The graphical execution plans displayed in SQL Server Profiler are just like the ones displayed in SSMS, and they also include the same detailed information available via the ToolTips. Figure 36.16 shows an example of a graphical execution plan being displayed in SQL Server Profiler.

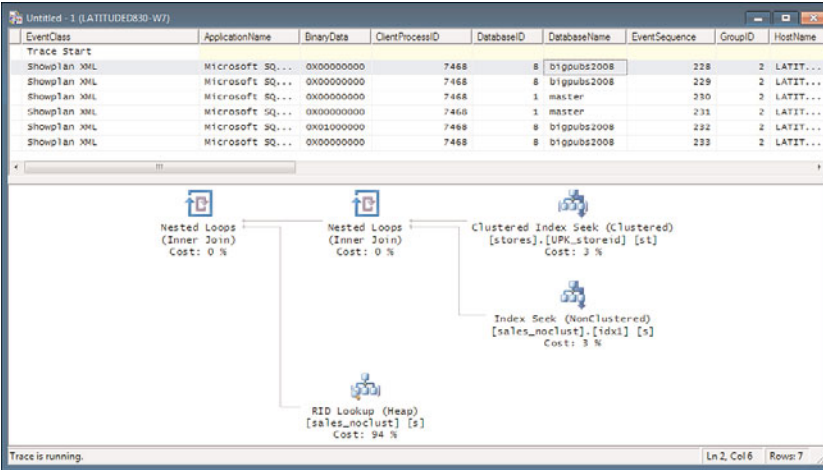

FIGURE 36.16 Displaying an XML Showplan event in SQL Server Profiler.

For more information on using SQL Server Profiler, see Chapter 6, “SQL Server Profiler.”

NOTE

Because of the capability to view the graphical execution plans in SQL Server Profiler as well as the capability to save the XML Showplan events to a separate file, which you can bring into SSMS for analysis, the XML Showplan events provide a significant benefit over the other, older-style showplan events provided. As a matter of fact, these other showplan events are provided primarily for backward-compatibility purposes. In a future version of SQL Server, the Showplan All, Showplan Statistics Profile, Showplan Text, and Showplan Text (Unencoded) event classes will be deprecated. It is recommended that you switch to using the newer XML event classes instead.

Summary

Between the features of SSMS and the text-based query analysis tools, SQL Server 2008 provides a number of powerful utilities to help you analyze and understand how your queries are performing and also help you develop a better understanding of how queries in general are processed and optimized in SQL Server 2008. Such an understanding can help ensure that the queries you develop will be optimized more effectively by SQL Server.

The tools discussed in this chapter are useful for analyzing individual query performance. However, in a multiuser environment, query performance is often affected by more than just how a single query is optimized. One of those factors is locking contention. Chapter 37, “Locking and Performance,” delves into locking in SQL Server, its impact on query and application performance, and ways to minimize locking performance issues in SQL Server systems.

CHAPTER 37

Locking and Performance

This chapter examines locking and its impact on transactions and performance in SQL Server. It also reviews locking hints that you can specify in queries to override SQL Server's default locking behavior.

What's New in Locking and Performance

SQL Server 2008 doesn't provide any significant changes in locking behavior or features over what was provided in SQL Server 2005 (such as Snapshot Isolation and improved lock and deadlock monitoring). The main new feature in SQL Server 2008 is the capability to control lock escalation behavior at the table level. The new `LOCK_ESCALATION` table option allows you to enable or disable table-level lock escalation. This new feature can reduce contention and improve concurrency, especially for partitioned tables.

One other change for SQL Server 2008 is the deprecation of the Locks configuration setting. This option, while still visible and settable in `sp_configure`, is simply ignored by SQL Server 2008. Also deprecated in SQL Server 2008 is the `timestamp` data type. It has been replaced with the `rowversion` data type. For more information on using the `rowversion` data type, see the "Optimistic Locking" section in this chapter.

IN THIS CHAPTER

- ▶ What's New in Locking and Performance
- ▶ The Need for Locking
- ▶ Transaction Isolation Levels in SQL Server
- ▶ The Lock Manager
- ▶ Monitoring Lock Activity in SQL Server
- ▶ SQL Server Lock Types
- ▶ SQL Server Lock Granularity
- ▶ Lock Compatibility
- ▶ Locking Contention and Deadlocks
- ▶ Table Hints for Locking
- ▶ Optimistic Locking

The Need for Locking

In any multiuser database, there must be a consistent set of rules for making changes to the data. For a true transaction-processing database, the database management system (DBMS) is responsible for resolving potential conflicts between two different processes that are attempting to change the same piece of information at the same time. Such a situation cannot occur because the consistency of a transaction cannot be guaranteed. For example, if two users were to change the same data at approximately the same time, whose change would be propagated? Theoretically, the results would be unpredictable because the answer is dependent on whose transaction completed last. Because most applications try to avoid “unpredictability” with data wherever possible (imagine a banking system returning “unpredictable” results, and you get the idea), some method must be available to guarantee sequential and consistent data changes.

Any relational database must support the ACID properties for transactions, as discussed in Chapter 31, “Transaction Management and the Transaction Log”:

- ▶ Atomicity
- ▶ Consistency
- ▶ Isolation
- ▶ Durability

These ACID properties ensure that data changes in a database are correctly collected together and that the data is going to be left in a consistent state that corresponds with the actions being taken.

The main role of locking is to provide the isolation that transactions need. Isolation ensures that individual transactions don’t interfere with one another, that a given transaction does not read or modify the data being modified by another transaction. In addition, the isolation that locking provides helps ensure consistency within transactions. Without locking, consistent transaction processing is impossible. Transactions are logical units of work that rely on a constant state of data, almost a “snapshot in time” of what they are modifying, to guarantee their successful completion.

Although locking provides isolation for transactions and helps ensure their integrity, it can also have a significant impact on the performance of the system. To keep your system performing well, you want to keep transactions as short, concise, and noninterfering as possible. This chapter explores the locking features of SQL Server that provide isolation for transactions. You’ll come to understand the performance impact of the various levels and types of locks in SQL Server and how to define transactions to minimize locking performance problems.

Transaction Isolation Levels in SQL Server

Isolation levels determine the extent to which data being accessed or modified in one transaction is protected from changes to the data by other transactions. In theory, each transaction should be fully isolated from other transactions. However, in practice, for prac-

tical and performance reasons, this might not always be the case. In a concurrent environment in the absence of locking and isolation, the following four scenarios can happen:

- ▶ **Lost update**—In this scenario, no isolation is provided to a transaction from other transactions. Multiple transactions can read the same copy of data and modify it. The last transaction to modify the data set prevails, and the changes by all other transactions are lost.
- ▶ **Dirty reads**—In this scenario, one transaction can read data that is being modified by other transactions. The data read by the first transaction is inconsistent because the other transaction might choose to roll back the changes.
- ▶ **Nonrepeatable reads**—In this scenario, which is somewhat similar to zero isolation, a transaction reads the data twice, but before the second read occurs, another transaction modifies the data; therefore, the values read by the first read are different from those of the second read. Because the reads are not guaranteed to be repeatable each time, this scenario is called nonrepeatable reads.
- ▶ **Phantom reads**—This scenario is similar to nonrepeatable reads. However, instead of the actual rows that were read changing before the transaction is complete, additional rows are added to the table, resulting in a different set of rows being read the second time. Consider a scenario in which Transaction A reads rows with key values within the range of 1 through 5 and returns three rows with key values 1, 3, and 5. Before Transaction A reads the data again within the transaction, Transaction B adds two more rows with the key values 2 and 4 and commits the changes. Assuming that Transaction A and Transaction B both can run independently without blocking each other, when Transaction A runs the query a second time, it now gets five rows with key values 1, 2, 3, 4, and 5. This phenomenon is called *phantom reads* because in the second pass, you get records you did not expect to retrieve.

Ideally, a DBMS must provide levels of isolation to prevent these types of scenarios. Sometimes, for practical and performance reasons, databases relax some of the rules. The American National Standards Institute (ANSI) has defined four transaction isolation levels, each providing a different degree of isolation to cover the previous scenarios. ANSI SQL-92 defines the following four standards for transaction isolation:

- ▶ Read Uncommitted (Level 0)
- ▶ Read Committed (Level 1)
- ▶ Repeatable Read (Level 2)
- ▶ Serializable (Level 3)

SQL Server 2008 supports all the ANSI isolation levels; in addition, SQL Server 2008 also supports two additional transaction isolation levels that use row versioning. One is an alternative implementation of Read Committed isolation called Read Committed Snapshot, and the other is the Snapshot transaction isolation level.

You can set the default transaction isolation for a user session by using the `SET TRANSACTION ISOLATION LEVEL T-SQL` command, or for individual SQL statements, you can specify

table-level isolation hints within the query. Using table-level hints is covered later in this chapter, in the section “Table Hints for Locking.”

Read Uncommitted Isolation

If you set the Read Uncommitted mode for a session, no isolation is provided to the SELECT queries in that session. A transaction that is running with this isolation level is not immune to dirty reads, nonrepeatable reads, or phantom reads.

To set the Read Uncommitted mode for a session, you run the following statements from the client:

- ▶ **T-SQL**—Use SET TRANSACTION ISOLATION LEVEL READ UNCOMMITTED.
- ▶ **ODBC**—Use the function call SQLSetConnectAttr with Attribute set to SQL_ATTR_TXN_ISOLATION and ValuePtr set to SQL_TXN_READ_UNCOMMITTED.
- ▶ **OLE DB**—Use the function call ITransactionLocal::StartTransaction with the isoLevel set to ISOLATIONLEVEL_READUNCOMMITTED.
- ▶ **ADO**—Set the IsolationLevel property of the Connection object to adXactReadUncommitted.
- ▶ **ADO.NET**—For applications using the System.Data.SqlClient managed namespace, call the SqlConnection.BeginTransaction method and set the IsolationLevel option to ReadUncommitted.

You need to be careful when running queries at Read Uncommitted isolation; it is possible to read changes that have been made to data that are subsequently rolled back. In essence, the accuracy of the results cannot be guaranteed. You should use this mode only when you need to get information quickly from an online transaction processing (OLTP) database, without affecting or being affected by the ongoing updates and when the accuracy of the results is not critical.

Read Committed Isolation

The Read Committed mode is the default locking-isolation mode for SQL Server. With Read Committed as the transaction isolation level, read operations can read pages only for transactions that have already been committed. No “dirty reads” are allowed. Locks acquired by update transactions are held for the duration of the transaction. However, in this mode, read requests within the transaction release locks as soon as the query finishes reading the data. Although this improves concurrent access to the data for updates, it does not prevent nonrepeatable reads or phantom reads. For example, within a transaction, a process could read one set of rows early in the transaction and then, before reading the information again, another process could modify the result set, resulting in a different result set being read the second time.

Because Read Committed is the default isolation level for SQL Server, you do not need to do anything to set this mode. If you need to set the isolation level back to Read Committed mode for a session, you run the following statements from the client:

- ▶ **T-SQL**—Use SET TRANSACTION ISOLATION LEVEL READ COMMITTED.

- ▶ **ODBC**—Use the function call `SQLSetConnectAttr` with `Attribute` set to `SQL_ATTR_TXN_ISOLATION` and `ValuePtr` set to `SQL_TXN_READ_COMMITTED`.
- ▶ **OLE DB**—Use the function call `ITransactionLocal::StartTransaction` with `isoLevel` set to `ISOLATIONLEVEL_READCOMMITTED`.
- ▶ **ADO**—Set the `IsolationLevel` property of the `Connection` object to `adXactReadcommitted`.
- ▶ **ADO.NET**—For applications using the `System.Data.SqlClient` managed namespace, call the `SqlConnection.BeginTransaction` method and set the `IsolationLevel` option to `ReadCommitted`.

Read Committed Snapshot Isolation

When the `READ_COMMITTED_SNAPSHOT` database option is set to `ON`, sessions running with the Read Committed isolation mode use row versioning to provide statement-level read consistency. When this database option is enabled and a transaction runs at the Read Committed isolation level, all statements within the transaction see a snapshot of the data as it exists at the start of the statement.

When the `READ_COMMITTED_SNAPSHOT` option is enabled for a database, SQL Server maintains versions of each row that is modified. Whenever a transaction modifies a row, an image of the row before modification is copied into a page in the version store, which is a collection of data pages in `tempdb`. If multiple transactions modify a row, multiple versions of the row are linked in a version chain. Queries running with Read Committed Snapshot isolation retrieve the last version of each row that had been committed when the statement started, providing a statement-level snapshot of the data.

In the Read Committed Snapshot isolation mode, read operations do not acquire shared page or row locks on the data. Therefore, readers using row versioning do not block other processes modifying the same data, and, similarly, processes modifying the data do not block the readers. In addition, because the read operations do not acquire locks, locking overhead is reduced. However, processes modifying data still block other processes modifying data because two operations cannot modify the same data at the same time. Exclusive locks on modified data are still acquired and held until the end of the transaction.

While locking overhead is reduced for read operations when using Read Committed Snapshot isolation, it does introduce overhead to maintain the row versions in `tempdb`. In addition, `tempdb` must have sufficient space to hold the row versions in addition to the space required for normal `tempdb` operations.

You might want to consider enabling the `READ_COMMITTED_SNAPSHOT` database option when blocking that occurs between read and write operations affects performance to the point that the overhead of creating and managing row versions is offset by the concurrency benefits. You may also consider using Read Committed Snapshot isolation when an application requires absolute accuracy for long-running aggregations or queries where data values must be consistent to the point in time that the query starts.

NOTE

You can use Read Committed Snapshot isolation mode with most existing SQL Server applications without making any change to the application code itself if the applications are written to use the default Read Committed isolation level. The behavior of Read Committed, whether to use row versioning or not, is determined by the database option setting, and this can be enabled or disabled without requiring any changes to the application code.

Repeatable Read Isolation

In Repeatable Read mode, SQL Server provides the same level of isolation for updates as in Read Committed mode, but it also allows the data to be read many times within the same transaction and guarantees that the same values will be read each time. Repeatable Read isolation mode prevents other users from updating data that has been read within the transaction until the transaction in which it was read is committed or rolled back. This way, the reading transaction does not pick up changes to the rows it read previously within the transaction. However, this isolation mode does not prevent additional rows (that is, phantom reads) from appearing in the subsequent reads.

Although preventing nonrepeatable reads is desirable for certain transactions, it requires holding locks on the data that has been read until the transaction is completed. This reduces concurrent access for multiple update operations and causes performance degradation due to lock waits and locking contention between transactions. It can also potentially lead to deadlocks. (Deadlocking is discussed in more detail in the “Deadlocks” section, later in this chapter.)

To set Repeatable Read mode for a session, you run the following statements from the client:

- ▶ **T-SQL**—Use `SET TRANSACTION ISOLATION LEVEL REPEATABLE READ`.
- ▶ **ODBC**—Use the function call `SQLSetConnectAttr` with `Attribute` set to `SQL_ATTR_TXN_ISOLATION` and `ValuePtr` set to `SQL_TXN_REPEATABLE_READ`.
- ▶ **OLE DB**—Use the function call `ITransactionLocal::StartTransaction` with `isoLevel` set to `ISOLATIONLEVEL_REPEATABLE_READ`.
- ▶ **ADO**—Set the `IsolationLevel` property of the `Connection` object to `adXactRepeatableRead`.
- ▶ **ADO.NET**—For applications using the `System.Data.SqlClient` managed namespace, call the `SqlConnection.BeginTransaction` method and set the `IsolationLevel` option to `RepeatableRead`.

Serializable Read Isolation

Serializable Read mode is similar to repeatable reads but adds to it the restriction that rows cannot be added to a result set that was read previously within a transaction. This prevents phantom reads. In other words, Serializable Read locks the existing data being read as well as rows that do not yet exist. It accomplishes this by locking the data being read. In addi-

tion, SQL Server puts locks on the range of values being read so that additional rows cannot be added to the range.

For example, say you run a query in a transaction that retrieves all records for the `Sales` table in the `bigpubs2008` database for a store with the `stor_id` of `7066`. To prevent additional sales records from being added to the `Sales` table for this store, SQL Server locks the range of values with `stor_id` of `7066`. It accomplishes this by using key-range locks, which are discussed in the “Serialization and Key-Range Locking” section, later in this chapter.

Although preventing phantom reads is desirable for certain transactions, Serializable Read mode, like Repeatable Read, reduces concurrent access for multiple update operations and can cause performance degradation due to lock waits and locking contention between transactions, and it can potentially lead to deadlocks.

To set Serializable Read mode for a session, you run the following statements from the client:

- ▶ **T-SQL**—Use `SET TRANSACTION ISOLATION LEVEL SERIALIZABLE`.
- ▶ **ODBC**—Use the function call `SQLSetConnectAttr` with `Attribute` set to `SQL_ATTR_TXN_ISOLATION` and `ValuePtr` set to `SQL_TXN_SERIALIZABLE`.
- ▶ **OLE DB**—Use the function call `ITransactionLocal::StartTransaction` with `isoLevel` set to `ISOLATIONLEVEL_SERIALIZABLE`.
- ▶ **ADO**—Set the `IsolationLevel` property of the `Connection` object to `adXactSERIALIZABLE`.
- ▶ **ADO.NET**—For applications using the `System.Data.SqlClient` managed namespace, call the `SqlConnection.BeginTransaction` method and set the `IsolationLevel` option to `Serializable`.

Snapshot Isolation

Snapshot Isolation is an additional isolation level available in SQL Server 2008. Similar to Read Committed Snapshot, Snapshot Isolation mode uses row versioning to take a point-in-time snapshot of the data. However, unlike Read Committed Snapshot isolation, which provides a statement-level snapshot of the data, Snapshot Isolation maintains a snapshot of the data for the duration of the entire transaction. A data snapshot is taken when the transaction starts and the snapshot remains consistent for the duration of the transaction.

Snapshot Isolation mode provides the benefit of repeatable reads without acquiring and holding shared locks on the data that is read. This can help minimize locking and blocking problems between read operations and update operations. Read operations do not have to wait for write operations and writes don't have to wait for reads.

To set the Snapshot Isolation mode for a session, you run the following statement:

```
SET TRANSACTION ISOLATION LEVEL SNAPSHOT
```

In addition, to be able to request the Snapshot Isolation mode in a session, you must enable the database option `ALLOW_SNAPSHOT_ISOLATION` with the `ALTER DATABASE` command:

```
ALTER DATABASE dbname SET ALLOW_SNAPSHOT_ISOLATION ON
```

When Snapshot Isolation mode is enabled, SQL Server assigns a transaction sequence number to each transaction that manipulates data using row versioning. When either the `READ_COMMITTED_SNAPSHOT` or `ALLOW_SNAPSHOT_ISOLATION` database option is set to `ON`, SQL Server stores a version of the previously committed image of the data row in `tempdb` whenever the row is modified by a transaction. Each of these versions is marked with the transaction sequence number of the transaction that made the change. The versions of the modified rows are linked together in a chain, with the most recent version of the row always stored in the current database and the versioned rows stored in `tempdb`.

When a transaction requests a read of data, it searches the version chain to locate the last committed version of the data row with a lower transaction sequence number than the current transaction. Row versions are kept in `tempdb` only long enough to satisfy the requirements of any transactions running under row versioning-based isolation levels. SQL Server keeps track of the sequence number of the oldest outstanding transaction and periodically deletes all row versions stamped with transaction sequence numbers lower than that.

You might consider using snapshot isolation in the following instances:

- ▶ When you want optimistic concurrency control
- ▶ When it is unlikely that your transaction would have to be rolled back because of an update conflict
- ▶ When an application generates reports based on long-running, multistatement queries that must have point-in-time consistency
- ▶ With systems that are incurring a high number of deadlocks because of read/write contention

There is a risk to using snapshot isolation, however. If two client applications both retrieve the same data and then both attempt to write changes to the data back to the database, the second application could potentially overwrite the first application's changes. This is called a *lost update error*. Fortunately, SQL Server 2008 resolves this problem by blocking the second transaction's writes. So, although snapshot isolation provides benefits for resolving conflicts between read and write operations, there can still be conflicts between multiple write operations. For systems with heavy read and insert activity and with little concurrent updating of the same resource, snapshot isolation can provide a solution for concurrency issues.

Another cost of snapshot isolation is that it can make heavy use of `tempdb`. For this reason, you should locate `tempdb` on its own high-performance drive system.

NOTE

Only one of the transaction isolation levels can be active at any given time for a user session. The isolation level you set within an application is active for the duration of the connection or until it is manually reset. To check the current transaction isolation level settings, you run the DBCC USEROPTIONS command and examine the value for isolation level, as in the following example:

```
DBCC USEROPTIONS
go
```

Set Option	Value
-----	-----
textsize	2147483647
language	us_english
dateformat	mdy
datefirst	7
lock_timeout	-1
quoted_identifier	SET
arithabort	SET
ansi_null_dflt_on	SET
ansi_warnings	SET
ansi_padding	SET
ansi_nulls	SET
concat_null_yields_null	SET
isolation level	snapshot

Be aware that DBCC USEROPTIONS reports an isolation level of Read Committed Snapshot when the database option READ_COMMITTED_SNAPSHOT is set to ON and the current transaction isolation level is set to Read Committed. The actual isolation level in effect for the user session is Read Committed.

The Lock Manager

The responsibility for ensuring lock conflict resolution between user processes falls on the SQL Server Lock Manager. SQL Server automatically assigns locks to processes to guarantee that the current user of a resource (for example, a data row or page, an index row or page, a table, an index, or a database) has a consistent view of that resource, from the beginning to the end of a particular operation. In other words, what you start with is what you work with throughout your transaction. Nobody can change what you are working on in midstate, thereby ensuring the consistency of your transaction.

The Lock Manager is responsible for deciding the appropriate lock type (for example, shared, exclusive, update) and the appropriate granularity of locks (for example, row, page, table), according to the type of operation being performed and the amount of data being affected. Based on the type of transaction, the SQL Server Lock Manager chooses different types of lock resources. For example, a `CREATE INDEX` statement might lock the entire table, whereas an `UPDATE` statement might lock only a specific row.

The Lock Manager also manages compatibility between lock types attempting to access the same resources, resolves deadlocks, and escalates locks to a higher level, if necessary.

The Lock Manager manages locks for both shared data and internal system resources. For shared data, the Lock Manager manages row locks, page locks, and table locks on tables, as well as data pages, text pages, and leaf-level index pages. Internally, the Lock Manager uses latches to manage locking on index rows and pages, controlling access to internal data structures and, in some cases, for retrieving individual rows of data. Latches provide better system performance because they are less resource intensive than locks. Latches also provide greater concurrency than locks. Latches are typically used for operations such as page splits, deletion of index rows, movement of rows in an index, and so on. The main difference between a lock and a latch is that a lock is held for the duration of the transaction, and a latch is held only for the duration of the operation for which it is required. Locks are used to ensure the logical consistency of data, whereas latches are used to ensure the physical consistency of the data and data structures.

The remainder of this chapter examines how the Lock Manager determines the type and level of lock to assign, based on the type of command being executed, number of rows affected, and lock isolation level in effect.

Monitoring Lock Activity in SQL Server

To monitor the performance of a system, you need to keep track of locking activity in SQL Server. The following are the most commonly used methods to do so:

- ▶ Querying the `sys.dm_tran_locks` dynamic management view directly
- ▶ Viewing locking activity with SQL Server Profiler
- ▶ Monitoring locks with Performance Monitor

As you read through the rest of this chapter, you might want to examine or monitor the locking activity for the examples presented. To assist you in that effort, the following sections describe the methods of examining lock activity in SQL Server 2008.

Querying the `sys.dm_tran_locks` View

The `sys.dm_tran_locks` dynamic management view returns information about all the locks currently granted or waiting to be granted in SQL Server. (The information is populated from the internal lock management structures in SQL Server 2008.) This view provides no historical information; rather, the data in this view corresponds to live Lock

Manager information. This data can change at any time for subsequent queries of the view as locks are acquired and released.

The information returned by the view can be divided into two main groups: resource information and lock request information. The resource information describes the resource on which the lock request is being made, and the request information provides details on the lock request itself. Table 37.1 describes the most useful data columns returned by the `sys.dm_tran_locks` view.

TABLE 37.1 Useful Columns Returned by the **sys.dm_tran_locks** View

Column Name	Description
<code>resource_type</code>	Indicates the type of resource the lock is being held or requested on.
<code>resource_subtype</code>	Indicates a subtype of the <code>resource_type</code> , if any.
<code>resource_database_id</code>	Indicates the database ID of the database where the resource resides.
<code>resource_description</code>	Provides information about the resource that is not available from other resource columns.
<code>resource_associated_entity_id</code>	Indicates the ID of the entity in a database that the resource is associated with.
<code>resource_lock_partition</code>	Indicates the ID of the associated partition for a resource that is partitioned.
<code>request_mode</code>	Indicates the lock mode of the request that has been granted or is being waited on.
<code>request_type</code>	Indicates the request type. (The only current value is LOCK.)
<code>request_status</code>	Indicates the current status of this request (GRANT, CONVERT, or WAIT).
<code>request_reference_count</code>	Returns an approximate number of times the same requestor has requested this resource.
<code>request_lifetime</code>	Specifies a code indicating when the lock on the resource is released.
<code>request_session_id</code>	Indicates the ID of the session that generated the corresponding request.
<code>request_exec_context_id</code>	Indicates the ID of the execution context of the process that generated the lock request.

TABLE 37.1 Useful Columns Returned by the `sys.dm_tran_locks` View

Column Name	Description
<code>request_request_id</code>	Indicates the batch ID of the process that generated the request.
<code>request_owner_type</code>	Indicates the type of entity that owns the request. Possible values include, but are not limited to, TRANSACTION, CURSOR, and SESSION.
<code>request_owner_id</code>	Specifies the ID of the specific owner of this request. This value is used for transactions for which this is the transaction ID.
<code>request_owner_guid</code>	Indicates the GUID of the specific owner of the lock request. This value is used only by a distributed transaction where the value corresponds to the MS DTC GUID for that transaction
<code>request_owner_lockspace_id</code>	Represents the lockspace ID of the requestor. The lockspace ID determines whether two requestors are compatible with each other and can be granted locks in modes that would otherwise conflict with one another.
<code>lock_owner_address</code>	Indicates the memory address of the internal data structure used to track the request.

Table 37.2 lists the possible lock request modes that can be displayed in the `request_mode` column of the `sys.dm_tran_locks` view.

TABLE 37.2 Lock Request Modes

Value	Lock Type	Description	Request Mode
1	N/A	No access provided to the requestor	NULL
2	Schema	Schema stability lock	Sch-S
3	Schema	Schema modification lock	Sch-M
4	Shared	Acquisition of a shared lock on the resource	S
5	Update	Acquisition of an update lock on the resource	U
6	Exclusive	Exclusive lock granted on the resource	X
7	Intent	Intent for a shared lock	IS
8	Intent	Intent for an update lock	IU
9	Intent	Intent for an exclusive lock	IX

TABLE 37.2 Lock Request Modes

Value	Lock Type	Description	Request Mode
10	Intent	Shared lock with intent for an update lock on subordinate resources	SIU
11	Intent	Shared lock with intent for an exclusive lock on subordinate resources	SIX
12	Intent	Update lock with an intent for an exclusive lock on subordinate resources	UIX
13	Bulk	BULK UPDATE lock used for bulk copy operations	BU
14	Key-Range	Shared lock on the range between keys and shared lock on the key at the end of the range; used for serializable range scan	Range_S_S
15	Key-Range	Shared lock on the range between keys, with an update lock on the key at the end of the range	Range_S_U
16	Key-Range	Exclusive lock used to prevent inserts into a range between keys	RangeIn-N
17	Key-Range	Key-range conversion lock created by overlap of RangeIn-N and shared (S) locks	RangeIn-S
18	Key-Range	Key-range conversion lock created by overlap of RangeIn-N and update (U) locks	RangeIn-U
19	Key-Range	Key-range conversion lock created by overlap of RangeIn-N and exclusive (X) locks	RangeIn-X
20	Key-Range	Key-range conversion lock created by overlap of RangeIn-N and RangeS_S locks	RangeX-S
21	Key-Range	Key-Range conversion lock created by overlap of RangeIn-N and RangeS_U locks	RangeX-U
22	Key-Range	Exclusive lock on range between keys, with an exclusive lock on the key at the end of the range	RangeX-X

Listing 37.1 provides an example of a query against the `sys.dm_tran_locks` view.

LISTING 37.1 An Example of a Query Against the `sys.dm_tran_locks` View

```
select str(request_session_id, 4,0) as spid,
       convert (varchar(12), db_name(resource_database_id)) As db_name,
       case when resource_database_id = db_id() and resource_type = 'OBJECT'
            then convert(char(20), object_name(resource_Associated_Entity_id))
            else convert(char(20), resource_Associated_Entity_id)
```

```

        end as object,
        convert(varchar(12), resource_type) as resrc_type,
        convert(varchar(12), request_type) as req_type,
        convert(char(1), request_mode) as mode,
        convert(varchar(8), request_status) as status
    from sys.dm_tran_locks
order by request_session_id, 3 desc
go

```

spid	db_name	object	resrc_type	req_type	mode	status
52	msdb	0	DATABASE	LOCK	S	GRANT
55	bigpubs2008	titles	OBJECT	LOCK	I	GRANT
55	bigpubs2008	sales_qty_rollup	OBJECT	LOCK	X	GRANT
55	bigpubs2008	sales	OBJECT	LOCK	X	GRANT
55	bigpubs2008	679707671068672	PAGE	LOCK	I	GRANT
55	bigpubs2008	679707671068672	KEY	LOCK	X	GRANT
55	bigpubs2008	398232694358016	KEY	LOCK	X	GRANT
55	bigpubs2008	398232694358016	PAGE	LOCK	I	GRANT
55	bigpubs2008	0	DATABASE	LOCK	S	GRANT
56	msdb	0	DATABASE	LOCK	S	GRANT
58	bigpubs2008	sales	OBJECT	LOCK	I	WAIT
58	bigpubs2008	0	DATABASE	LOCK	S	GRANT

Note that the query in Listing 37.1 contains a CASE expression for displaying the object name. If the resource type is OBJECT and the database ID of the locked resource is the same as the current database context, it returns the object name; otherwise, it returns the object ID because the `object_name()` function operates only in the current database context.

TIP

To save yourself the trouble of having to type in the query listed in Listing 37.1, or having to read it in from a file each time you want to run it, you might want to consider creating your own stored procedure or view that invokes this query.

NOTE

In SQL Server 2005, you could monitor lock activity via the Activity Monitor in SQL Server Management Studio (SSMS). If you're looking for this tool in SQL Server 2008, you won't find it. For some reason, this feature was removed from SSMS in SQL Server 2008. The only locking information provided by the SSMS Activity Monitor in SQL Server 2008 is the indication of lock blocking and wait time provided by the Process Monitor and the Lock Waits information provided by the Resource Waits Monitor. There is no GUI-based lock monitoring tool provided with SQL Server 2008 to display the specific locks being held by processes or the locks being held on objects as there was in SQL Server 2005.

Viewing Locking Activity with SQL Server Profiler

Another tool to help you monitor locking activity in SQL Server 2008 is SQL Server Profiler. SQL Server Profiler provides a number of lock events that you can capture in a trace. The trace information can be viewed in real-time or saved to a file or database table for further analysis at a later date. Saving the information to a table allows you to run different reports on the information to help in the analysis.

NOTE

This chapter provides only a brief overview of how to capture and view locking information using SQL Server Profiler. For more information on the features and capabilities of SQL Server Profiler and how to use it, see Chapter 6, “SQL Server Profiler.”

SQL Profiler provides the following lock events that can be captured in a trace:

- ▶ **Lock:Acquired**—Indicates when a lock on a resource, such as a data page or row, has been acquired.
- ▶ **Lock:Cancel**—Indicates when the acquisition of a lock on a resource has been canceled (for example, as the result of a deadlock).
- ▶ **Lock:Deadlock**—Indicates when two or more concurrent processes have deadlocked with each other.
- ▶ **Lock:Deadlock Chain**—Provides the information for each of the events leading up to a deadlock. This information is similar to that provided by the 1204 trace flag, which is covered in the “Deadlocks” section, later in this chapter.
- ▶ **Lock:Escalation**—Indicates when a lower-level lock has been converted to a higher-level lock (for example, when page-level locks are escalated to table-level locks).
- ▶ **Lock:Released**—Indicates that a process has released a previously acquired lock on a resource.
- ▶ **Lock:Timeout**—Indicates that a lock request that is waiting on a resource has timed out due to another transaction holding a blocking lock.
- ▶ **Lock:Timeout (timeout >0)**—Is similar to Lock:Timeout but does not include any events where the lock timeout is 0 seconds.
- ▶ **Deadlock Graph**—Generates an XML description of a deadlock.

Figure 37.1 shows an example of choosing a set of locking events to monitor with SQL Server Profiler.

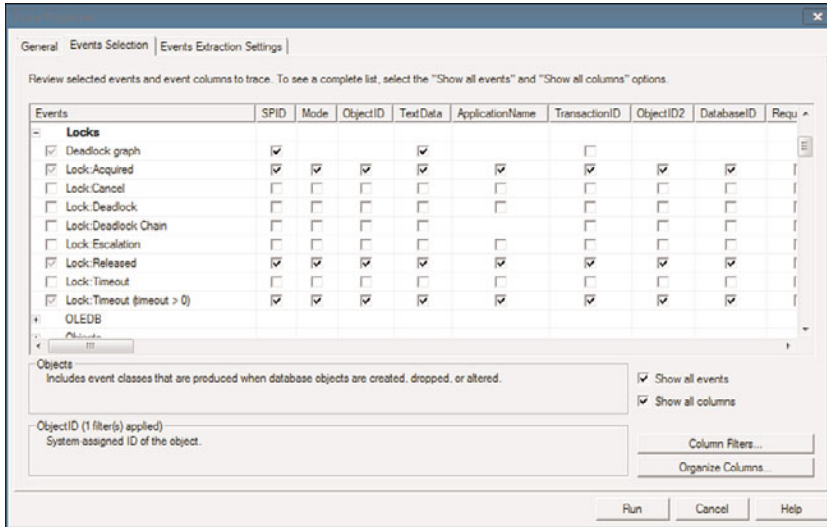

FIGURE 37.1 Choosing lock events in SQL Server Profiler.

SQL Server Profiler also provides a number of data values to display for the events being monitored. You might find the following data columns useful when monitoring locking activity:

- ▶ **spid**—The process ID of the process that generated the event.
- ▶ **EventClass**—The type of event being captured.
- ▶ **Mode**—For lock monitoring, the type of lock involved in the captured event.
- ▶ **ObjectID**—The ID of the object involved in the locking event—that is, the object that the lock is associated with.
- ▶ **DatabaseID**—The ID of the database involved in the locking event
- ▶ **TextData**—The query that generated the lock event.
- ▶ **LoginName**—The login name associated with the process.
- ▶ **ApplicationName**—The name of the application generating the lock event.

Keep in mind that many internal system processes also acquire locks in SQL Server. If you want to filter out those processes and focus on specific processes, users, or applications, you use the filters in SQL Server Profiler to include the information you want to trace or exclude the information you don't want to trace (see Figure 37.2).

After you set up your events, data columns, and filters, you can begin the trace. Figure 37.3 shows an example of the type of information captured.

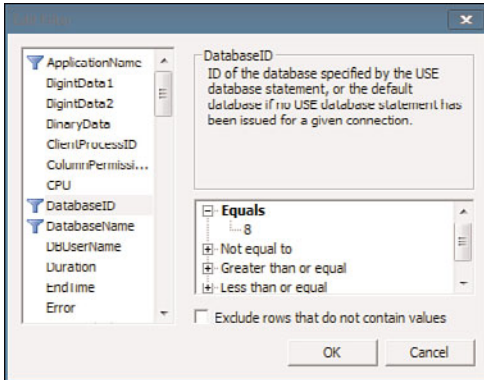

FIGURE 37.2 Filtering out unwanted information in SQL Server Profiler.

Monitoring Locks with Performance Monitor

Another method of monitoring locking in SQL Server is through the Performance Monitor. The `sys.dm_tran_locks` view and SSMS Activity Monitor provide a snapshot of the actual locks currently in effect in SQL Server. If you want to monitor the locking activity as a whole on a continuous basis, you can use the Windows Performance Monitor and monitor the counters available for the `SQLServer:Locks` performance object (see Figure 37.4).

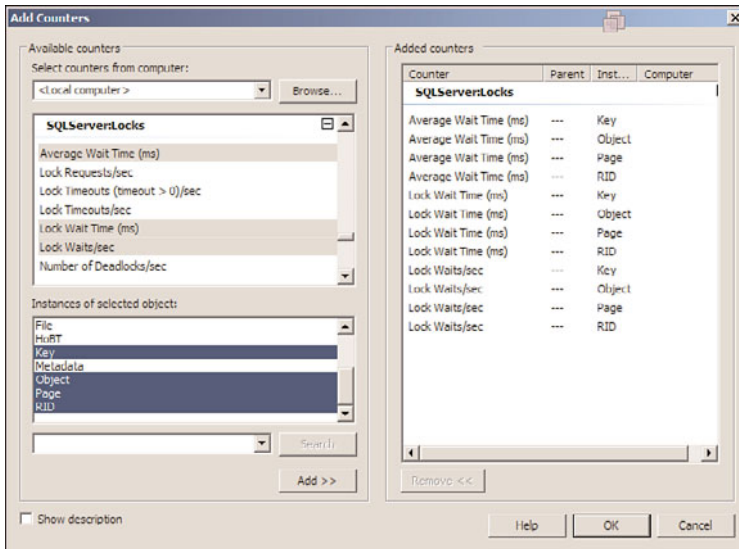

FIGURE 37.4 Choosing counters for the **SQLServer:Locks** performance object in Performance Monitor.

NOTE

If you are monitoring a SQL Server 2008 named instance rather than a default instance of SQL Server 2008, the SQL Server performance counters are listed under the name of the SQL Server instance rather than under the generic SQLServer performance counters.

You can use the **SQLServer:Locks** object to help detect locking bottlenecks and contention points in the system as well as to provide a summary of the overall locking activity in SQL Server. You can use the information that Performance Monitor provides to identify whether locking problems are the cause of any performance problems. You can then take appropriate corrective actions to improve concurrency and the overall performance of the system. The counters that belong to the **SQLServer:Locks** object are as follows:

- ▶ **Average Wait Time**—This counter represents the average wait time (in milliseconds) for each lock request. A high value is an indication of locking contention that could be affecting performance of concurrent processes.
- ▶ **Lock Requests/sec**—This counter represents the total number of new locks and lock conversion requests made per second. A high value for this counter is not necessarily a cause for alarm; it might simply indicate a system with a high number of concurrent users.
- ▶ **Lock Timeouts (timeout > 0)/sec**—This counter is similar to the **LockTimeouts/sec** counter but does not include **NOWAIT** lock requests that time out immediately.

- ▶ **Lock Timeouts/sec**—This counter represents the total number of lock timeouts per second that occur for lock requests on a resource that cannot be granted before the lock timeout interval is exceeded. By default, a blocked process waits indefinitely unless the application specifies a maximum timeout limit, using the `SET LOCK_TIMEOUT` command. A high value for this counter might indicate that the timeout limit is set to a low value in the application or that you are experiencing excessive locking contention.
- ▶ **Lock Wait Time**—This counter represents the cumulative wait time for each lock request. It is given in milliseconds. A high value here indicates that you might have long-running or inefficient transactions that are causing blocking and locking contention.
- ▶ **Lock Waits/sec**—This counter represents the total number of lock requests generated per second for which a process had to wait before a lock request on a resource was granted. A high value might indicate inefficient or long-running transactions or a poor database design that is causing a large number of transactions to block one another.
- ▶ **Number of Deadlocks/sec**—This number represents the total number of lock requests per second that resulted in deadlocks. Deadlocks and ways to avoid them are discussed in the “Deadlocks” section, later in this chapter.

For more information on using Windows Performance Monitor for monitoring SQL Server performance, see Chapter 39, “Monitoring SQL Server Performance.”

SQL Server Lock Types

Locking is handled automatically in SQL Server. The Lock Manager chooses the type of lock, based on the type of transaction (such as `SELECT`, `INSERT`, `UPDATE`, or `DELETE`). Lock Manager uses the following types of locks:

- ▶ Shared locks
- ▶ Update locks
- ▶ Exclusive locks
- ▶ Intent locks
- ▶ Schema locks
- ▶ Bulk update locks

In addition to choosing the type of lock, the Lock Manager in SQL Server 2008 automatically adjusts the granularity of the locks (for example, row, page, table), based on the nature of the statement that is executed and the number of rows that are affected.

Shared Locks

By default, SQL Server uses shared locks for all read operations. A shared lock is, by definition, not exclusive. Theoretically, an unlimited number of shared locks can be held on a resource at any given time. In addition, shared locks are unique in that, by default, a process locks a resource only for the duration of the read on the resource (row, page, or table). For example, the query `SELECT * from authors` locks the first row in the authors table when the query starts. After the first row is read, the lock on that row is released, and a lock on the second row is acquired. After the second row is read, its lock is released, and a lock on the third row is acquired, and so on. In this fashion, a `SELECT` query allows other data rows that are not being read to be modified during the read operation. This increases concurrent access to the data.

Shared locks are compatible with other shared locks as well as with update locks. A shared lock does not prevent the acquisition of additional shared locks or an update lock by other processes on a given row or page. Multiple shared locks can be held at any given time, for a number of transactions or processes. These transactions do not affect the consistency of the data. However, shared locks do prevent the acquisition of exclusive locks. Any transaction attempting to modify data on a page or a row on which a shared lock is placed is blocked until all the shared locks are released.

NOTE

It is important to note that within a transaction running at the default isolation level of Read Committed, shared locks are not held for the duration of the transaction or even the duration of the statement that acquires the shared locks. Shared lock resources (row, page, table, and so on) are normally released as soon as the read operation on the resource is completed. SQL Server provides the `HOLDLOCK` clause for the `SELECT` statement, which you can use if you want to continue holding the shared lock for the duration of the transaction. `HOLDLOCK` is explained later in this chapter, in the section “Table Hints for Locking.” Another way to hold shared locks for the duration of a transaction is to set the isolation level for the session or the query to Repeatable Read or Serializable Reads.

Update Locks

Update locks are used to lock rows or pages that a user process intends to modify. When a transaction tries to update a row, it must first read the row to ensure that it is modifying the appropriate record. If the transaction were to put a shared lock on the resource initially, it would eventually need to get an exclusive lock on the resource to modify the record and prevent any other transaction from modifying the same record. The problem is that this could lead to deadlocks in an environment in which multiple transactions are trying to modify data on the same resource at the same time. Figure 37.5 demonstrates how deadlocks can occur if lock conversion takes place from shared locks to exclusive locks. When both processes attempt to escalate the shared lock they both hold on a resource to an exclusive lock, it results in a deadlock situation.

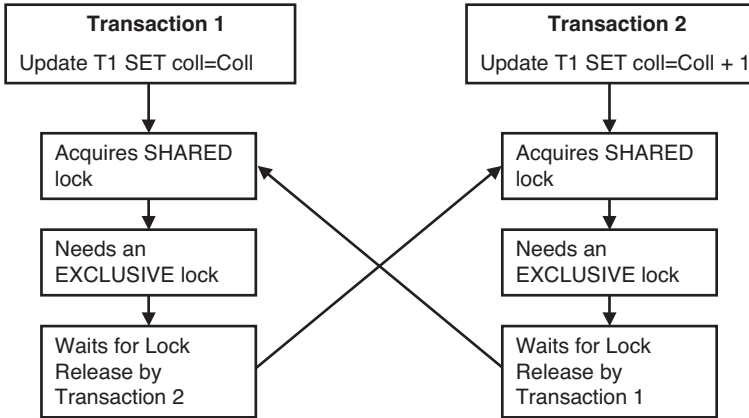

FIGURE 37.5 A deadlock scenario with shared and exclusive locks.

Update locks in SQL Server are provided to prevent this kind of deadlock scenario. Update locks are partially exclusive in that only one update lock can be acquired at a time on any resource. However, an update lock is compatible with shared locks, in that both can be acquired on the same resource simultaneously. In effect, an update lock signifies that a process wants to change a record, and it keeps out other processes that also want to change that record. However, an update lock allows other processes to acquire shared locks to read the data until the UPDATE or DELETE statement is finished locating the records to be affected. The process then attempts to escalate each update lock to an exclusive lock. At this time, the process waits until all currently held shared locks on the same records are released. After the shared locks are released, the update lock is escalated to an exclusive lock. The data change is then carried out, and the exclusive lock is held for the remainder of the transaction.

NOTE

Update locks are not used just for update operations. SQL Server uses update locks any time a search for data is required prior to performing the actual modification, such as with qualified updates and deletes (that is, when a WHERE clause is specified). Update locks are also used for insertions into a table with a clustered index because SQL Server must first search the data and clustered index to identify the correct position at which to insert the new row to maintain the sort order. After SQL Server has found the correct location and begins inserting the record, it escalates the update lock to an exclusive lock.

Exclusive Locks

As mentioned earlier, an exclusive lock is granted to a transaction when it is ready to perform data modifications. An exclusive lock on a resource makes sure no other transaction can interfere with the data locked by the transaction that is holding the exclusive lock. SQL Server releases the exclusive lock at the end of the transaction.

Exclusive locks are incompatible with other lock types. If an exclusive lock is held on a resource, any other read or data modification request for the same resource by other processes is forced to wait until the exclusive lock is released. Likewise, if a resource currently has read locks held on it by other processes, the exclusive lock request is forced to wait in a queue for the resource to become available.

Intent Locks

Intent locks do not really constitute a locking mode; rather, they act as a mechanism to indicate at a higher level of granularity the types of locks held at a lower level. The types of intent locks mirror the lock types previously discussed: shared intent locks, exclusive intent locks, and update intent locks. SQL Server Lock Manager uses intent locks as a mechanism to indicate that a shared, update, or exclusive lock is held at a lower level. For example, a shared intent lock on a table by a process signifies that the process currently holds a shared lock on a row or page within the table. The presence of the intent lock prevents other transactions from attempting to acquire a table-level lock that would be incompatible with the existing row or page locks.

Intent locks improve locking performance by allowing SQL Server to examine locks at the table level to determine the types of locks held on the table at the row or page level rather than searching through the multiple locks at the page or row level within the table. Intent locks also prevent two transactions that are both holding locks at a lower level on a resource from attempting to escalate those locks to a higher level while the other transaction still holds the intent lock. This prevents deadlocks during lock escalation.

You typically see three types of intent locks when monitoring locking activity: intent shared (IS) locks, intent exclusive (IX) locks, and shared with intent exclusive (SIX) locks. An IS lock indicates that the process currently holds, or has the intention of holding, shared locks on lower-level resources (row or page). An IX lock indicates that the process currently holds, or has the intention of holding, exclusive locks on lower-level resources. An SIX (pronounced as the letters *S-I-X*, not like the number six) lock occurs under special circumstances when a transaction is holding a shared lock on a resource, and later in the transaction, an IX lock is needed. At that point, the IS lock is converted to an SIX lock.

In the following example, the `SELECT` statement running at the serializable level acquires a shared table lock. It then needs an exclusive lock to update the row in the `sales_big` table:

```
SET TRANSACTION ISOLATION LEVEL serializable
go
BEGIN TRAN
    select sum(qty) FROM sales_big
UPDATE sales_big
    SET qty = 0
    WHERE sales_id = 1001
COMMIT TRAN
```

Because the transaction initially acquired a shared (S) table lock and then needed an exclusive row lock, which requires an intent exclusive (IX) lock on the table within the same transaction, the S lock is converted to an SIX lock.

NOTE

If only a few rows were in `sales_big`, SQL Server might acquire only individual row or key locks rather than a table-level lock. SQL Server would then have an intent shared (IS) lock on the table rather than a full shared (S) lock. In that instance, the `UPDATE` statement would then acquire a single exclusive lock to apply the update to a single row, and the X lock at the key level would result in the IS locks at the page and table levels being converted to an IX lock at the page and table level for the remainder of the transaction.

Schema Locks

SQL Server uses schema locks to maintain structural integrity of SQL Server tables. Unlike other types of locks that provide isolation for the data, schema locks provide isolation for the schema of database objects, such as tables, views, and indexes within a transaction. The Lock Manager uses two types of schema locks:

- ▶ **Schema stability locks**—When a transaction is referencing either an index or a data page, SQL Server places a schema stability lock on the object. This ensures that no other process can modify the schema of an object—such as dropping an index or dropping or altering a stored procedure or table—while other processes are still referencing the object.
- ▶ **Schema modification locks**—When a process needs to modify the structure of an object (for example, alter the table, recompile a stored procedure), the Lock Manager places a schema modification lock on the object. For the duration of this lock, no other transaction can reference the object until the changes are complete and committed.

Bulk Update Locks

A bulk update lock is a special type of lock used only when bulk copying data into a table using the `bcp` utility or the `BULK INSERT` command. This special lock is used for these operations only when either the `TABLOCK` hint is specified to `bcp` or the `BULK INSERT` command or when the `table lock on bulk load table` option has been set for the table. Bulk update locks allow multiple bulk copy processes to bulk copy data into the same

table in parallel, while preventing other processes that are not bulk copying data from accessing the table. If there are any indexes on the table, or any other processes already holding locks on the table, a bulk update lock cannot be granted.

SQL Server Lock Granularity

Lock granularity is essentially the amount of data locked as part of a query or update to provide complete isolation and serialization for the transaction. The Lock Manager needs to balance the concurrent access to resources versus the overhead of maintaining a large number of lower-level locks. For example, the smaller the lock size, the greater the number of concurrent users who can access the same table at the same time but the greater the overhead in maintaining those locks. The greater the lock size, the less overhead required to manage the locks, but concurrency is also less. Figure 37.6 demonstrates the trade-offs between lock size and concurrency.

FIGURE 37.6 Trade-offs between performance and concurrency, depending on lock granularity.

Currently, SQL Server balances performance and concurrency by locking at the row level or higher. Based on a number of factors, such as key distribution, number of rows, row density, search arguments (SARGs), and so on, the Query Optimizer makes lock granularity decisions internally, and the programmer does not have to worry about such issues. SQL Server provides a number of T-SQL extensions that give you better control over query behavior from a locking standpoint. These Query Optimizer overrides are discussed in the “Table Hints for Locking” section, later in this chapter.

SQL Server provides the following locking levels:

- ▶ **DATABASE**—Whenever a SQL Server process is using a database other than `master`, the Lock Manager grants a database lock to the process. These are always shared locks, and they are used to keep track of when a database is in use to prevent another process from dropping the database, setting the database offline, or restoring the database. Note that because `master` and `tempdb` cannot be dropped or set offline, database locks are not required on those databases.
- ▶ **FILE**—A file lock is a lock acquired on a database file.
- ▶ **EXTENT**—Extent locks are used for locking extents, usually only during space allocation and deallocation. An extent consists of eight contiguous data or index pages. Extent locks can be shared extent or exclusive extent locks.
- ▶ **ALLOCATION_UNIT**—This type of lock is acquired on a database allocation unit.

- ▶ **TABLE**—With this type of lock, the entire table, inclusive of data and indexes, is locked. Examples of when table-level locks may be acquired include selecting all rows from a large table at the serializable level and performing unqualified updates or deletes on a table.
- ▶ **Heap or B-Tree (HOBT)**—This type of lock is acquired on a heap of data pages or on the B-Tree structure of an index.
- ▶ **PAGE**—With a page lock, the entire page, consisting of 8KB of data or index information, is locked. Page-level locks might be acquired when all rows on a page need to be read or when page-level maintenance needs to be performed, such as updating page pointers after a page split.
- ▶ **Row ID (RID)**—With an RID lock, a single row within a page is locked. RID locks are acquired whenever efficient and possible to do so in an effort to provide maximum concurrent access to the resource.
- ▶ **KEY**—SQL Server uses two types of key locks. The one that is used depends on the locking isolation level of the current session. For transactions that run in Read Committed or Repeatable Read isolation modes, SQL Server locks the actual index keys associated with the rows being accessed. (If a clustered index is on the table, the data rows are the leaf level of the index. You see key locks instead of row locks on those rows.) When in Serializable Read isolation mode, SQL Server prevents phantom rows by locking a range of key values so that no new rows can be inserted into the range. These are referred to as *key-range locks*. Key-range locks associated with a particular key value lock that key and the previous one in the index to indicate that all values between them are locked. Key-range locks are covered in more detail in the next section.
- ▶ **METADATA**—This type of lock is acquired on system catalog information
- ▶ **APPLICATION**—An application lock allows users to essentially define their own locks by specifying a name for the resource, a lock mode, an owner, and a timeout interval. Using application locks is discussed later in this chapter, in the section “Using Application Locks.”

Serialization and Key-Range Locking

As mentioned in the previous section, SQL Server provides serialization (Isolation Level 3) through the `SET TRANSACTION ISOLATION SERIALIZABLE` command. One of the isolations provided by this isolation level is the prevention against phantom reads. Preventing phantom reads means that the recordset that a query obtains within a transaction must return the same result set when it is run multiple times within the same transaction. That is, while a transaction is active, another transaction should not be allowed to insert new rows that would appear in the recordset of a query that were not in the original recordset retrieved by the transaction. SQL Server provides this capability through key-range locking.

As described earlier in this chapter, key-range locking in SQL Server provides isolation for a transaction from data modifications made by other transactions. This means that a transaction should return the same recordset each time. The following sections show how

key-range locking works with various lock modes. Key-range locking covers the scenarios of a range search that returns a result set as well as searches against nonexistent rows.

Key-Range Locking for a Range Search

In a scenario that involves key-range locking for a range search, SQL Server places locks on the index pages for the range of data covered in the WHERE clause of the query. (For a clustered index, the rows would be the actual data rows in the table.) Because the range is locked, no other transaction can insert new rows that fall within the range. In Figure 37.7, for example, transaction A has issued the following SELECT statement:

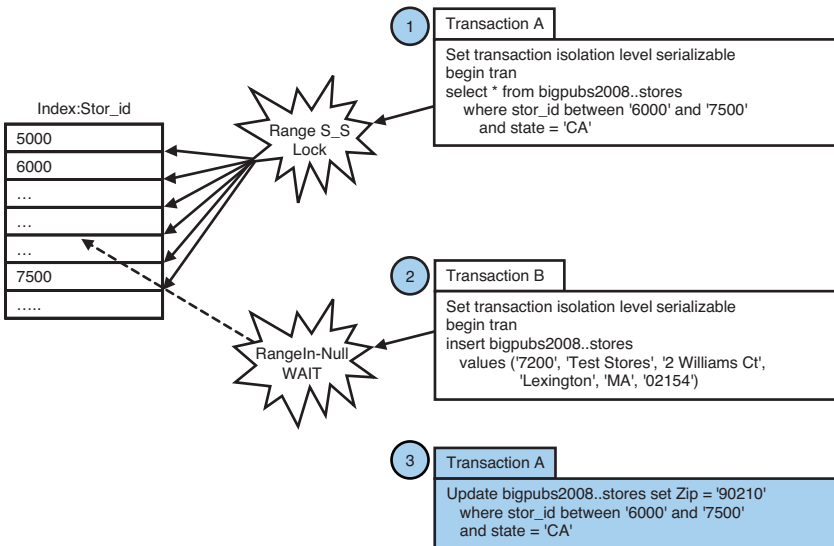

FIGURE 37.7 Key-range locking with a range search.

```
Set transaction isolation level serializable
begin tran
select * from bigpubs2008..stores
where stor_id between '6000' and '7500'
      and state = 'CA'
```

Transaction B is performing the following INSERT statement, attempting to insert a row that falls within the range being retrieved by transaction A (`stor_id >= '6000'` and `stor_id <= '7500'`):

```
begin tran
insert bigpubs2008..stores
values ('7200', 'Test Stores', '2 Williams Ct', 'Lexington', 'MA', '02154')
```

Listing 37.2 shows the locks acquired when using the `sys.dm_tran_locks` catalog view. (In this sample output, SPID 53 is executing the SELECT statement, and SPID 57 is attempting the INSERT.)

LISTING 37.2 Viewing Key-Range Locks Using the **sys.dm_tran_locks** View

```

select str(request_session_id, 4,0) as spid,
       convert (varchar(12), db_name(resource_database_id)) As db_name,
       case when resource_database_id = db_id() and resource_type = 'OBJECT'
            then convert(char(20), object_name(resource_Associated_Entity_id))
            else convert(char(20), resource_Associated_Entity_id)
            end as object,
       convert(varchar(12), resource_type) as resource_type,
       convert(varchar(10), request_mode) as mode,
       convert(varchar(8), request_status) as status
  from sys.dm_tran_locks
 order by request_session_id, 3 desc
go

```

spid	db_name	object	resource_type	mode	status
52	msdb	0	DATABASE	S	GRANT
53	bigpubs2008	391941215944704	PAGE	IS	GRANT
53	bigpubs2008	391941215944704	KEY	RangeS-S	GRANT
53	bigpubs2008	391941215944704	KEY	RangeS-S	GRANT
53	bigpubs2008	391941215944704	KEY	RangeS-S	GRANT
53	bigpubs2008	391941215944704	KEY	RangeS-S	GRANT
53	bigpubs2008	391941215944704	KEY	RangeS-S	GRANT
53	bigpubs2008	1685581043	OBJECT	IS	GRANT
53	bigpubs2008	0	DATABASE	S	GRANT
57	bigpubs2008	673416192655360	PAGE	IX	GRANT
57	bigpubs2008	673416192655360	KEY	X	GRANT
57	bigpubs2008	391941215944704	PAGE	IX	GRANT
57	bigpubs2008	391941215944704	PAGE	IX	GRANT
57	bigpubs2008	391941215944704	KEY	RangeI-N	WAIT
57	bigpubs2008	391941215944704	KEY	RangeI-N	GRANT
57	bigpubs2008	391941215944704	KEY	X	GRANT
57	bigpubs2008	391941215944704	PAGE	IX	GRANT
57	bigpubs2008	1685581043	OBJECT	IX	GRANT
57	bigpubs2008	0	DATABASE	S	GRANT

To provide key-range isolation, SQL Server places RangeS-S locks (that is, a shared lock on the key range and a shared lock on the key at the end of the range) on the index keys for the rows with the matching values. It also places intent share (IS) locks on the page(s) and the table that contain the rows. The insert process acquires intent exclusive (IX) locks on the destination page(s) and the table. In this case, the insert process is waiting for a RangeIn-Null lock on the key range until the RangeS-S locks in the key range are released. The RangeIn-Null lock is an exclusive lock on the range between keys, with no lock on the key. This lock is acquired because the insert process is attempting to insert a new store ID that has no associated key value.

Key-Range Locking When Searching Nonexistent Rows

In a scenario that involves key-range locking when searching nonexistent rows, if a transaction is trying to delete or retrieve a row that does not exist in the database, it still should not find any rows at a later stage in the same transaction with the same query. For example, in Figure 37.8, Transaction A is trying to fetch a nonexistent row with the key value 7200 using the following query:

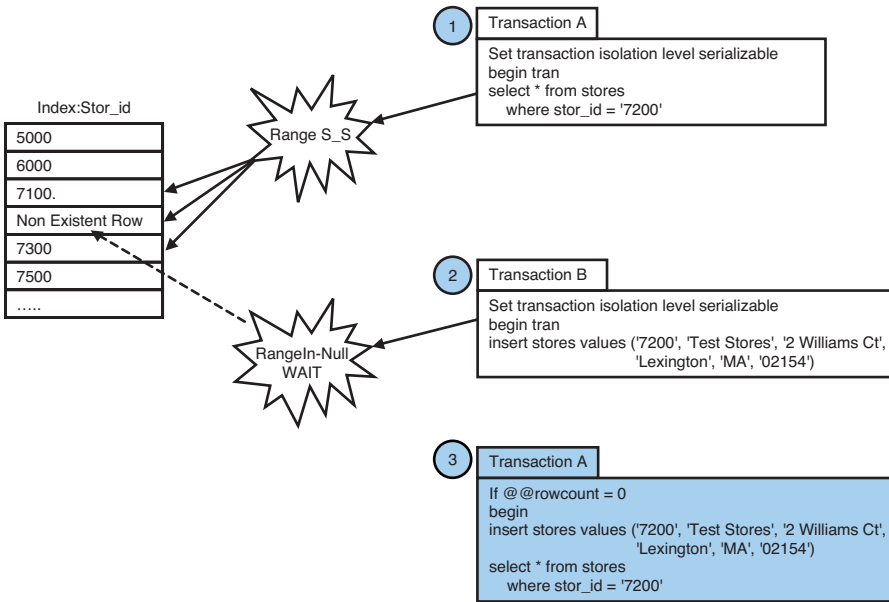

FIGURE 37.8 Key-range locking with a nonexistent data set.

```
SET TRANSACTION ISOLATION LEVEL serializable
go
BEGIN TRAN
select * FROM bigpubs2008..stores
where stor_id = '7200'
```

In another concurrent transaction, Transaction B is executing the following statement to insert a record with the same key value (stor_id = 7200):

```
begin tran
insert bigpubs2008..stores
values ('7200', 'Test Stores', '2 Williams Ct', 'Lexington', 'MA', '02154')
```

In this mode, SQL Server prevents Transaction B (SPID 57) from inserting a new row by using a RangeS-S lock for Transaction A (SPID 53). This lock is placed on the index key

rows for the rows in the range between $\text{MAX}(\text{stor_id}) < 7200$ (key value 7100 in Figure 37.8) and $\text{MIN}(\text{stor_id}) > 7200$ (key value 7300 in Figure 37.8). Transaction B holds a RangeIn-Null lock and waits for the RangeS-S lock to be released.

Listing 37.3 provides an example of the query against the `sys.dm_tran_locks` catalog view for these two transactions.

LISTING 37.3 Viewing Key-Range Locks on Nonexistent Row

```
select str(request_session_id, 4,0) as spid,
       convert (varchar(12), db_name(resource_database_id)) As db_name,
       case when resource_database_id = db_id() and resource_type = 'OBJECT'
            then convert(char(20), object_name(resource_Associated_Entity_id))
            else convert(char(20), resource_Associated_Entity_id)
            end as object,
       convert(varchar(12), resource_type) as resource_type,
       convert(varchar(10), request_mode) as mode,
       convert(varchar(8), request_status) as status
  from sys.dm_tran_locks
 order by request_session_id, 3 desc
go
```

Using Application Locks

The SQL Server Lock Manager knows nothing about the object or the structure of the object it is locking. The Lock Manager simply checks whether two processes are trying to obtain incompatible locks on the same resource. If so, blocking occurs.

SQL Server allows you to extend the resources that can be locked beyond the ones automatically provided. You can define your own custom locking resources and let the Lock Manager control the access to those resources as it would for any resource in a database. This essentially allows you to choose to lock anything you want. These user-defined lock

resources are called *application locks*. To define an application lock, you use the `sp_getapplock` stored procedure and specify a name for the resource you are locking, a mode, an optional lock owner, and an optional lock timeout interval. The syntax for `sp_getapplock` is as follows:

```
sp_getapplock [ @Resource = ] 'resource_name',
    [ @LockMode = ] 'lock_mode'
    [ , [ @LockOwner = ] { 'transaction' | 'session' } ]
    [ , [ @LockTimeout = ] 'value' ]
    [ , [ @DbPrincipal = ] 'database_principal' ]
```

Two resources are considered to be the same resource and are subject to lock contention if they have the same name and the same lock owner in the same database. The resource name used in these procedures can be any identifier up to 255 characters long. The lock owner can be specified as either `transaction` or `session`. Multiple requests for locks on the same resource can be granted only if the locking modes of the requests are compatible. (See the “Lock Compatibility” section, later in this chapter, for a lock compatibility matrix.) The possible modes of the lock allowed are shared, update, exclusive, intent exclusive, and intent shared. The database principal is the user, role, or application role that has permissions to an object in a database. The default is `public`.

For what purpose can you use application locks, and how do you use them? Suppose you have a table that contains a queue of items to be processed by the system. You need a way to serialize the retrieval of the next item from the queue so that the multiple concurrent processes do not grab the same item at the same time. In the past, one way this could be accomplished was by forcing an exclusive lock on the table. (The use of table hints to override default locking behavior is covered in the “Table Hints for Locking” section, later in this chapter.) Only the first process to acquire the exclusive lock would be able to retrieve the next item from the queue. The other processes would have to wait until the exclusive lock was released. The problem with this approach is that the exclusive lock would also block other processes that might need to simply retrieve data from the table.

You can use application locks to avoid having to place an exclusive lock on the entire table. By using `sp_getapplock`, you can define and lock a custom lock resource for a transaction or session. Locks that are owned by the current transaction are released when the transaction commits or rolls back. Locks that are owned by the session are released when the session is closed. Locks can also be explicitly released at any time, with the `sp_releaseapplock` stored procedure. The syntax for `sp_releaseapplock` is as follows:

```
sp_releaseapplock [ @Resource = ] 'resource_name'
    [ , [ @LockOwner = ] { 'transaction' | 'session' } ]
    [ , [ @DbPrincipal = ] 'database_principal' ]
```

NOTE

If a process calls `sp_getapplock` multiple times for the same lock resource, `sp_releaseapplock` must be called the same number of times to fully release the lock. In addition, if `sp_getapplock` is called multiple times on the same lock resource but specifies different lock modes each time, the resulting lock on the resource is a union of the different lock modes. Generally, the lock mode ends up being promoted to the more restrictive level of the existing lock mode and the newly requested mode. The resulting lock mode is held until the last lock release call is made to fully release the lock. For example, assume that a process initially called `sp_getapplock` requested a shared lock. If it subsequently called `sp_getapplock` again and requested an exclusive lock, an exclusive lock would be held on the resource until `sp_releaseapplock` was executed twice.

In the following example, you first request an exclusive lock on an application lock called 'QueueLock' by using `sp_getapplock`. You then invoke the procedure to get the next item in the queue. After the procedure returns, you call `sp_releaseapplock` to release the application lock called 'QueueLock' to let another session acquire the application lock:

```
exec sp_getapplock 'QueueLock', 'Exclusive', 'session'
exec get_next_item_from_queue
exec sp_releaseapplock 'QueueLock', 'session'
```

As long as all processes that need to retrieve items from the queue execute this same sequence of statements, no other process can execute the `get_next_item_from_queue` process until the application lock is released. The other processes block attempts to acquire the exclusive lock on the resource 'QueueLock'. For example, Listing 37.4 shows an example of a query against the `sys.dm_tran_locks` view, showing one process (SPID 53) holding an exclusive lock on QueueLock, while another process (SPID 57) is waiting for an exclusive lock on QueueLock. (The hash value generated internally for QueueLock is shown as 18fb067e in the `Resource_Desc` field.)

LISTING 37.4 Viewing Application Locks Using **sys.dm_tran_locks**

```
select str(request_session_id, 4,0) as spid,
       convert (varchar(12), db_name(resource_database_id)) As db_name,
       case when resource_database_id = db_id() and resource_type = 'OBJECT'
            then convert(char(6), object_name(resource_Associated_Entity_id))
            else convert(char(6), resource_Associated_Entity_id)
       end as object,
       convert(varchar(12), resource_type) as resource_type,
       convert(varchar(4), request_mode) as mode,
       convert(varchar(24), resource_description) as resource_desc,
```

```

        convert(varchar(6), request_status) as status
    from sys.dm_tran_locks
order by request_session_id, 3 desc
go

```

spid	db_name	object	resource_type	mode	resource_desc	status
52	msdb	0	DATABASE	S		GRANT
53	bigpubs2008	0	DATABASE	S		GRANT
53	bigpubs2008	0	APPLICATION	X	0:[QueueLock]:(18fb067e)	GRANT
57	bigpubs2008	0	APPLICATION	X	0:[QueueLock]:(18fb067e)	WAIT
57	bigpubs2008	0	DATABASE	S		GRANT

CAUTION

This method of using application locks to control access to the queue works only if all processes that are attempting to retrieve the next item in the queue follow the same protocol. The `get_next_item_from_queue` procedure itself is not actually locked. If another process attempts to execute the `get_next_item_from_queue` process without attempting to acquire the application lock first, the Lock Manager in SQL Server does not prevent the session from executing the stored procedure.

Index Locking

As with locks on data pages, SQL Server manages locks on index pages internally. There is the opportunity for greater locking contention in index pages than in data pages. Contention at the root page of the index is the highest because the root is the starting point for all searches via the index. Contention usually decreases as you move down the various levels of the B-tree, but it is still higher than contention at the data page level due to the typically greater number of index rows per index page than data rows per data page.

If locking contention in the index becomes an issue, you can use `ALTER INDEX` to manage the locking behavior at the index level. The syntax of this command is as follows:

```

ALTER INDEX { index_name | ALL } ON object
{   ALLOW_ROW_LOCKS = { ON | OFF }
  | ALLOW_PAGE_LOCKS = { ON | OFF }
}

```

The default for both `ALLOW_ROW_LOCKS` and `ALLOW_PAGE_LOCKS` is `ON`. When both of these options are enabled, SQL Server automatically makes the decision whether to apply row or page locks on the indexes and can escalate locks from the row or page level to the table level. When `ALLOW_ROW_LOCKS` is set to `OFF`, row locks on indexes are not used. Only page- or table-level locks are applied. When `ALLOW_PAGE_LOCKS` is set to `OFF`, no page locks are used on indexes, and only row- or table-level locks are applied. When `ALLOW_ROW_LOCKS`

and `ALLOW_PAGE_LOCK` are both set to `OFF`, only a table-level lock is applied when the index is accessed.

NOTE

When `ALLOW_PAGE_LOCKS` is set to `OFF` for an index, the index cannot be reorganized.

SQL Server usually makes good choices for the index locks, but based on the distribution of data and nature of the application, you might want to force a specific locking option on a selective basis. For example, if you are experiencing a high level of locking contention at the page level of an index, you might want to force SQL Server to use row-level locks by turning off page locks.

As another example, if you have a lookup table that is primarily read-only (for example, one that is only refreshed by a weekly or monthly batch process), it may be more efficient to turn off page and row locking so that all readers simply acquire shared table-level locks, thereby reducing locking overhead. When the weekly or monthly batch update runs, the update process acquires an exclusive table-level lock when refreshing the table.

To display the current locking option for a given index, you use the `INDEXPROPERTY` function:

```
select INDEXPROPERTY(object_ID , index_name,
                    { 'IsPageLockDisallowed' | 'IsRowLockDisallowed' } )
```

CAUTION

SQL Server generally makes the correct decision in choosing the appropriate locking granularity for a query. It is generally not recommended that you override the locking granularity choices that the Query Optimizer makes unless you have good reason to do so and have evaluated all options first. Setting the inappropriate locking level can adversely affect the concurrency for a table or index.

Row-Level Versus Page-Level Locking

For years, it was often debated whether row-level locking was better than page-level locking. That debate still goes on in some circles. Many people argue that if databases and applications are well designed and tuned, row-level locking is unnecessary. This is borne out somewhat by the number of large and high-volume applications that were developed when row-level locking wasn't even an option. (Prior to SQL Server version 7, the smallest unit of data that SQL Server could lock was the page.) However, at that time, the page size in SQL Server was only 2KB. With page sizes expanded to 8KB, a greater number of rows (four times as many) can be contained on a single page. Page-level locks on 8KB pages

could lead to greater page-level contention because the likelihood of the data rows being requested by different processes residing on the same page is greater. Using row-level locking increases the concurrent access to the data.

On the other hand, row-level locking consumes more resources (memory and CPU) than page-level locks simply because there is a greater number of rows than pages in a table. If a process needed to access all rows on a page, it would be more efficient to lock the entire page than acquire a lock for each individual row. This would result in a reduction in the number of lock structures in memory that the Lock Manager would have to manage.

Which is better—greater concurrency or lower overhead? As shown earlier, in Figure 37.6, it's a trade-off. As lock size decreases, concurrency improves, but performance degrades due to the extra overhead. As the lock size increases, performance improves due to less overhead, but concurrency degrades. Depending on the application, the database design, and the data, either page-level or row-level locking can be shown to be better than the other in different circumstances.

SQL Server makes the determination automatically at runtime—based on the nature of the query, the size of the table, and the estimated number of rows affected—of whether to initially lock rows, pages, or the entire table. In general, SQL Server attempts to first lock at the row level more often than the page level, in an effort to provide the best concurrency. With the speed of today's CPUs and the large memory support, the overhead of managing row locks is not as expensive as in the past. However, as the query processes and the actual number of resources locked exceed certain thresholds, SQL Server might attempt to escalate locks from a lower level to a higher level, as appropriate.

At times, SQL Server might choose to do both row and page locking for the same query. For example, if a query returns multiple rows, and if enough contiguous keys in a nonclustered index page are selected to satisfy the query, SQL Server might place page locks on the index while using row locks on the data. This reduces the need for lock escalation.

Lock Escalation

When SQL Server detects that the locks acquired by a query are using too much memory and consuming too many system resources for the Lock Manager to manage the locks efficiently, it automatically attempts to escalate row, key, or page locks to table-level locks. For example, because a query on a table continues to acquire row locks and every row in the table will eventually be accessed, it makes sense for SQL Server to escalate the row locks to a table-level lock. After the table-level lock is acquired, the row-level locks are released. This helps reduce locking overhead and keeps the system from running out of available lock structures. Recall from earlier sections in this chapter that the potential need for lock escalation is reflected in the intent locks that are acquired on the table by the process locking at the row or page level. While the default behavior in SQL Server is to escalate to table-level locks, SQL Server 2008 introduces the capability to escalate row or page locks to a single partition via the `LOCK_ESCALATION` setting in `ALTER TABLE`. This new option allows you to specify whether escalation is always to the table or partition level. The `LOCK_ESCALATION` setting can also be used to prevent lock escalation entirely.

NOTE

SQL Server never escalates row locks to page locks, only to table or partition-level locks. Also, multiple partition-level locks are never escalated to a single table-level lock.

What are the lock escalation thresholds in SQL Server? Currently, SQL Server attempts lock escalation under the following conditions:

- ▶ Whenever a single T-SQL statement acquires at least 5,000 locks on a single reference of a table, table partition, or index (this value is subject to change in subsequent service packs). Note that lock escalation does not occur if the locks are spread across multiple objects in the same statement—for example, 4,000 locks on one index and 2,500 locks on another.
- ▶ When the amount of memory required by lock resources exceeds 40% of the available Database Engine memory pool

NOTE

Generally, if more memory is required for lock resources than is currently available in the Database Engine memory pool, the Database Engine allocates additional memory dynamically to satisfy the request for locks as long as more computer memory is available and the `max_server_memory` threshold has not been reached. However, if allocating additional memory would cause paging at the operating system level, more lock space is not allocated. If no more memory is available, or the amount of memory allocated to lock resources reaches 60% of the memory acquired by an instance of the Database Engine, further requests for locks generate an out-of-lock memory error.

If locks cannot be escalated because of lock conflicts, SQL Server reattempts lock escalation when every 1,250 additional locks are acquired. For example, if another process is also holding locks at the page or row level on the same table (indicated by the presence of that process's intent lock on the table), lock escalation cannot take place if the lock types are not compatible until the lower-level locks are released by the other processes. In this case, SQL Server continues acquiring locks at the row or page level until the table lock becomes available.

Controlling Lock Escalation

Escalating locks to the table or partition level can lead to locking contention or blocking for other transactions attempting to access a row or page in the same table. Under certain circumstances, you might want to disable lock escalation.

As mentioned previously, lock escalation can be enabled or disabled at the table level using the `ALTER TABLE` command:

```
ALTER TABLE tablename set (LOCK_ESCALATION = { AUTO | TABLE | DISABLE } )
```

Setting the option to `AUTO` allows SQL Server to escalate to the table or partition level. Setting the option to `DISABLE` prevents escalation to the table or partition level.

SQL Server 2008 also supports disabling lock escalation for all tables in all databases within a SQL Server instance using either the 1211 or 1224 trace flags. Trace flag 1211 completely disables lock escalation, regardless of the memory required for lock resources. However, when the amount of memory required for lock resources exceeds 60% of the maximum available Database Engine memory, an out-of-lock memory error is generated. Alternatively, trace flag 1224 disables the built-in lock escalation based on the number of locks acquired, but lock escalation is still possible when the 40% of available Database Engine memory threshold is reached. However, as noted previously, if the locks cannot be escalated, SQL Server could still run out of available memory for locks.

NOTE

You should be extremely careful when considering disabling lock escalation via the trace flags. A poorly designed application could potentially exhaust the available SQL Server memory with excessive lock structures and seriously degrade SQL Server performance. It is usually preferable to control lock escalation at the object level via the `ALTER TABLE` command.

Lock Compatibility

If a process has already locked a resource, the granting of lock requests by other transactions on the same resource is governed by the lock compatibility matrix within SQL Server. Table 37.3 shows the lock compatibility matrix for the locks most commonly acquired by the SQL Server Lock Manager, indicating which lock types are compatible and which lock types are incompatible when requested on the same resource.

TABLE 37.3 SQL Server Lock Compatibility Matrix

Requested Lock Type	Existing Lock Type								
	IS	S	U	IX	SIX	X	Sch-S	SCH-M	BU
Intent shared	Yes	Yes	Yes	Yes	Yes	No	Yes	No	No
Shared	Yes	Yes	Yes	No	No	No	Yes	No	No
Update	Yes	Yes	No	No	No	No	Yes	No	No
Intent exclusive	Yes	No	No	Yes	No	No	Yes	No	No
Shared with intent exclusive	Yes	No	No	No	No	No	Yes	No	No
Exclusive	No	No	No	No	No	No	Yes	No	No
Schema stability	Yes	Yes	Yes	Yes	Yes	Yes	Yes	No	Yes
Schema modify	No	No	No	No	No	No	No	No	No
Bulk update	No	No	No	No	No	No	Yes	No	Yes

For example, if a transaction has acquired a shared lock on a resource, the possible lock types that can be acquired on the resource by other transactions are intent shared, shared, update, and schema stability locks. Intent exclusive, SIX, exclusive, schema modification, and bulk update locks are incompatible with a shared lock and cannot be acquired on the resource until the shared lock is released.

Locking Contention and Deadlocks

In the grand scheme of things, the most likely culprits of SQL Server application performance problems are typically poorly written queries, poor database and index design, and locking contention. Whereas the first two problems result in poor application performance, regardless of the number of users on the system, locking contention becomes more of a performance problem as the number of users increases. It is further compounded by increasingly complex or long-running transactions.

Locking contention occurs when a transaction requests a lock type on a resource that is incompatible with an existing lock type on the resource. By default, the process waits indefinitely for the lock resource to become available. Locking contention is noticed in the client application through the apparent lack of response from SQL Server.

Figure 37.9 demonstrates an example of locking contention. Process 1 has initiated a transaction and acquired an exclusive lock on page 1:325. Before Process 1 can acquire the lock that it needs on page 1:341 to complete its transaction, Process 2 acquires an exclusive lock on page 1:341. Until Process 2 commits or rolls back its transaction and releases the lock on Page 1:341, the lock continues to be held. Because this is not a deadlock scenario (which is covered in the “Deadlocks” section, later in this chapter), by default, SQL Server takes no action. Process 1 simply waits indefinitely.

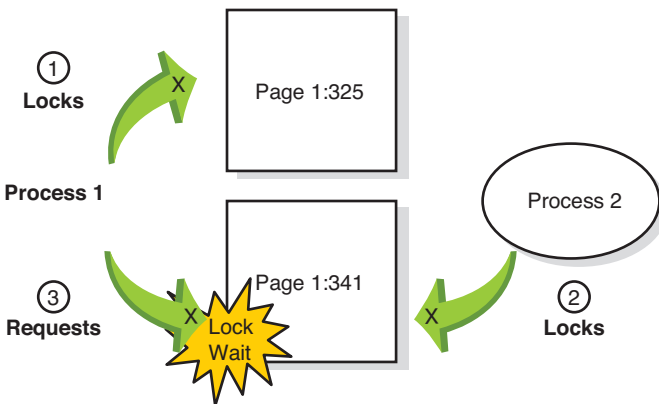

FIGURE 37.9 Locking contention between two processes.

Identifying Locking Contention

When a client application appears to freeze after submitting a query, this is often due to locking contention. To identify locking contention between processes, you can use the SSMS Activity Monitor, as discussed earlier in this chapter, in the “Monitoring Lock Activity in SQL Server” section; use the `sp_who2` stored procedure; or query the `sys.dm_tran_locks` system catalog view. Figure 37.10 shows an example of a blocking lock as viewed in the SSMS Activity Monitor.

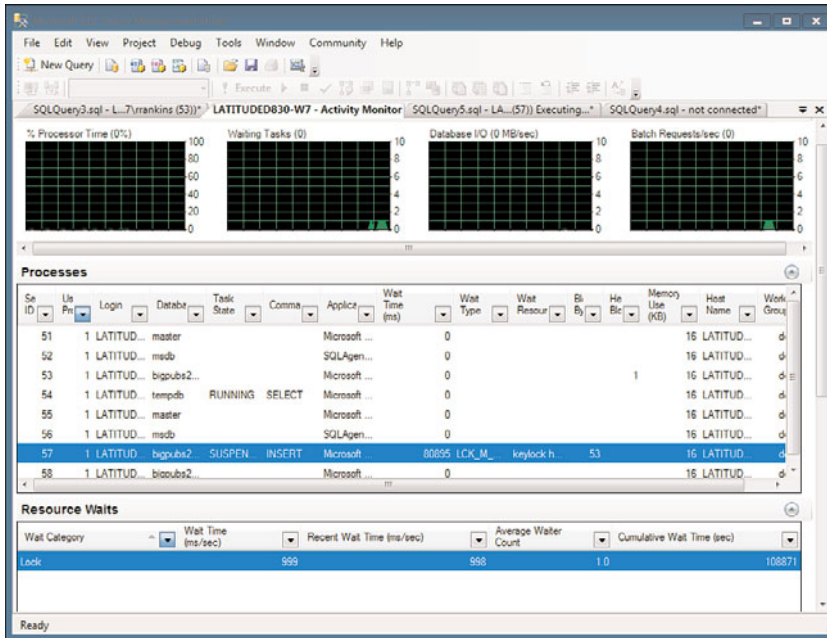

FIGURE 37.10 Examining locking contention between two processes in SSMS Activity Monitor.

To identify whether a process is being blocked using `sp_who2`, examine the `BlkBy` column. If any value besides ‘-’ is displayed, it is the SPID of the process that is holding the blocking lock. In the following output of `sp_who2` (edited for space), you can see that process 57 is `SUSPENDED`, waiting on a lock held by process 53:

```
exec sp_who2
```

```
go
SPID Status      Login      HostName      BlkBy DBName      Command
-----
*** info for internal processes deleted ***
51    sleeping      rrankins   LATITUDE830-W7 .      master      AWAITING COMMAND
52    sleeping      SQLADMIN   LATITUDE830-W7 .      msdb        AWAITING COMMAND
53    sleeping      rrankins   LATITUDE830-W7 .      bigpubs2008 AWAITING COMMAND
54    sleeping      rrankins   LATITUDE830-W7 .      tempdb      AWAITING COMMAND
```

```

55 sleeping rrankins LATITUDE830-W7 . master AWAITING COMMAND
56 sleeping SQLADMIN LATITUDE830-W7 . msdb AWAITING COMMAND
57 SUSPENDED rrankins LATITUDE830-W7 53 bigpubs2008 INSERT
58 sleeping rrankins LATITUDE830-W7 . bigpubs2008 AWAITING COMMAND
59 RUNNABLE rrankins LATITUDE830-W7 . master SELECT INTO

```

To determine what table, page, or rows are involved in blocking and at what level the blocking is occurring, you can query the `sys.dm_tran_locks` catalog view, as shown in Listing 37.5.

LISTING 37.5 Viewing Locking Contention by Using the `sys.dm_tran_locks` View

```

use bigpubs2008
go
select str(request_session_id, 4,0) as spid,
       convert (varchar(12), db_name(resource_database_id)) As db_name,
       case when resource_database_id = db_id() and resource_type = 'OBJECT'
            then convert(char(12), object_name(resource_Associated_Entity_id))
            else convert(char(16), resource_Associated_Entity_id)
            end as object,
       convert(varchar(12), resource_type) as resource_type,
       convert(varchar(8), request_mode) as mode,
       convert(varchar(14), resource_description) as resource_desc,
       convert(varchar(6), request_status) as status
  from sys.dm_tran_locks
 order by request_session_id, 3 desc
go

```

spid	db_name	object	resource_type	mode	resource_desc	status
52	msdb	0	DATABASE	S		GRANT
53	bigpubs2008	673416192655360	PAGE	IX	1:608	GRANT
53	bigpubs2008	673416192655360	KEY	X	(928195c101b1)	GRANT
53	bigpubs2008	391941215944704	KEY	X	(59d1a826552c)	GRANT
53	bigpubs2008	391941215944704	PAGE	IX	1:280	GRANT
53	bigpubs2008	stores	OBJECT	IX		GRANT
53	bigpubs2008	0	DATABASE	S		GRANT
56	msdb	0	DATABASE	S		GRANT
57	bigpubs2008	391941215944704	PAGE	IS	1:280	GRANT
57	bigpubs2008	391941215944704	KEY	S	(59d1a826552c)	WAIT
57	bigpubs2008	stores	OBJECT	IS		GRANT
57	bigpubs2008	0	DATABASE	S		GRANT

From this output, you can see that Process 57 is waiting for a shared (S) lock on key 59d1a826552c of page 1:280 of the stores table. Process 53 has an intent exclusive (IX)

lock on that page because it has an exclusive (X) lock on a key on that page. (Both have the same `resource_Associated_Entity_id` of 59d1a826552c.)

As an alternative to `sp_who` and the `sys.dm_tran_locks` view, you can also get specific information on any blocked processes by querying the `sys.dm_os_waiting_tasks` system catalog view, as shown in Listing 37.6.

LISTING 37.6 Viewing Blocked Processes by Using the `sys.dm_os_waiting_tasks` View

```
select convert(char(4), session_id) as spid,
       convert(char(8), wait_duration_ms) as duration,
       convert(char(8), wait_type) as wait_type,
       convert(char(3), blocking_session_id) as blk,
       resource_description
from sys.dm_os_waiting_tasks
where blocking_session_id is not null
go
```

```
spid duration wait_type blk resource_description
-----
```

```
57 134118 LCK_M_S 53 keylock hobtid=391941215944704 dbid=8 id=lockfd43800
mode=X associatedObjectId=391941215944704
```

Setting the Lock Timeout Interval

If you do not want a process to wait indefinitely for a lock to become available, SQL Server allows you to set a lock timeout interval by using the `SET LOCK_TIMEOUT` command. You specify the timeout interval in milliseconds. For example, if you want your processes to wait only 5 seconds (that is, 5,000 milliseconds) for a lock to become available, you execute the following command in the session:

```
SET LOCK_TIMEOUT 5000
```

If your process requests a lock resource that cannot be granted within 5 seconds, the statement is aborted, and you get the following error message:

```
Server: Msg 1222, Level 16, State 52, Line 1
Lock request time out period exceeded.
```

To examine the current `LOCK_TIMEOUT` setting, you can query the system function `@@lock_timeout`:

```
select @@lock_timeout
go
```

```
-----
5000
```

If you want processes to abort immediately if the lock cannot be granted (in other words, no waiting at all), you set the timeout interval to 0. If you want to set the timeout interval back to infinity, execute the `SET_LOCK_TIMEOUT` command and specify a timeout interval of -1.

Minimizing Locking Contention

Although setting the lock timeout prevents a process from waiting indefinitely for a lock request to be granted, it doesn't address the cause of the locking contention. In an effort to maximize concurrency and application performance, you should minimize locking contention between processes as much as possible. Some general guidelines to follow to minimize locking contention include the following:

- ▶ Keep transactions as short and concise as possible. The shorter the period of time locks are held, the less chance for lock contention. Keep commands that are not essential to the unit of work being managed by the transaction (for example, assignment selects, retrieval of updated or inserted rows) outside the transaction.
- ▶ Keep statements that comprise a transaction in a single batch to eliminate unnecessary delays caused by network input/output (I/O) between the initial `BEGIN TRAN` statement and the subsequent `COMMIT TRAN` commands.
- ▶ Consider coding transactions entirely within stored procedures. Stored procedures typically run faster than commands executed from a batch. In addition, because they are server resident, stored procedures reduce the amount of network I/O that occurs during execution of the transaction, resulting in faster completion of the transaction.
- ▶ Commit updates in cursors frequently and as soon as possible. Cursor processing is much slower than set-oriented processing and causes locks to be held longer.

NOTE

Even though cursors might run more slowly than set-oriented processing, cursors can sometimes be used to minimize locking contention for updates and deletions of a large number of rows from a table, which might result in a table lock being acquired. The `UPDATE` or `DELETE` statement itself might complete faster; however, if it is running with an exclusive lock on the table, then no other process can access the table until it completes. By using a cursor to update a large number of rows one row at a time and committing the changes frequently, the cursor uses page- or row-level locks rather than a table-level lock. It might take longer for the cursor to complete the actual update or delete, but while the cursor is running, other processes are still able to access other rows or pages in the table that the cursor doesn't currently have locked.

- ▶ Use the lowest level of locking isolation required by each process. For example, if dirty reads are acceptable and accurate results are not imperative, consider using transaction Isolation Level 0. Use the Repeatable Read or Serializable Read isolation levels only if absolutely necessary.

- ▶ Never allow user interaction between a `BEGIN TRAN` statement and a `COMMIT TRAN` statement because doing so may cause locks to be held for an indefinite period of time. If a process needs to return rows for user interaction and then update one or more rows, consider using optimistic locking or Snapshot Isolation in your application. (Optimistic locking is covered in the “Optimistic Locking” section, later in this chapter.)
- ▶ Minimize “hot spots” in a table. Hot spots occur when the majority of the update activity on a table occurs within a small number of pages. For example, hot spots occur for concurrent insertions to the last page of a heap table or the last pages of a table with a clustered index on a sequential key. You can often eliminate hot spots by creating a clustered index in a table on a column or columns to order the rows in the table in such a way that insert and update activity is spread out more evenly across the pages in the table.

Deadlocks

A *deadlock* occurs when two processes are each waiting for a locked resource that the other process currently holds. Neither process can move forward until it receives the requested lock on the resource, and neither process can release the lock it is currently holding until it can receive the requested lock. Essentially, neither process can move forward until the other one completes, and neither one can complete until it can move forward.

Two primary types of deadlocks can occur in SQL Server:

- ▶ **Cycle deadlocks**—A cycle deadlock occurs when two processes acquire locks on different resources, and then each needs to acquire a lock on the resource that the other process has. Figure 37.11 demonstrates an example of a cycle deadlock.

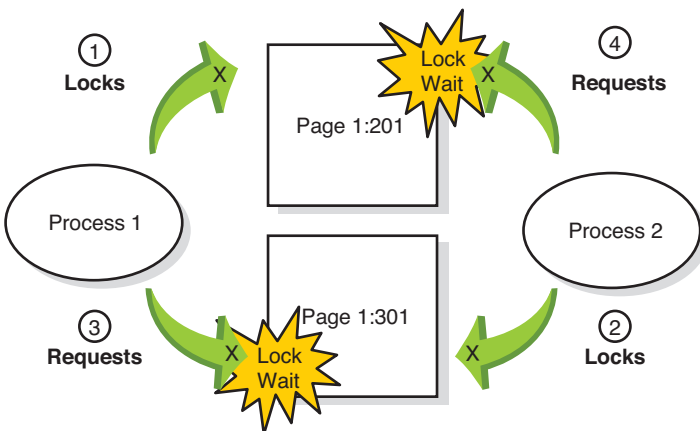

FIGURE 37.11 An example of a cycle deadlock.

In Figure 37.11, Process 1 acquires an exclusive lock on page 1:201 in a transaction. At the same time, Process 2 acquires an exclusive lock on page 1:301 in a transac-

tion. Process 1 then attempts to acquire a lock on page 1:301 and begins waiting for the lock to become available. Simultaneously, Process 2 requests an exclusive lock on page 1:201, and a deadlock, or “deadly embrace,” occurs.

- **Conversion deadlocks**—A conversion deadlock occurs when two or more processes each hold a shared lock on the same resource within a transaction and each wants to promote the shared lock to an exclusive lock, but neither can do so until the other releases the shared lock. An example of a conversion deadlock is shown in Figure 37.12.

FIGURE 37.12 An example of a conversion deadlock.

It is often assumed that deadlocks happen at the data page or data row level. In fact, deadlocks often occur at the index page or index key level. Figure 37.13 depicts a scenario in which a deadlock occurs due to contention at the index key level.

SQL Server automatically detects when a deadlock situation occurs. A separate process in SQL Server, called `LOCK_MONITOR`, checks the system for deadlocks roughly every 5 seconds. In the first pass, this process detects all the processes that are waiting on a lock resource. The `LOCK_MONITOR` thread checks for deadlocks by examining the list of waiting lock requests to see if any circular lock requests exist between the processes holding locks and the processes waiting for locks. When the `LOCK_MONITOR` detects a deadlock, SQL Server aborts the transaction of one of the involved processes. How does SQL Server determine which process to abort? It attempts to choose as the deadlock victim the transaction that it estimates would be least expensive to roll back. If both processes involved in the deadlock have the same rollback cost and the same deadlock priority, the deadlock victim is chosen randomly.

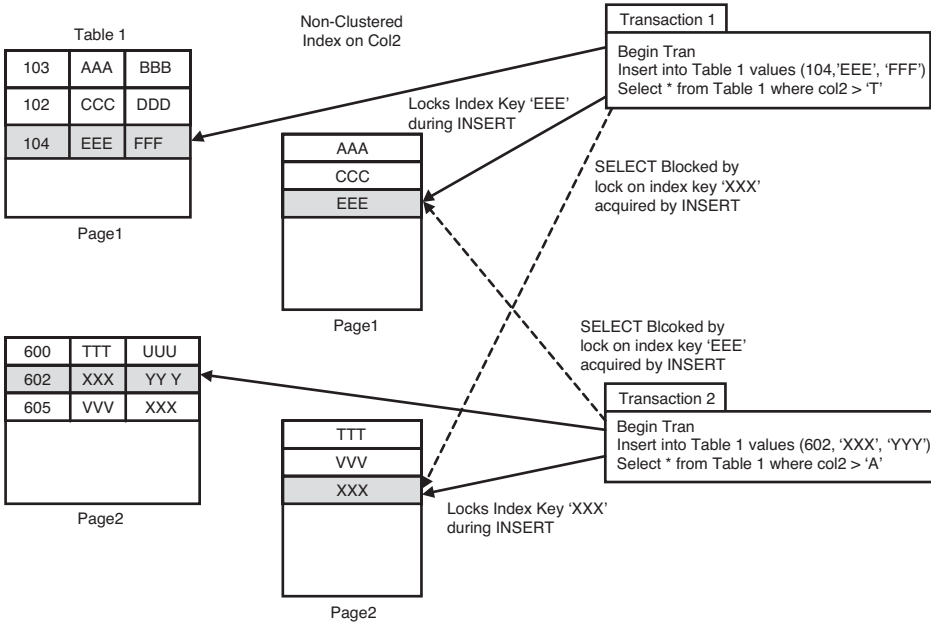

FIGURE 37.13 Deadlock scenario due to locks on index keys.

NOTE

As deadlocks occur, SQL Server begins reducing the deadlock detection interval and can potentially go as low as 100ms. In addition, the first few lock requests that cannot be satisfied after a deadlock is detected immediately trigger a deadlock search instead of waiting for the next deadlock detection interval. When deadlock frequency declines, the deadlock detection interval begins to increase back to 5 seconds.

You can influence which process will be the deadlock victim by using the >SET DEADLOCK_PRIORITY statement. DEADLOCK_PRIORITY can be set to LOW, NORMAL, or HIGH. Alternatively, DEADLOCK_PRIORITY can also be set to any integer value from -10 to 10. The default deadlock priority is NORMAL. When two sessions deadlock, and the deadlock priority has been set to something other than the default, the session with the lower priority is chosen as the deadlock victim. If you have lower-priority processes that you would prefer always be chosen as the deadlock victims, you might want to set the process's deadlock priority to LOW. Alternatively, for critical processes, you might want to set the deadlock priority to HIGH to specify processes that should always come out as the winners in a deadlock scenario.

Avoiding Deadlocks

Although SQL Server automatically detects and handles deadlocks, you should try to avoid deadlocks in your applications. When a process is chosen as a deadlock victim, it has to

resubmit its work because it has been rolled back. Frequent deadlocks create performance problems if you have to keep repeating work.

You can follow a number of guidelines to minimize, if not completely eliminate, the number of deadlocks that occur in your application(s). Following the guidelines presented earlier to minimize locking contention and speed up your transactions also helps to eliminate deadlocks. The less time for which a transaction is holding locks, the less likely the transition will be around long enough for a conflicting lock request to be requested at the same time. In addition, you might want to follow this list of additional guidelines when designing applications:

- ▶ Be consistent about the order in which you access the data from tables to avoid cycle deadlocks.
- ▶ Minimize the use of `HOLDLOCK` or queries that are running using Repeatable Read or Serializable Read isolation levels. This helps avoid conversion deadlocks. If possible, perform `UPDATE` statements before `SELECT` statements so that your transaction acquires an update or exclusive lock first. This eliminates the possibility of a conversion deadlock. (Later, in the “Table Hints for Locking” section in this chapter, you see how to use table-locking hints to force `SELECT` statements to use update or exclusive locks as another strategy to avoid conversion deadlocks.)
- ▶ Choose the transaction isolation level judiciously. You might be able to reduce deadlocks by choosing lower isolation levels.

Handling and Examining Deadlocks

SQL Server returns error number 1205 to the client when it aborts a transaction as a result of deadlock. The following is an example of a 1205 error message:

```
Msg 1205, Level 13, State 51, Line 1
Transaction (Process ID 53) was deadlocked on lock resources with another process
and has been chosen as the deadlock victim. Rerun the transaction.
```

Because a deadlock is not a logical error but merely a resource contention issue, the client can resubmit the entire transaction. To handle deadlocks in applications, be sure to trap for message 1205 in the error handler. When a 1205 error occurs, the application can simply resubmit the transaction automatically. It is considered bad form to allow end users of an application to see the deadlock error message returned from SQL Server.

Earlier in this chapter, you learned how to use `sp_who2` and the `sys.dm_tran_locks` and `sys.dm_os_waiting_tasks` system catalog views to monitor locking contention between processes. However, when a deadlock occurs, one transaction is rolled back, and one is allowed to continue. If you examine the output from `sp_who2` or the system catalog views after a deadlock occurs, the information likely will not be useful because the locks on the resources involved will have since been released.

Fortunately, SQL Server provides a couple of trace flags to monitor deadlocks within SQL Server. They are trace flag 1204 and trace flag 1222. When enabled, they print deadlock information to the SQL Server error log. Trace flag 1204 provides deadlock information

generated by each process involved in the deadlock. Trace flag 1222 provides deadlock information by processes and by resources. Both trace flags can be enabled to capture a complete representation of a deadlock event.

You use the `DBCC TRACEON` command to turn on the trace flags and `DBCC TRACEOFF` to turn them off. The 1204 and 1222 trace flags are global trace flags. Global trace flags are set at the server level and are visible to every connection on the server. They cannot be set for a specific session only. They enable or disable a global trace flag, and the `-1` option must be specified as the second argument to the `DBCC TRACEON` and `DBCC TRACEOFF` commands. The following example shows how to globally enable the 1204 trace flag:

```
dbcc traceon(1204, -1)
```

If possible, it is best to set global trace flags whenever SQL Server is started up by adding the `-T` option with the appropriate trace flag value to the SQL Server startup parameters. For example, to have SQL Server turn on the 1204 trace flag automatically on startup, you use the SQL Server Configuration Manager. In the SQL Server Configuration Manager window, you click SQL Server 2005 Services; in the right pane, right-click the SQL Server service for the appropriate SQL Server instance name and then click Properties. On the Advanced tab, expand the Startup Parameters box and type a semicolon (;) and `-T1204` after the last startup parameter listed (see Figure 37.14); then click OK to save the changes. You then need to stop and restart SQL Server for the trace flag to take effect.

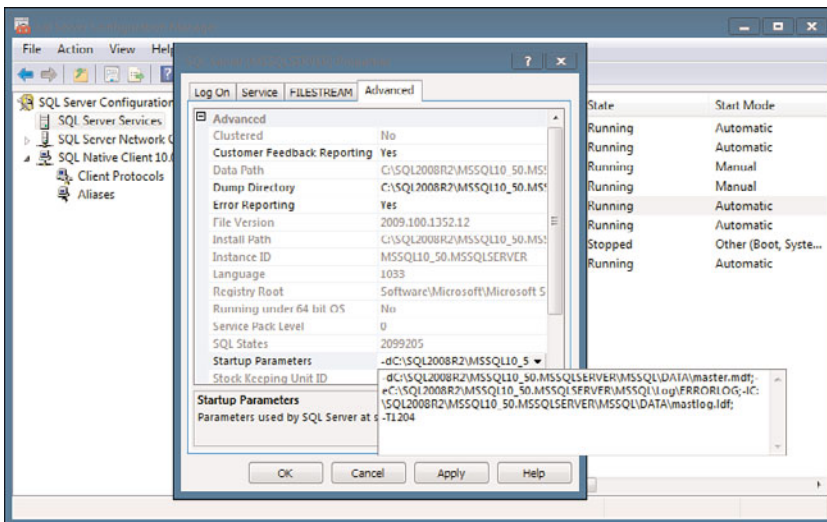

FIGURE 37.14 Setting the 1204 trace flag to be enabled on SQL Server startup.

CAUTION

The 1204 and 1222 trace flags may incur some additional processing overhead in SQL Server. They should be used only when you are debugging and tuning SQL Server performance, and they should not be left on indefinitely in a production environment. You should turn them off after you have diagnosed and fixed the problems.

The 1204 Trace Flag Trace flag 1204 prints useful information to the SQL Server error log when a deadlock is detected. The following output is from the error log for this trace flag:

```

```

Although the 1204 output is somewhat cryptic, it is not too difficult to read if you know what to look for. If you look through the output, you can see where it lists the SPIDs of the processes involved in the deadlock (in this example, SPIDs 53 and 57) and indicates which process was chosen as the deadlock victim (SPID:57). The type of statement involved is indicated by `Statement Type`. In this example, both processes were attempting a DELETE statement. You can also examine the actual text of the query (`Input Buf`) that each process was executing at the time the deadlock occurred. The output also displays the locks granted to each process (`Grant List`), the lock types (`Mode:`) of the locks held, and the lock resources requested by the deadlock victim.

The 1222 Trace Flag Trace flag 1222 provides deadlock information, first by processes and then by resources. The information is returned in an XML-like format that does not conform to an XML schema definition. The output has three major sections:

- ▶ The first section declares the deadlock victim.
- ▶ The second section describes each process involved in the deadlock
- ▶ The third section describes the resources involved

The following example shows the 1222 trace flag output for the same deadlock scenario displayed by the 1204 trace flag output in the previous section:

```

Monitoring Deadlocks with SQL Server Profiler

If you still find the 1204 and 1222 trace flag output too difficult to interpret, you'll be pleased to know that SQL Server Profiler provides a much more user-friendly way of capturing and examining deadlock information. As discussed in the "Monitoring Lock Activity in SQL Server" section, earlier in this chapter, SQL Profiler provides three deadlock events that can be monitored:

- ▶ Lock:Deadlock
- ▶ Lock:Deadlock Chain
- ▶ Deadlock Graph

The Lock:Deadlock and Lock:Deadlock Chain events aren't really very useful in SQL Server 2008. The Lock:Deadlock event generates a simple trace record that indicates when a deadlock occurs between two processes. The SPID column indicates what process was chosen as the deadlock victim. The Lock:Deadlock Chain event generates a trace record for each process involved in the deadlock. Unfortunately, neither of these trace events provides any detailed information, such as the queries involved in the deadlock. (You would need to also trace the T-SQL commands executed to capture this information, but you would then be capturing all SQL statements, not just those involved in the deadlock.)

Fortunately, SQL Server Profiler provides the new Deadlock Graph event. When this event is enabled, SQL Server Profiler populates the TextData data column in the trace with XML data about the process and objects involved in the deadlock. This XML data can then be used to display a Deadlock Graph in SQL Server Profiler itself, or the XML can be extracted to a file, which can be read in and viewed in SSMS. Figure 37.15 shows an example of a Deadlock Graph being displayed in SQL Server Profiler.

The Deadlock Graph displays the processes, resources, and relationships between the processes and resources. The following components make up a Deadlock Graph:

- ▶ **Process node**—An oval containing information about each thread that performs a task involved in the deadlock (for example, INSERT, UPDATE, or DELETE).
- ▶ **Resource node**—A rectangle containing information about each database object being referenced (for example, a table, an index, a page, a row, or a key).
- ▶ **Edge**—A line representing a relationship between a process and resource. A request edge occurs when a process waits for a resource. An owner edge occurs when a resource waits for a process. The lock mode is included in the edge description.

Figure 37.15 displays the deadlock information for the processes involved in the deadlocks displayed by the 1204 and 1222 trace flag output listed in the previous sections. You can see that it displays the resource(s) involved in the deadlock in the Resource node (Key Lock), the lock type held on the resource by each process (Owner Mode: S), the lock type being requested by each process (Request Mode: X), and general information about each

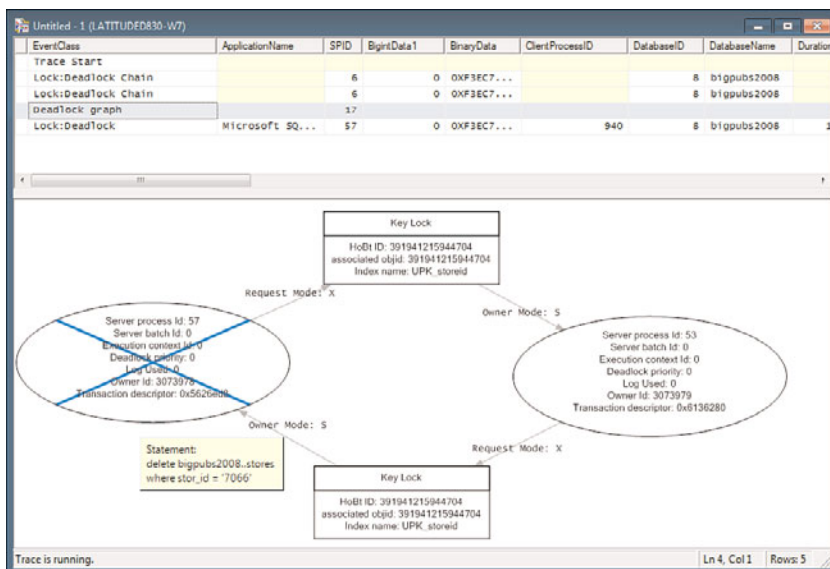

FIGURE 37.15 Displaying a Deadlock Graph in SQL Server Profiler.

process (for example, SPID, deadlock priority) displayed in each process node. The process node of the process chosen as the deadlock victim has an X through it. If you place the mouse pointer over a process node, a ToolTip displays the SQL statement for that process involved in the deadlock. If the graph appears too large or too small for the profiler window, you can right-click anywhere within the graph to bring up a context menu that allows you to increase or decrease the size of the graph.

To save a Deadlock Graph to a file for further analysis at a later date, you can right-click the Deadlock Graph event in the top panel and choose the Extract Event Data option. To save all Deadlock Graph events contained in a SQL Server trace to one or more files, you select File, Export, Extract SQL Server Events and then choose the Extract Deadlock Events option. In the dialog that appears, you have the option to save all Deadlock Graphs contained in the trace to a single file or to save each to a separate file.

SQL Server Profiler can also save all Deadlock Graphs to a file automatically. When you are configuring a trace with the Deadlock Graph event selected, you go to the Events Extraction Settings tab and click Save Deadlock XML Events Separately. Then you specify the file where you want the deadlock events to be saved. You can select to save all Deadlock Graph events in a single XML file or to create a new XML file for each Deadlock Graph. If you choose to create a new XML file for each Deadlock Graph, SQL Server Profiler automatically appends a sequential number to the filename. Figure 37.16 shows an example of the Events Extraction Settings tab to have a Profiler trace automatically generate a separate file for each deadlock trace.

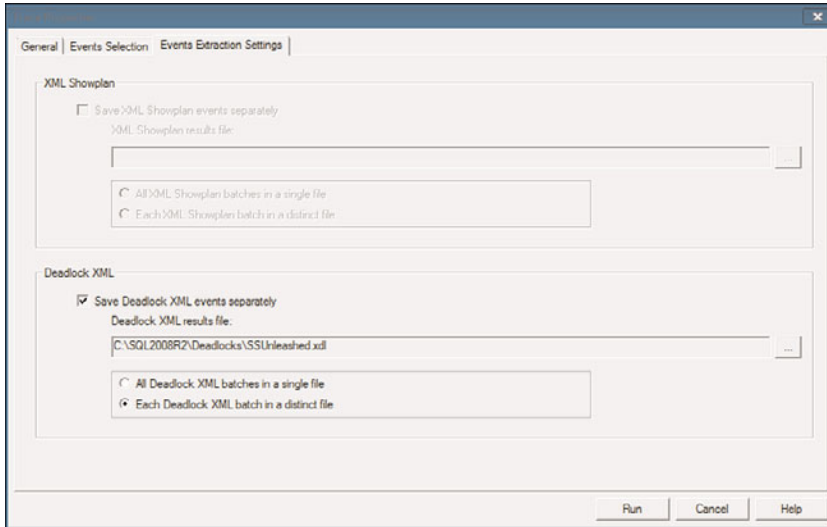

FIGURE 37.16 Configuring SQL Server Profiler to export Deadlock Graphs to individual files.

You can use SSMS to open and analyze any SQL Server Profiler Deadlock Graphs that you have saved to a file. To do so, in SSMS you choose File, Open and then click File. In the Open File dialog box, you select the .xd1 file type as the type of file. You now have a filtered list of only deadlock files (see Figure 37.17). After you select the file or files, you are able to view them in SSMS.

FIGURE 37.17 Opening a Deadlock Graph file in SSMS.

Table Hints for Locking

As mentioned previously in this chapter, in the “Transaction Isolation Levels in SQL Server” section, you can set an isolation level for your connection by using the `SET TRANSACTION ISOLATION LEVEL` command. This command sets a global isolation level for an entire session, which is useful if you want to provide a consistent isolation level for an application. However, sometimes you might want to specify different isolation levels for specific queries or for different tables within a single query. SQL Server allows you to do this by supporting table hints in the `SELECT`, `MERGE`, `UPDATE`, `INSERT`, and `DELETE` statements. In this way, you can override the isolation level currently set at the session level.

In this chapter, you have seen that locking is dynamic and automatic in SQL Server. Based on certain factors (for example, SARGs, key distribution, data volume), the Query Optimizer chooses the granularity of the lock (that is, row, page, or table level) on a resource. Although it is usually best to leave such decisions to the Query Optimizer, you might encounter certain situations in which you want to force a different lock granularity on a resource than what the optimizer has chosen. SQL Server provides additional table hints that you can use in the query to force lock granularity for various tables participating in a join.

SQL Server also automatically determines the lock type (`SHARED`, `UPDATE`, `EXCLUSIVE`) to use on a resource, depending on the type of command being executed on the resource. For example, a `SELECT` statement uses a shared lock. SQL Server also provides additional table hints to override the default lock type.

The table hints to override the lock isolation, granularity, or lock type for a table can be provided using the `WITH` operator of the `SELECT`, `UPDATE`, `INSERT`, and `DELETE` statements.

The following sections discuss the various locking hints that can be passed to an optimizer to manage isolation levels and the lock granularity of a query.

NOTE

Although many of the table-locking hints can be combined, you cannot combine more than one isolation level or lock granularity hint at a time on a single table. Also, the `NOLOCK`, `READUNCOMMITTED`, and `READPAST` hints described in the following sections cannot be used on tables that are the target of `INSERT`, `UPDATE`, `MERGE`, or `DELETE` queries.

Transaction Isolation–Level Hints

SQL Server provides a number of hints that you can use in a query to override the default transaction isolation level:

- ▶ **HOLDLOCK**—`HOLDLOCK` maintains shared locks for the duration of the entire statement or for the entire transaction, if the statement is in a transaction. This option is

equivalent to the Serializable Read isolation level. The following hypothetical example demonstrates the usage of the HOLDLOCK statement within a transaction:

```
declare @seqno int
begin transaction
-- get a UNIQUE sequence number from sequence table
SELECT @seqno = isnull(seq#,0) + 1
from sequence WITH (HOLDLOCK)

-- in the absence of HOLDLOCK, shared lock will be released
-- and if some other concurrent transaction ran the same
-- command, both of them could get the same sequence number

UPDATE sequence
set seq# = @seqno

--now go do something else with this unique sequence number
commit tran
```

NOTE

As discussed earlier in this chapter, in the “Deadlocks” section, using HOLDLOCK in this manner leads to potential deadlocks between processes executing the transaction at the same time. For this reason, the HOLDLOCK hint, as well as the REPEATABLE_READ and SERIALIZABLE hints, should be used sparingly, if at all. In this example, it might be better for the SELECT statement to use an update or an exclusive lock on the sequence table, using the hints discussed later in this chapter, in the section “Lock Type Hints.” Another option would be to use an application lock, as discussed previously in this chapter, in the section “Using Application Locks.”

- ▶ **NOLOCK**—You can use this option to specify that no shared lock be placed on the resource. This option is similar to running a query at Isolation Level 0 (Read Uncommitted), which allows the query to ignore exclusive locks and read uncommitted changes. The NOLOCK option is a useful feature in reporting environments, where the accuracy of the results is not critical.
- ▶ **READUNCOMMITTED**—This is the same as specifying the Read Uncommitted mode when using the SET TRANSACTION ISOLATION LEVEL command, and it is the same as the NOLOCK table hint.
- ▶ **READCOMMITTED**—This is the same as specifying the Read Committed mode when you use the SET TRANSACTION ISOLATION LEVEL command. The query waits for exclusive locks to be released before reading the data. This is the default locking isolation mode for SQL Server. If the database option READ_COMMITTED_SNAPSHOT is ON, SQL Server does not acquire shared locks on the data and uses row versioning.

- ▶ **READCOMMITTEDLOCK**—This option specifies that read operations acquire shared locks as data is read and release those locks when the read operation is completed, regardless of the setting of the `READ_COMMITTED_SNAPSHOT` database option.
- ▶ **REPEATABLEREAD**—This is the same as specifying Repeatable Read mode with the `SET TRANSACTION ISOLATION LEVEL` command. It prevents nonrepeatable reads within a transaction and behaves similarly to the `HOLDLOCK` hint.
- ▶ **SERIALIZABLE**—This is the same as specifying Serializable Read mode with the `SET TRANSACTION ISOLATION LEVEL` command. It prevents phantom reads within a transaction and behaves similarly to using the `HOLDLOCK` hint.
- ▶ **READPAST**—This hint specifies that the query skip over the rows or pages locked by other transactions, returning only the data that can be read. Read operations specifying `READPAST` are not blocked. When specified in an `UPDATE` or `DELETE` statement, `READPAST` is applied only when reading data to identify which records to update. `READPAST` can be specified only in transactions operating at the Read Committed or Repeatable Read isolation levels. This lock hint is useful when reading information from a SQL Server table used as a work queue. A query using `READPAST` skips past queue entries locked by other transactions to the next available queue entry, without having to wait for the other transactions to release their locks.

Lock Granularity Hints

You can use to override lock granularity:

- ▶ **ROWLOCK**—You can use this option to force the Lock Manager to place a row-level lock on a resource instead of a page-level or a table-level lock. You can use this option in conjunction with the `XLOCK` lock type hint to force exclusive row locks.
- ▶ **PAGLOCK**—You can use this option to force a page-level lock on a resource instead of a row-level or table-level lock. You can use this option in conjunction with the `XLOCK` lock type hint to force exclusive page locks.
- ▶ **TABLOCK**—You can use this option to force a table-level lock instead of a row-level or page-level lock. You can use this option in conjunction with the `HOLDLOCK` table hint to hold the table lock until the end of the transaction.
- ▶ **TABLOCKX**—You can use this option to force a table-level exclusive lock instead of a row-level or page-level lock. No shared or update locks are granted to other transactions as long as this option is in effect. If you are planning maintenance on a SQL Server table and you don't want interference from other transactions, using this option is one of the ways to essentially put a table into a single-user mode.

Lock Type Hints

You can use the following optimizer hints to override the lock type that SQL Server uses:

- ▶ **UPDLOCK**—This option is similar to `HOLDLOCK` except that whereas `HOLDLOCK` uses a shared lock on the resource, `UPDLOCK` places an update lock on the resource for the

duration of the transaction. This allows other processes to read the information, but not acquire update or exclusive locks on the resource. This option provides read repeatability within the transaction while preventing deadlocks that can result when using `HOLDLOCK`.

- ▶ **XLOCK**—This option places an exclusive lock on the resource for the duration of the transaction. This prevents other processes from acquiring locks on the resource.

Optimistic Locking

With many applications, clients need to fetch the data to browse through it, make modifications to one or more rows, and then post the changes back to the database in SQL Server. These human-speed operations are slow in comparison to machine-speed operations, and the time lag between the fetch and post might be significant. (Consider a user who goes to lunch after retrieving the data.)

For these applications, you would not want to use normal locking schemes such as `SERIALIZABLE` or `HOLDLOCK` to lock the data so it can't be changed from the time the user retrieves it to the time he or she applies any updates. This would violate one of the key rules for minimizing locking contention and deadlocks that you should not allow user interaction within transactions. You would also lose all control over the duration of the transaction. In a multiuser OLTP environment, the indefinite holding of the shared locks could significantly affect concurrency and overall application performance due to blocking on locks and locking contention.

On the other hand, if the locks are not held on the rows being read, another process could update a row between the time it was initially read and when the update is posted. When the first process applies the update, it would overwrite the changes made by the other process, resulting in a lost update.

So how do you implement such an application? How do you allow users to retrieve information without holding locks on the data and still ensure that lost updates do not occur?

Optimistic locking is a technique used in situations in which reading and modifying data processes are widely separated in time. Optimistic locking helps a client avoid overwriting another client's changes to a row without holding locks in the database.

One approach for implementing optimistic locking is to use the `rowversion` data type. Another approach is to take advantage of the optimistic concurrency features of snapshot isolation.

Optimistic Locking Using the `rowversion` Data Type

SQL Server 2008 provides a special data type called `rowversion` that can be used for optimistic locking purposes within applications. The purpose of the `rowversion` data type is to serve as a version number in optimistic locking schemes. SQL Server automatically generates the value for a `rowversion` column whenever a row that contains a column of this type is inserted or updated. The `rowversion` data type is an 8-byte binary data type, and

other than guaranteeing that the value is unique and monotonically increasing, the value is not meaningful; you cannot look at the individual bytes and make any sense of them.

NOTE

In previous versions of SQL Server, the `rowversion` data type was also referred to as the `timestamp` data type. While this data type synonym still exists in SQL Server 2008, it has been deprecated and the `rowversion` data type name should be used instead to ensure future compatibility.

In an application that uses optimistic locking, the client reads one or more records from the table, being sure to retrieve the primary key and current value of the `rowversion` column for each row, along with any other desired data columns. Because the query is not run within a transaction, any locks acquired for the `SELECT` are released after the data has been read. At some later time, when the client wants to update a row, it must ensure that no other client has changed the same row in the intervening time. The `UPDATE` statement must include a `WHERE` clause that compares the `rowversion` value retrieved with the original query, with the current `rowversion` value for the record in the database. If the `rowversion` values match—that is, if the value that was read is the same as the value currently in the database—no changes to that row have occurred since it was originally retrieved. Therefore, the change attempted by the application can proceed. If the `rowversion` value in the client application *does not* match the value in the database, that particular row has been changed since the original retrieval of the record. As a result, the state of the row that the application is attempting to modify is not the same as the row that currently exists in the database. As a result, the transaction should not be allowed to take place, to avoid the lost update problem.

To ensure that the client application does not overwrite the changes made by another process, the client needs to prepare the T-SQL `UPDATE` statement in a special way, using the `rowversion` column as a versioning marker. The following pseudocode represents the general structure of such an update:

```
UPDATE theTable
  SET theChangedColumns = theirNewValues
  WHERE primaryKeyColumns = theirOldValues
     AND rowversion = itsOldValue
```

Because the `WHERE` clause includes the primary key, the `UPDATE` can apply only to exactly one row or to no rows; it cannot apply to more than one row because the primary key is unique. The second part of the `WHERE` clause provides the optimistic “locking.” If another client has updated the row, the `rowversion` no longer has its old value (remember that the server changes the `rowversion` value automatically with each update), and the `WHERE` clause does not match any rows. The client needs to check whether any rows were updated. If the number of rows affected by the update statement is zero, the row has been modified since

it was originally retrieved. The application can then choose to reread the data or do whatever recovery it deems appropriate. This approach has one problem: how does the application know whether it didn't match the row because the rowversion was changed, because the primary key had changed, or because the row had been deleted altogether?

In SQL Server 2000, there was an undocumented `tsequal()` function (which was documented in prior releases) that could be used in a `WHERE` clause to compare the rowversion value retrieved by the client application with the rowversion value in the database. If the rowversion values matched, the update would proceed. If not, the update would fail, with error message 532, to indicate that the row had been modified. Unfortunately, this function is no longer provided in SQL Server 2005 and later releases. Any attempt to use it now results in a syntax error. As an alternative, you can programmatically check whether the update modified any rows, and if not, you can check whether the row still exists and return the appropriate message. Listing 37.7 provides an example of a stored procedure that implements this strategy.

LISTING 37.7 An Example of a Procedure for Optimistic Locking

```
create proc optimistic_update
    @id int, -- provide the primary key for the record
    @data_field_1 varchar(10), -- provide the data value to be updated
    @rowversion rowversion -- pass in the rowversion value retrieved with
        -- the initial data retrieval
as
-- Attempt to modify the record
update data_table
    set data_field_1 = @data_field_1
    where id = @id
        and versioncol = @rowversion
-- Check to see if no rows updated
IF @@ROWCOUNT=0
BEGIN
    if exists (SELECT * FROM data_table WHERE id=@id)
        -- The row exists but the rowversions don't match
        begin
            raiserror ('The row with id "%d" has been updated since it was read',
                10, 1, @id)
            return -101
        end
    else -- the row has been deleted
        begin
            raiserror ('The row with id "%d" has been deleted since it was read',
                10, 2, @id)
            return -102
        end
end
end
```

```
ELSE
    PRINT 'Data Updated'
return 0
```

Using this approach, if the update doesn't modify any rows, the application receives an error message and knows for sure that the reason the update didn't take place is that either the rowversion value didn't match or the row was deleted. If the row is found and the rowversion values match, the update proceeds normally.

Optimistic Locking with Snapshot Isolation

SQL Server 2008's Snapshot Isolation mode provides another mechanism for implementing optimistic locking through its automatic row versioning. If a process reads data within a transaction when Snapshot Isolation mode is enabled, no locks are acquired or held on the current version of the data row. The process reads the version of the data at the time of the query. Because no locks are held, it doesn't lead to blocking, and another process can modify the data after it has been read. If another process does modify a data row read by the first process, a new version of the row is generated. If the original process then attempts to update that data row, SQL Server automatically prevents the lost update problem by checking the row version. In this case, because the row version is different, SQL Server prevents the original process from modifying the data row. When it attempts to modify the data row, the following error message appears:

```
Msg 3960, Level 16, State 4, Line 2
Snapshot isolation transaction aborted due to update conflict. You cannot use
snapshot isolation to access table 'dbo.data_table' directly or indirectly in
database 'bigpubs2008' to update, delete, or insert the row that has been modified
or deleted by another transaction. Retry the transaction or change the isolation
level for the update/delete statement.
```

To see how this works, you can create the following table:

```
use bigpubs2008
go
--The first statement is used to disable any previously created
--DDL triggers in the database which would prevent creating a new table.
DISABLE TRIGGER ALL ON DATABASE
go
create table data_table
    (id int identity,
     data_field_1 varchar(10),
     timestamp timestamp)
go
insert data_table (data_field_1) values ('foo')
go
```

Next, you need to ensure that bigpubs2008 is configured to allow snapshot isolation:

```
ALTER DATABASE bigpubs2008 SET ALLOW_SNAPSHOT_ISOLATION ON
```

In one user session, you execute the following SQL statements:

```
SET TRANSACTION ISOLATION LEVEL SNAPSHOT
go
begin tran
select * from data_table
go
```

```
id          data_field_1 timestamp
-----
1          foo          0x00000000000000BC4
```

Now, in another user session, you execute the following UPDATE statement:

```
update data_table set data_field_1 = 'bar'
where id = 1
```

Then you go back to the original session and attempt the following update:

```
update data_table set data_field_1 = 'fubar'
where id = 1
go
```

```
Msg 3960, Level 16, State 4, Line 2
```

```
Snapshot isolation transaction aborted due to update conflict. You cannot use
snapshot isolation to access table 'dbo.data_table' directly or indirectly in
database 'bigpubs2008' to update, delete, or insert the row that has been modified
or deleted by another transaction. Retry the transaction or change the isolation
level for the update/delete statement.
```

Note that for the first process to hold on to the row version, the SELECT and UPDATE statements must be run in the same transaction. When the transaction is committed or rolled back, the row version acquired by the SELECT statement is released. However, because the SELECT statement run at the Snapshot Isolation level does not hold any locks, there are no locks being acquired or held by that SELECT statement within the transaction, so it avoids the problems that would normally be encountered by using HOLDLOCK or the Serializable Read isolation level. Because no locks were held on the data row, the other process was allowed to update the row after it was retrieved, generating a new version of the row. The automatic row versioning provided by SQL Server's Snapshot Isolation mode prevented the first process from overwriting the update performed by the second process, thereby preventing a lost update.

CAUTION

Locking contention is prevented in the preceding example only because the transaction performed only a `SELECT` before attempting the `UPDATE`. A `SELECT` run with Snapshot Isolation mode enabled reads the current version of the row and does not acquire or hold locks on the actual data row. However, if the process were to perform any other modification on the data row, the update or exclusive locks acquired would be held until the end of the transaction, which could lead to locking contention, especially if user interaction is allowed within the transaction after the update or exclusive locks are acquired.

Also, be aware of the overhead generated in `tempdb` when Snapshot Isolation mode is enabled for a database, as described in the section “Transaction Isolation Levels in SQL Server,” earlier in this chapter.

Because of the overhead incurred by snapshot isolation and the cost of having to roll back update conflicts, you should consider using Snapshot Isolation mode only to provide optimistic locking for systems where there is little concurrent updating of the same resource so that it is unlikely that your transactions have to be rolled back because of an update conflict.

Summary

Locking is critical in a multiuser environment for providing transaction isolation. SQL Server supports all ANSI-defined transaction isolation levels, including the Snapshot Isolation level for applications that can benefit from optimistic concurrency. The Lock Manager in SQL Server automatically locks data at the row level or higher, as necessary, to provide the appropriate isolation while balancing the locking overhead with concurrent access to the data. It is important to understand how locking works and what its effect is on application performance to develop efficient queries and applications.

SQL Server provides a number of tools for monitoring and identifying locking problems and behavior. In addition, SQL Server provides a number of table-locking hints that give the developer better control over the default lock types and granularity used for certain queries.

Although following the guidelines to minimize locking contention in applications is important, another factor that affects locking behavior and query performance is the actual database design. Chapter 38, “Database Design and Performance,” discusses database design and its effect on database performance and provides guidelines to help ensure that transactions and T-SQL code run efficiently.

CHAPTER 38

Database Design and Performance

Various factors contribute to the optimal performance of a database application. Some of these factors include logical database design (rules of normalization), physical database design (denormalization, indexes, data placement), choice of hardware (SMP servers/multiprocessor servers), network bandwidth (LAN versus WAN), client and server configuration (memory, CPU), data access techniques (ODBC, ADO, OLEDB), and application architecture (two-tier versus n-tier). This chapter helps you understand some of the key database design issues to ensure that you have a reliable high-performance application.

NOTE

Index design is often considered part of physical database design. Because index design guidelines and the impact of indexes on query and update performance are covered in detail in Chapter 34, “Data Structures, Indexes and Performance,” this chapter does not discuss index design. It focuses instead on other aspects of database design and performance.

What’s New in Database Design and Performance

Many of the database design and performance considerations that applied to previous versions of SQL Server still apply to SQL Server 2008. These principles are basic in

IN THIS CHAPTER

- ▶ What’s New in Database Design and Performance
- ▶ Basic Tenets of Designing for Performance
- ▶ Logical Database Design Issues
- ▶ Denormalizing a Database

- ▶ RAID Technology
- ▶ SQL Server and SAN Technology

nature and are not affected by the version of the database management system. This chapter focuses on those relatively unchanged principles.

There are, however, some new features in SQL Server 2008 that will augment these basic principles. Filtered indexes, new query and table hints, plus other table-oriented features are just a few things you should consider when designing your database for performance. These features are discussed in detail in Chapter 24, “Creating and Managing Tables,” Chapter 34, “Data Structures, Indexes, and Performance,” and other chapters in Part V, “SQL Server Performance and Optimization.”

Basic Tenets of Designing for Performance

Designing for performance requires making trade-offs. For example, to get the best write performance out of a database, you must sacrifice read performance. Before you tackle database design issues for an application, it is critical to understand your goals. Do you want faster read performance? Faster write performance? A more understandable design?

Following are some basic truths about physical database design for SQL Server 2008 and the performance implications of each:

- ▶ It's important to keep table row sizes as small as possible. Doing so is not about saving disk space. Having smaller rows means more rows fit on a single 8KB page, which means fewer physical disk reads are required to read a given number of rows.
- ▶ You should use indexes to speed up read access. However, the more indexes a table has, the longer it takes to insert, update, and delete rows from the table.
- ▶ Using triggers to perform any kind of work during an insert, an update, or a delete exacts a performance toll and decreases concurrency by lengthening transaction duration.
- ▶ Implementing declarative referential integrity (via primary and foreign keys) helps maintain data integrity, but enforcing foreign key constraints requires extra lookups on the primary key table to ensure existence.
- ▶ Using `ON DELETE CASCADE` referential integrity constraints helps maintain data integrity but requires extra work on the server's part.

Keeping tables as narrow as possible—that is, ensuring that the row size is as small as possible—is one of the most important things you can do to ensure that a database performs well. To keep your tables narrow, you should choose column data types with size in mind. You shouldn't use the `bigint` data type if the `int` will do. If you have zero-to-one relationships in tables, you should consider vertically partitioning the tables. (See the “Vertical Data Partitioning” section, later in this chapter, for details on this scenario.)

Cascading deletes (and updates) cause extra lookups to be done whenever a delete runs against the parent table. In many cases, the optimizer uses worktables to resolve delete and update queries. Enforcing these constraints manually, from within stored procedures, for example, can give better performance. This is not a wholehearted endorsement against

referential integrity constraints. In most cases, the extra performance hit is worth the saved aggravation of coding everything by hand. However, you should be aware of the cost of this convenience.

Logical Database Design Issues

A good database design is fundamental to the success of any application. Logical database design for relational databases follows rules of normalization. As a result of normalization, you create a data model that is usually, but not necessarily, translated into a physical data model. A logical database design does not depend on the relational database you intend to use. The same data model can be applied to Oracle, Sybase, SQL Server, or any other relational database. On the other hand, a physical data model makes extensive use of the features of the underlying database engine to yield optimal performance for the application. Physical models are much less portable than logical models.

TIP

If portability is a big concern to you, consider using a third-party data modeling tool, such as ERwin or ERStudio. These tools have features that make it easier to migrate your logical data models to physical data models on different database platforms. Of course, using these tools just gets you started; to get the best performance out of your design, you need to tweak the physical design for the platform you have chosen.

Normalization Conditions

Any database designer must address two fundamental issues:

- ▶ Designing the database in a simple, understandable way that is maintainable and makes sense to its developers and users
- ▶ Designing the database such that data is fetched and saved with the fastest response time, resulting in high performance

Normalization is a technique used on relational databases to organize data across many tables so that related data is kept together based on certain guidelines. Normalization results in controlled redundancy of data; therefore, it provides a good balance between disk space usage and performance. Normalization helps people understand the relationships between data and enforces rules to ensure that the data is meaningful.

TIP

Normalization rules exist, among other reasons, to make it easier for people to understand the relationships between data. But a perfectly normalized database sometimes doesn't perform well under certain circumstances, and it may be difficult to understand. There are good reasons to deviate from a perfectly normalized database.

Normalization Forms

Five normalization forms exist, represented by the symbol 1NF for first normal form, 2NF for second normal form, and so on. If you follow the rules for the first rule of normalization, your database can be described as “in first normal form.”

Each rule of normalization depends on the previous rule for successful implementation, so to be in second normal form (2NF), your database must also follow the rules for first normal form.

A typical relational database used in a business environment falls somewhere between second and third normal forms. It is rare to progress past the third normal form because fourth and fifth normal forms are more academic than practical in real-world environments.

Following is a brief description of the first three rules of normalization.

First Normal Form

The first rule of normalization requires removing repeating data values and specifies that no two rows in a table can be identical. This means that each table must have a logical primary key that uniquely identifies a row in the table.

Consider a table that has four columns—`PublisherName`, `Title1`, `Title2`, and `Title3`—for storing up to three titles for each publisher. This table is not in first normal form due to the repeating `Title` columns. The main problem with this design is that it limits the number of titles associated with a publisher to three.

Removing the repeating columns so there is just a `PublisherName` column and a single `Title` column puts the table in first normal form. A separate data row is stored in the table for each title published by each publisher. The combination of `PublisherName` and `Title` becomes the primary key that uniquely identifies each row and prevents duplicates.

Second Normal Form

A table is considered to be in second normal form if it conforms to the first normal form and all nonkey attributes of the table are fully dependent on the entire primary key. If the primary key consists of multiple columns, nonkey columns should depend on the entire key and not just on a part of the key. A table with a single column as the primary key is automatically in second normal form if it satisfies first normal form as well.

Assume that you need to add the publisher address to the database. Adding it to the table with the `PublisherName` and `Title` column would violate second normal form. The primary key consists of both `PublisherName` and `Title`, but the `PublisherAddress` attribute is an attribute of the publisher only. It does not depend on the entire primary key.

To put the database in second normal form requires adding an additional table for storing publisher information. One table consists of the `PublisherName` column and `PublisherAddress`. The second table contains the `PublisherName` and `Title` columns. To

retrieve the `PublisherName`, `Title`, and `PublisherAddress` information in a single result would require a join between the two tables on the `PublisherName` column.

Third Normal Form

A table is considered to be in third normal form if it already conforms to the first two normal forms and if none of the nonkey columns are dependent on any other nonkey columns. All such attributes should be removed from the table.

Let's look at an example that comes up often during database architecture. Suppose that an employee table has four columns: `EmployeeID` (the primary key), `salary`, `bonus`, and `total_salary`, where `total_salary = salary + bonus`. Existence of the `total_salary` column in the table violates the third normal form because a nonkey column (`total_salary`) is dependent on two other nonkey columns (`salary` and `bonus`). Therefore, for the table to conform to the third rule of normalization, you must remove the `total_salary` column from the employee table.

Benefits of Normalization

Following are the major advantages of normalization:

- ▶ Because information is logically kept together, normalization provides improved overall understanding of the system.
- ▶ Because of controlled redundancy of data, normalization can result in fast table scans and searches (because less physical data has to be processed).
- ▶ Because tables are smaller with normalization, index creation and data sorts are much faster.
- ▶ With less redundant data, it is easier to maintain referential integrity for the system.
- ▶ Normalization results in narrower tables. Because you can store more rows per page, more rows can be read and cached for each I/O performed on the table. This results in better I/O performance.

Drawbacks of Normalization

One result of normalization is that data is stored in multiple tables. To retrieve or modify information, you usually have to establish joins across multiple tables. Joins are expensive from an I/O standpoint. Multitable joins can have an adverse impact on the performance of the system. The following sections discuss some of the denormalization techniques you can use to improve the performance of a system.

TIP

An adage for normalization is “Normalize ’til it hurts; denormalize ’til it works.” To put this maxim into use, try to put your database in third normal form initially. Then, when you’re ready to implement the physical structure, drop back from third normal form, where excessive table joins are hurting performance. A common mistake is that developers make too many assumptions and over-denormalize the database design before even a single line of code has been written to even begin to assess the database performance.

Denormalizing a Database

After a database has been normalized to the third form, database designers intentionally backtrack from normalization to improve the performance of the system. This technique of rolling back from normalization is called *denormalization*. Denormalization allows you to keep redundant data in the system, reducing the number of tables in the schema and reducing the number of joins to retrieve data.

TIP

Duplicate data is more helpful when the data does not change very much, such as in data warehouses. If the data changes often, keeping all “copies” of the data in sync can create significant performance overhead, including long transactions and excessive write operations.

Denormalization Guidelines

When should you denormalize a database? Consider the following points:

- ▶ Be sure you have a good overall understanding of the logical design of the system. This knowledge helps in determining how other parts of the application are going to be affected when you change one part of the system.
- ▶ Don’t attempt to denormalize the entire database at once. Instead, focus on the specific areas and queries that are accessed most frequently and are suffering from performance problems.
- ▶ Understand the types of transactions and the volume of data associated with specific areas of the application that are having performance problems. You can resolve many such issues by tuning the queries without denormalizing the tables.
- ▶ Determine whether you need virtual (computed) columns. Virtual columns can be computed from other columns of the table. Although this violates third normal form, computed columns can provide a decent compromise because they do not actually store another exact copy of the data in the same table.
- ▶ Understand data integrity issues. With more redundant data in the system, maintaining data integrity is more difficult, and data modifications are slower.

- ▶ Understand storage techniques for the data. You may be able to improve performance without denormalization by using RAID, SQL Server filegroups, and table partitioning.
- ▶ Determine the frequency with which data changes. If data is changing too often, the cost of maintaining data and referential integrity might outweigh the benefits provided by redundant data.
- ▶ Use the performance tools that come with SQL Server (such as SQL Server Profiler) to assess performance. These tools can help isolate performance issues and give you possible targets for denormalization.

TIP

If you are experiencing severe performance problems, denormalization should *not* be the first step you take to rectify the problem. You need to identify specific issues that are causing performance problems. Usually, you discover factors such as poorly written queries, poor index design, inefficient application code, or poorly configured hardware. You should try to fix these types of issues *before* taking steps to denormalize database tables.

Essential Denormalization Techniques

You can use various methods to denormalize a database table and achieve desired performance goals. Some of the useful techniques used for denormalization include the following:

- ▶ Keeping redundant data and summary data
- ▶ Using virtual columns
- ▶ Performing horizontal data partitioning
- ▶ Performing vertical data partitioning

Redundant Data

From an I/O standpoint, joins in a relational database are inherently expensive. To avoid common joins, you can add redundancy to a table by keeping exact copies of the data in multiple tables. The following example demonstrates this point. This example shows a three-table join to get the title of a book and the primary author's name:

```
select c.title,
       a.au_lname,
       a.au_fname
from   authors a join titleauthor b on a.au_id = b.au_id
join   titles c on b.title_id = c.title_id
where  b.au_ord = 1
order by c.title
```

You could improve the performance of this query by adding the columns for the first and last names of the primary author to the `titles` table and storing the information in the

titles table directly. This would eliminate the joins altogether. Here is what the revised query would look like if this denormalization technique were implemented:

```
select title,
       au_lname,
       au_fname
from titles
order by title
```

As you can see, the au_lname and au_fname columns are now redundantly stored in two places: the titles table and authors table. It is obvious that with more redundant data in the system, maintaining referential integrity and data integrity is more difficult. For example, if the author's last name changed in the authors table, to preserve data integrity, you would also have to change the corresponding au_lname column value in the titles table to reflect the correct value. You could use SQL Server triggers to maintain data integrity, but you should recognize that update performance could suffer dramatically. For this reason, it is best if redundant data is limited to data columns whose values are relatively static and are not modified often.

Computed Columns

A number of queries calculate aggregate values derived from one or more columns of a table. Such computations can be CPU intensive and can have an adverse impact on performance if they are performed frequently. One of the techniques to handle such situations is to create an additional column that stores the computed value. Such columns are called *virtual columns*, or *computed columns*. Since SQL Server 7.0, computed columns have been natively supported. You can specify such columns in create table or alter table commands. The following example demonstrates the use of computed columns:

```
create table emp (
    empid int not null primary key,
    salary money not null,
    bonus money not null default 0,
    total_salary as ( salary+bonus )
)
go
insert emp (empid, salary, bonus) values (100, $150000.00, $15000)
go
select * from emp
go
```

empid	salary	bonus	total_salary
100	150000.0000	15000.0000	165000.0000

By default, virtual columns are not physically stored in SQL Server tables. SQL Server internally maintains a column property named iscomputed that can be viewed from the sys.columns system view. It uses this column to determine whether a column is computed. The value of the virtual column is calculated at the time the query is run. All columns

referenced in the computed column expression must come from the table on which the computed column is created. You can, however, reference a column from another table by using a function as part of the computed column's expression. The function can contain a reference to another table, and the computed column calls this function.

Since SQL Server 2000, computed columns have been able to participate in joins to other tables, and they can be indexed. Creating an index that contains a computed column creates a physical copy of the computed column in the index tree. Whenever a base column participating in the computed column changes, the index must also be updated, which adds overhead and may possibly slow down update performance.

In SQL Server 2008, you also have the option of defining a computed column so that its value is physically stored. You accomplish this with the `ADD PERSISTED` option, as shown in the following example:

```
--Alter the computed SetRate column to be PERSISTED
ALTER TABLE Sales.CurrencyRate
  alter column SetRate ADD PERSISTED
```

SQL Server automatically updates the persisted column values whenever one of the columns that the computed column references is changed. Indexes can be created on these columns, and they can be used just like nonpersisted columns. One advantage of using a computed column that is persisted is that it has fewer restrictions than a nonpersisted column. In particular, a persisted column can contain an imprecise expression, which is not possible with a nonpersisted column. Any float or real expressions are considered imprecise. To ensure that you have a precise column you can use the `COLUMNPROPERTY` function and review the `IsPrecise` property to determine whether the computed column expression is precise.

Summary Data

Summary data is most helpful in a decision support environment, to satisfy reporting requirements and calculate sums, row counts, or other summary information and store it in a separate table. You can create summary data in a number of ways:

- ▶ **Real-time**—Every time your base data is modified, you can recalculate the summary data, using the base data as a source. This is typically done using stored procedures or triggers.
- ▶ **Real-time incremental**—Every time your base data is modified, you can recalculate the summary data, using the old summary value and the new data. This approach is more complex than the real-time option, but it could save time if the increments are relatively small compared to the entire dataset. This, too, is typically done using stored procedures or triggers.
- ▶ **Delayed**—You can use a scheduled job or custom service application to recalculate summary data on a regular basis. This is the recommended method to use in an OLTP system to keep update performance optimal.

Horizontal Data Partitioning

As tables grow larger, data access time also tends to increase. For queries that need to perform table scans, the query time is proportional to the number of rows in the table. Even when you have proper indexes on such tables, access time slows as the depth of the index trees increases. The solution is splitting the table into multiple tables such that each table has the same table structure as the original one but stores a different set of data. Figure 38.1 shows a billing table with 90 million records. You can split this table into 12 monthly tables (all with the identical table structure) to store billing records for each month.

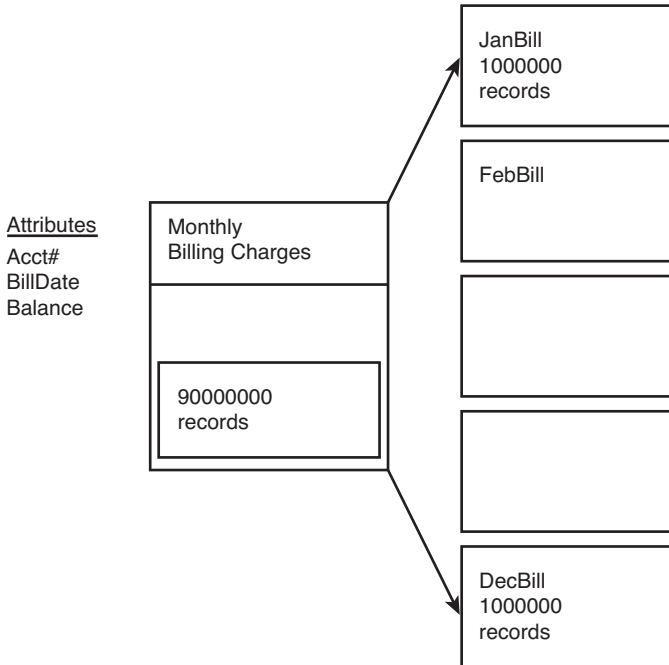

FIGURE 38.1 Horizontal partitioning of data.

You should carefully weigh the options when performing horizontal splitting. Although a query that needs data from only a single month gets much faster, other queries that need a full year's worth of data become more complex. Also, queries that are self-referencing do not benefit much from horizontal partitioning. For example, the business logic might dictate that each time you add a new billing record to the billing table, you need to check any outstanding account balance for previous billing dates. In such cases, before you do an insert in the current monthly billing table, you must check the data for all the other months to find any outstanding balance.

TIP

Horizontal splitting of data is useful where a subset of data might see more activity than the rest of the data. For example, say that in a healthcare provider setting, 98% of the patients are inpatients, and only 2% are outpatients. In spite of the small percentage involved, the system for outpatient records sees a lot of activity. In this scenario, it makes sense to split the patient table into two tables—one for the inpatients and one for the outpatients.

When splitting tables horizontally, you must perform some analysis to determine the optimal way to split the table. You need to find a logical dimension along which to split the data. The best choice takes into account the way your users use your data. In the example that involves splitting the data among 12 tables, date was mentioned as the optimal split candidate. However, if the users often did ad hoc queries against the billing table for a full year's worth of data, they would be unhappy with the choice to split that data among 12 different tables. Perhaps splitting based on a customer type or another attribute would be more useful.

NOTE

You can use partitioned views to hide the horizontal splitting of tables. The benefit of using partitioned views is that multiple horizontally split tables appear to the end users and applications as a single large table. When this is properly defined, the optimizer automatically determines which tables in the partitioned view need to be accessed, and it avoids searching all tables in the view. The query runs as quickly as if it were run only against the necessary tables directly. For more information on defining and using partitioned views, see Chapter 27, “Creating and Managing Views.”

In SQL Server 2008, you also have the option of physically splitting the rows in a single table over more than one partition. This feature, called *partitioned tables*, utilizes a partitioning function that splits the data horizontally and a partitioning scheme that assigns the horizontally partitioned data to different filegroups. When a table is created, it references the partitioned schema, which causes the rows of data to be physically stored on different filegroups. No additional tables are needed, and the table is still referenced with the original table name. The horizontal partitioning happens at the physical storage level and is transparent to the user.

Vertical Data Partitioning

As you know, a database in SQL Server consists of 8KB pages, and a row cannot span multiple pages. Therefore, the total number of rows on a page depends on the width of the table. This means the wider the table, the smaller the number of rows per page. You can achieve significant performance gains by increasing the number of rows per page,

which in turn reduces the number of I/Os on the table. Vertical splitting is a method of reducing the width of a table by splitting the columns of the table into multiple tables. Usually, all frequently used columns are kept in one table, and others are kept in the other table. This way, more records can be accommodated per page, fewer I/Os are generated, and more data can be cached into SQL Server memory. Figure 38.2 illustrates a vertically partitioned table. The frequently accessed columns of the authors table are stored in the `author_primary` table, whereas less frequently used columns are stored in the `author_secondary` table.

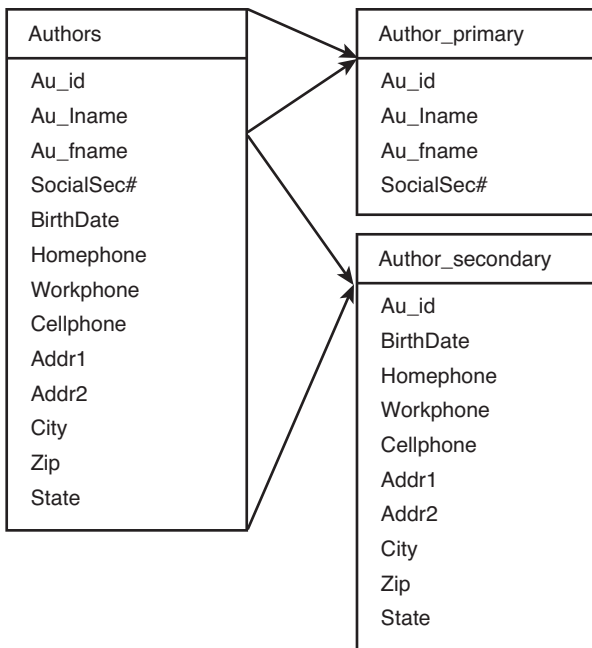

FIGURE 38.2 Vertical partitioning of data.

TIP

Make the decision to split data very carefully, especially when the system is already in production. Changing the data structure might have a system-wide impact on a large number of queries that reference the old definition of the object. In such cases, to minimize risks, you might want to use SQL Server views to hide the vertical partitioning of data. Also, if you find that users and developers are frequently joining between the vertically split tables because they need to pull data together from the two tables, you might want to reconsider the split point or the splitting of the table itself. Doing frequent joins between split tables with smaller rows requires more I/Os to retrieve the same data than if the data resided in a single table with wider rows.

Performance Implications of Zero-to-One Relationships

Suppose that one of the development managers in your company, Bob, approaches you to discuss some database schema changes. He is one of several managers whose groups all use the central `User` table in your database. Bob's application makes use of about 5% of the users in the `User` table. Bob has a requirement to track five yes/no/undecided flags associated with those users. He would like you to add five one-character columns to the `User` table to track this information. What do you tell Bob?

Bob has a classic zero-to-one problem. He has some data he needs to track, but it applies to only a small subset of the data in the table. You can approach this problem in one of three ways:

- ▶ **Option 1: Add the columns to the `User` table**—In this case, 95% of your users will have `NULL` values in those columns, and the table will become wider for everybody.
- ▶ **Option 2: Create a new table with a vertical partition of the `User` table**—The new table will contain the `User` primary key and Bob's five flags. In this case, 95% of your users will still have `NULL` data in the new table, but the `User` table is protected against these effects. Because other groups don't need to use the new partition table, this is a nice compromise.
- ▶ **Option 3: Create a new vertically partitioned table as in Option 2 but populate it only with rows that have at least one non-`NULL` value for the columns in the new partition**—This option is great for database performance, and searches in the new table will be wonderfully fast. The only drawback to this approach is that Bob's developers will have to add additional logic to their applications to determine whether a row exists during updates. Bob's folks will need to use an outer join to the table to cover the possibility that a row doesn't exist.

Depending on the goals of the project, any one of these options can be appropriate. Option 1 is simple and is the easiest to code for and understand. Option 2 is a good compromise between performance and simplicity. Option 3 gives the best performance in certain circumstances but impacts performance in certain other situations and definitely requires more coding work to be done.

Database Filegroups and Performance

Filegroups allow you to decide where on disk a particular object should be placed. You can do this by defining a filegroup within a database, extending the database onto a different drive or set of drives, and then placing a database object on the new filegroup.

Every database, by default, has a primary filegroup that contains the primary data file. There can be only one primary filegroup. This primary filegroup contains all the pages

assigned to system tables. It also contains any additional database files created without specifying filegroup. Initially, the primary filegroup is also the default file group. There can be only one default filegroup, and indexes and tables that are created without specifying a filegroup are placed in the default filegroup. You can change the default filegroup to another filegroup after it has been created for a database.

In addition to the primary filegroup, you can add one or more additional filegroups to the database that are named user-defined filegroups. Each of those filegroups can contain one or more files. The main purpose of using filegroups is to provide more control over the placement of files and data on the server. When you create a table or an index, you can map it to a specific filegroup, thus controlling the placement of data. A typical SQL Server database installation generally uses a single RAID array to spread I/O across disks and create all files in the primary filegroup; more advanced installations or installations with very large databases spread across multiple array sets can benefit from the finer level of control of file and data placement afforded by additional filegroups.

For example, for a simple database such as *AdventureWorks2008*, you can create just one primary file that contains all data and objects and a log file that contains the transaction log information. For a larger and more complex database, such as a securities trading system, where large data volumes and strict performance criteria are the norm, you might create the database with one primary file and four secondary files. You can then set up filegroups so you can place the data and objects within the database across all five files. If you have a table that itself needs to be spread across multiple disk arrays for performance reasons, you can place multiple files in a filegroup, each of which resides on a different disk, and create the table on that filegroup. For example, you can create three files (*Data1.ndf*, *Data2.ndf*, and *Data3.ndf*) on three disk arrays and then assign them to the filegroup called *spread_group*. Your table can then be created specifically on the *spread_group* filegroup. Queries for data from the table are then spread across the three disk arrays, thereby improving I/O performance.

Filegroups are most often used in high-performance environments to isolate key tables or indexes on their own set of disks, which are in turn typically part of a high-performance RAID array. Assuming that you start with a database that has just a PRIMARY filegroup (the default), the following example shows how you would add an index filegroup on a new drive and move some nonclustered indexes to it:

```
-- add the filegroup
alter database Grocer
    add filegroup FG_INDEX

-- Create a new database file and add it to the FG_INDEX filegroup
alter database Grocer
add file(
    NAME = Grocer_Index,
    FILENAME = 'g:\Grocer_Index.ndf',
    SIZE = 2048MB,
    MAXSIZE = 8192MB,
```

```

        FILEGROWTH = 10%
    ) to filegroup FG_INDEX

create nonclustered index xOrderDetail_ScanDT
    on OrderDetail(ScanDT)
    on FG_INDEX

```

Moving the indexes to a separate RAID array minimizes I/O contention by spreading out the I/O generated by updates to the data that affect data rows and require changes to index rows as well.

NOTE

Because the leaf level of a clustered index is the data page, if you create a clustered index on a filegroup, the entire table moves from the existing filegroup to the new filegroup. If you want to put indexes on a separate filegroup, you should reserve that space for nonclustered indexes only.

Having your indexes on a separate filegroup gives you the following advantages:

- ▶ Index scans and index page reads come from a separate disk, so they need not compete with other database processes for disk time.
- ▶ Inserts, updates, and deletes on the table are spread across two separate disk arrays. The clustered index, including all the table data, is on a separate array from the nonclustered indexes.
- ▶ You can target your budget dollars more precisely because the faster disks improve system performance more if they are given to the index filegroup rather than the database as a whole.

The next section gives specific recommendations on how to architect a hardware solution based on using separate filegroups for data and indexes.

RAID Technology

Redundant array of inexpensive disks (RAID) is used to configure a disk subsystem to provide better performance and fault tolerance for an application. The basic idea behind using RAID is that you spread data across multiple disk drives so that I/Os are spread across these drives. RAID has special significance for database-related applications, where you want to spread random I/Os (data changes) and sequential I/Os (for the transaction

log) across different disk subsystems to minimize disk head movement and maximize I/O performance.

The four significant levels of RAID implementation that are of most interest in database implementations are as follows:

- ▶ RAID 0 is data striping with no redundancy or fault tolerance.
- ▶ RAID 1 is mirroring, where every disk in the array has a mirror (copy).
- ▶ RAID 5 is striping with parity, where parity information for data on one disk is spread across the other disks in the array. The contents of a single disk can be re-created from the parity information stored on the other disks in the array.
- ▶ RAID 10, or 1+0, is a combination of RAID 1 and RAID 0. Data is striped across all drives in the array, and each disk has a mirrored duplicate, offering the fault tolerance of RAID 1 with the performance advantages of RAID 0.

RAID Level 0

RAID Level 0 provides the best I/O performance among all other RAID levels. A file has sequential segments striped across each drive in the array. Data is written in a round-robin fashion to ensure that data is evenly balanced across all drives in the array. However, if a media failure occurs, no fault tolerance is provided, and all data stored in the array is lost. RAID 0 should not be used for a production database where data loss or loss of system availability is not acceptable. RAID 0 is occasionally used for `tempdb` to provide the best possible read and (especially) write performance. RAID 0 is helpful for random read requirements, such as those that occur on `tempdb` and in data segments.

TIP

Although the data stored in `tempdb` is temporary and noncritical data, failure of a RAID 0 stripeset containing `tempdb` results in loss of system availability because SQL Server requires a functioning `tempdb` to carry out many of its activities. If loss of system availability is not an option, you should not put `tempdb` on a RAID 0 array. You should use one of the RAID technologies that provides redundancy.

If momentary loss of system availability is acceptable in exchange for the improved I/O and reduced cost of RAID 0, recovery of `tempdb` is relatively simple. The `tempdb` database is re-created each time the SQL Server instance is restarted. If the disk that contained your `tempdb` was lost, you could replace the failed disk, restart SQL Server, and the files would automatically be re-created. This scenario is complicated if the failed disk with the `tempdb` file also contains your master database or other system databases. See Chapter 14, “Database Backup and Restore,” for a more detailed discussion of restoring system databases.

RAID 0 is the least expensive of the RAID configurations because 100% of the disks in the array are available for data, and none are used to provide fault tolerance. Performance is also the best of the RAID configurations because there is no overhead required to maintain redundant data.

Figure 38.3 depicts a RAID 0 disk array configuration.

FIGURE 38.3 RAID Level 0.

RAID Level 1

With RAID 1, known as disk mirroring, every write to the primary disk is written to the mirror set. Either member of the set can satisfy a read request. RAID 1 devices provide excellent fault tolerance because in the event of a media failure, either on the primary disk or mirrored disk, the system can still continue to run. Writes are much faster than with RAID 5 arrays because no parity information needs to be calculated first. The data is simply written twice.

RAID 1 arrays are best for transaction logs and index filegroups. RAID 1 provides the best fault tolerance and best write performance, which is critical to log and index performance. Because log writes are sequential write operations and not random access operations, they are best supported by a RAID 1 configuration.

RAID 1 arrays are the most expensive RAID configurations because only 50% of total disk space is available for actual storage. The rest is used to provide fault tolerance.

Figure 38.4 shows a RAID 1 configuration.

FIGURE 38.4 RAID Level 1.

Because RAID 1 requires that the same data be written to two drives at the same time, write performance is slightly less than when writing data to a single drive because the write is not considered complete until both writes have been done. Using a disk controller with a battery-backed write cache can mitigate this write penalty because the write is considered complete when it occurs to the battery-backed cache. The actual writes to the disks occur in the background.

RAID 1 read performance is often better than that of a single disk drive because most controllers now support split seeks. Split seeks allow each disk in the mirror set to be read independently of each other, thereby supporting concurrent reads.

RAID Level 10

RAID 10, or RAID 1+0, is a combination of mirroring and striping. It is implemented as a stripe of mirrored drives. The drives are mirrored first, and then a stripe is created across the mirrors to improve performance. This should not be confused with RAID 0+1, which is different and is implemented by first striping the disks and then mirroring.

Many businesses with high-volume OLTP applications opt for RAID 10 configurations. The shrinking cost of disk drives and the heavy database demands of today's business applications are making this a much more viable option. If you find that your transaction log or index segment is pegging your RAID 1 array at 100% usage, you can implement a RAID 10 array to get better performance. This type of RAID carries with it all the fault tolerance (and cost!) of a RAID 1 array, with all the performance benefits of RAID 0 striping.

RAID Level 5

RAID 5 is most commonly known as striping with parity. In this configuration, data is striped across multiple disks in large blocks. At the same time, parity bits are written across all the disks for a given block. Information is always stored in such a way that any one disk can be lost without any information in the array being lost. In the event of a disk failure, the system can still continue to run (at a reduced performance level) without downtime by using the parity information to reconstruct the data lost on the missing drive.

Some arrays provide “hot-standby” disks. The RAID controller uses the standby disk to rebuild a failed drive automatically, using the parity information stored on all the other drives in the array. During the rebuild process, performance is markedly worse.

The fault tolerance of RAID 5 is usually sufficient, but if more than one drive in the array fails, you lose the entire array. It is recommended that a spare drive be kept on hand in the event of a drive failure, so the failed drive can be replaced quickly before any other drives fail.

NOTE

Many of the RAID solutions available today support “hot-spare” drives. A hot-spare drive is connected to the array but doesn’t store any data. When the RAID system detects a drive failure, the contents of the failed drive are re-created on the hot-spare drive, and it is automatically swapped into the array in place of the failed drive. The failed drive can then be manually removed from the array and replaced with a working drive, which becomes the new hot spare.

RAID 5 provides excellent read performance but expensive write performance. A write operation on a RAID 5 array requires two writes: one to the data drive and one to the parity drive. After the writes are complete, the controller reads the data to ensure that the information matches (that is, that no hardware failure has occurred). A single write operation causes four I/Os on a RAID 5 array. For this reason, putting log files or tempdb on a RAID 5 array is not recommended. Index filegroups, which suffer worse than data filegroups from bad write performance, are also poor candidates for RAID 5 arrays. Data filegroups where more than 10% of the I/Os are writes are also not good candidates for RAID 5 arrays.

Note that if write performance is not an issue in your environment—for example, in a DSS/data warehousing environment—you should, by all means, use RAID 5 for your data and index segments.

In any environment, you should avoid putting tempdb on a RAID 5 array. tempdb typically receives heavy write activity, and it performs better on a RAID 1 or RAID 0 array.

RAID 5 is a relatively economical means of providing fault tolerance. No matter how many drives are in the array, only the space equivalent to a single drive is used to support

fault tolerance. This method becomes more economical with more drives in the array. You must have at least three drives in a RAID 5 array. Three drives would require that 33% of available disk space be used for fault tolerance, four would require 25%, five would require 20%, and so on.

Figure 38.5 shows a RAID 5 configuration.

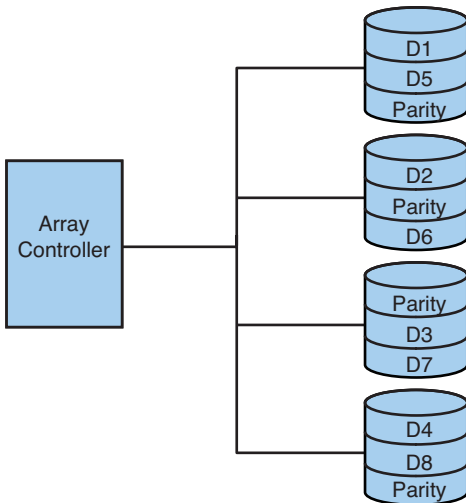

FIGURE 38.5 RAID Level 5.

NOTE

Although the recommendations for using the various RAID levels presented here can help ensure that your database performance will be optimal, reality often dictates that your optimum disk configuration might not be available. You may be given a server with a single RAID 5 array and told to make it work. Although RAID 5 is not optimal for tempdb or transaction logs, the write performance can be mitigated by using a controller with a battery-backed write cache.

If possible, you should also try to stripe database activity across multiple RAID 5 arrays rather than a single large RAID 5 array to avoid overdriving the disks in the array.

SQL Server and SAN Technology

With to the increased use of storage area networks (SANs) in SQL Server environments, it is important to understand the design and performance implications of implementing SQL Server databases on SANs. SANs are becoming increasingly more common in SQL Server environments these days for a number of reasons:

- ▶ Increasing database sizes
- ▶ The increasing prevalence of clustered environments
- ▶ The performance advantages and storage efficiencies and flexibilities of SANs
- ▶ The increasing needs of recoverability and disaster recovery
- ▶ Simplified disk administration

In large enterprises, a SAN can be used to connect multiple servers to a centralized pool of disk storage. Compared to managing hundreds of servers, each with its own separate disk arrays, SANs help simplify disk administration by treating all the company's storage as a single resource. Disk allocation, maintenance, and routine backups are easier to manage, schedule, and control. In some SANs, the disks themselves can copy data to other disks for backup without any processing overhead at the host computers.

What Is a SAN?

A SAN contains multiple high-performance hard drives coupled with high-performance caching controllers. The hard drives are often configured into various RAID configurations. These drive configurations are virtualized so that the consumer does not know which hard drives a SQL Server or other device connected to the SAN will access. Essentially, the SAN presents blocks of storage to servers that can consist of a single hard drive, multiple hard drives, or portions of hard drives in a logical unit called a Logical Unit Number (LUN). Connection to a SAN is typically through fiber channel, a high-speed optical network.

SANS can provide advantages over locally attached storage. Most SANs provide features that allow you to clone, snapshot, or rapidly move data (replicate) from one location to another, much faster than file copies or data transfers over your network. This increases the usefulness of SANs for disaster recovery. SANs also provide a shared disk resource for building server clusters, even allowing a cluster or server to boot off a SAN.

Another reason for the increased use of SANs is that they offer increased utilization of storage. With locally attached storage, large amounts of disk space can end up being wasted. With a SAN, you can expand or contract the amount of disk space allocated to a server or cluster as needed.

Due to their cost and complexity, however, SANs are not for everybody. They only really make sense in large enterprises. They are not a good choice for small environments with relatively small databases, for companies with limited budgets (SANs are expensive), or for companies that require disaster recovery on only one or a few SQL Servers.

SAN Considerations for SQL Server

Before you rush out and purchase a SAN or two for your SQL Server environments, there are some considerations to keep in mind when using SANs with SQL Server.

Cache Performance

One of the reasons SANs can offer superior performance to locally attached storage is they typically are configured with a significant amount of cache space. This is normally a good thing. However, because the SAN provides storage services to multiple servers, the available cache space is shared as well. If there is significant activity against the SAN, there can be extensive cache turnover. This means that the large cache space may not always be available to SQL Server, so some of the performance gains provided by the large cache are not realized.

NOTE

Cache turnover in a SAN can lead to widely varying physical I/O response times. When SQL Server performs I/O against the SAN, it's considered a physical I/O whether or not the data resides in the SAN cache. When the physical I/O performance for SQL Server is measured, the performance can be orders of magnitude faster when the data is residing in the SAN cache than when the data has to be physically read from the disks in the SAN. It is important that you perform benchmarking with your SAN vendor to ensure that your SAN cache will be adequate to provide optimal database performance.

Avoid Disk Drive Contention

SAN storage is divided into LUNs. Servers attached to the SAN recognize one or more of these units as a disk partition or drive. However, these LUNs may share the same disk drives. For example, consider six 100GB drives in the SAN. Theoretically, this could be divided into two LUNs of 300GB each. Although each LUN may be allocated to different SQL Servers, some of the drives shared between the two LUNs could experience twice the I/O from both servers than if the drives were dedicated to a single server. To avoid this situation, most SANs support *zoning*, which allows the SAN administrator to dedicate entire disks in the SAN to your LUN to isolate the I/O on the drives in the LUN to your SQL Server.

In addition, you should try to ensure that your database log files are on a LUN consisting of dedicated drives separate from the LUN (or LUNs) used for your SQL Server data files. Log files typically are written sequentially, unlike data files where data access tends to consist more of random reads and writes. Sharing a LUN between data files and log files generally does not provide optimal IO performance. Unfortunately, your SAN administrator may not permit you to dedicate a separate disk or set of disks to your log files. An alternative may be to place your log files on a local RAID 1 or RAID 10 array. However, you might want to benchmark to determine which solution provides better performance because the caching capabilities of the SAN may offset the potential drive contention in the SAN.

Additional SAN Performance Considerations

Some SAN administrators may attempt to convince you to use RAID 5 for all data and log files. Before following their advice, you should benchmark the system using a representative load to ensure that RAID 5 will offer the best performance for your log files, tempdb, and any write-intensive filegroups.

You should also ensure that the hardware your SQL Server system uses to connect to the SAN provides optimal performance. Make sure that you have the correct and most up-to-date drivers for your SAN components. If you can, consider using multiple high-speed host bus adapters (HBAs) to connect your servers to your SAN to avoid the I/O contention that can occur with a single HBA. If you do use multiple HBAs, try to ensure they are on different buses to prevent bus saturation and that the HBAs are plugged into the PCI slots offering the highest speed.

SANs are complex, and delivering optimal performance for a SQL Server solution using a SAN is challenging. Benchmark your SQL Server to determine if bottlenecks exist with your SAN. Be willing to work with your SAN administrator or vendor to fine-tune your SAN configuration and carefully consider and benchmark any recommendations they may make to ensure optimal performance.

Summary

A good database design is the best place to start to ensure that your database application runs smoothly. This chapter outlined some of the fundamental aspects a database design that you should consider. If you have the luxury of designing the database system from the ground up, be sure to use what you learned in this chapter in the early stages of developing your database system. If you inherit a database with an inadequate design, the design principles described in this chapter still apply, but they may be a bit harder to implement.

The next chapter, “Monitoring SQL Server Performance,” delves into the tools and techniques you can use to evaluate the performance of your SQL Server instance. Monitoring is tightly linked to database design and is essential in achieving optimal database performance.

CHAPTER 39

Monitoring SQL Server Performance

No SQL Server implementation is perfect out of the box. As you build and add SQL Server–based applications to your server, you should take an active approach to monitoring performance. You also need to keep reevaluating as more and more load is placed on your servers and data volumes grow. This chapter focuses on SQL Server monitoring and leaves monitoring of the other types of servers (including application servers, backup servers, domain controllers, file and print servers, mail/messaging servers, and web servers) for the specialists in those areas.

You can monitor many things on your SQL Server platform, ranging from physical and logical I/O to the network packets passing between the server and your client applications. To make this monitoring task a little cleaner, this chapter classifies the key monitoring elements into network, processors, memory/cache, and disk systems. Figure 39.1 shows how these key elements interrelate with SQL Server 2008 and Windows. The aspect of utilization—whether CPU utilization, memory utilization, or something else—is at the center of most of the discussions in this chapter. The important concept to remember is how to monitor or measure utilization and how to make changes to improve this utilization because you are still not in a perfect world of infinite CPU power, infinite disk space, infinite network load capability, and infinite memory.

It is essential that you know which tools you can use to get this valuable information. These tools include SQL Server Management Studio (SSMS) Activity Monitor, Data Collector, Extended Events, Windows Performance Monitor and its various counters, a few SQL Server DBCC options, SQL Server Profiler, and a variety of SQL Server dynamic

IN THIS CHAPTER

- ▶ What's New in Monitoring SQL Server Performance
- ▶ Performance Monitoring Tools
- ▶ A Performance Monitoring Approach

management views (DMVs). Although many other third-party products are available for performance monitoring, some of which do a fantastic job of gathering and aggregating performance data from a number of sources, there is just not enough space in this chapter to cover all the various third-party tools and their features. Instead, this chapter focuses on the performance monitoring tools provided out of the box with SQL Server 2008.

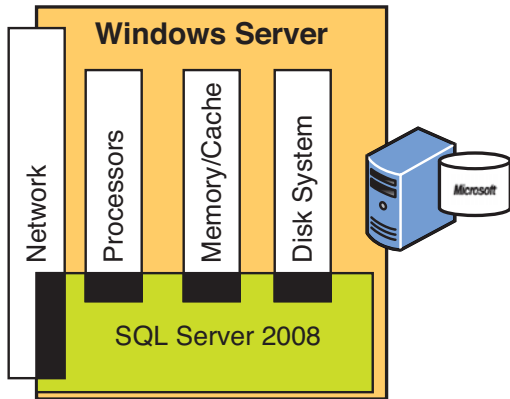

FIGURE 39.1 Key elements of SQL Server 2008 performance monitoring: network, processors, memory/cache, and disks.

What's New in Monitoring SQL Server Performance

Performance tuning and troubleshooting are time-consuming tasks for the administrator. To help provide insights quickly into performance issues, SQL Server 2008 provides a number of new and enhanced features for monitoring SQL Server performance.

In SQL Server 2005, the Activity Monitor in SSMS showed only the current running processes and the locks currently being held in the system. In SQL Server 2008, the Activity Monitor has been enhanced and now provides a graphical overview of SQL Server activity, as well as information on active user tasks, resource waits, data file I/O, and the recent most expensive queries. Unfortunately, the new information and fancier interface come with the loss of the useful lock monitor that was available in SQL Server 2005 Activity Monitor.

SQL Server 2008 also introduced a new performance monitoring tool called the Data Collector. The Data Collector gathers performance data from multiple sources and stores the data in the management data warehouse (MDW). The MDW is simply a database setup within a SQL Server instance where the data is collected for subsequent viewing and reporting.

SQL Server Extended Events is a general event-handling system for the server. The Extended Events infrastructure is a lightweight mechanism that supports capturing, filtering, and acting on events generated by the server process. Extended Events is designed to be a foundation that users can configure to monitor and capture different types of data, including performance data. It's a flexible and powerful way to provide a low granular level of information about the server system. Events can be used to diagnose runtime

problems by adding contextual data, such as Transact-SQL (T-SQL) call stacks or query plan handles, to any event. Events can be captured into several different output types, including Event Tracing for Windows (ETW), which enables you to correlate events with operating system and application events and performance counters.

SQL Server 2008 also introduces a number of new dynamic management views to simplify retrieval of information that can be helpful with memory troubleshooting. These new DMVs are described in more detail later in this chapter.

Performance Monitoring Tools

In prior versions of SQL Server, the tools available for monitoring SQL Server performance were somewhat limited. Yes, you had the Windows Performance Monitor, Activity Monitor, SQL Server Profiler, and SQL Trace, but performing in-depth performance monitoring usually required the purchase of third-party tools to collect, monitor, and view performance information in a useful way.

SQL Server 2008 provide a number of tools you can use to collect, analyze, monitor, and report performance-related data. The usual old-timers such as SQL Server Profiler and Database Engine Tuning Advisor still exist and are available to you, but SQL Server 2008 also includes a new Activity Monitor, the Data Collector and management data warehouse, SQL Utility, and SQL Server Extended Events.

NOTE

For a discussion on using SQL Server Profiler for monitoring and analyzing performance, see Chapter 6, “SQL Server Profiler.” For more information on the Database Engine Tuning Advisor, see Chapter 55, “Configuring, Tuning, and Optimizing SQL Server Options.” In addition, the Activity Monitor is already covered in detail in Chapter 4, “SQL Server Management Studio,” so detailed information on Activity Monitor is not provided in this chapter.

The Data Collector and the MDW

As mentioned previously, SQL Server 2008 introduces a new performance monitoring tool called the Data Collector. The Data Collector is designed to collect performance-related data from multiple sources from one or more SQL Servers, store it in a central data warehouse, and present the data through reports in SQL Server Management Studio. The main purpose of the Data Collector is to provide an easy way to automate the collection of critical performance data. The Data Collector gathers information from Windows performance counters, snapshots of data grabbed from dynamic management views, and details on disk utilization.

Data collection can be configured to run continuously or on a user-defined schedule. You can adjust the scope of data collection to suit the needs of your test and production environments. The Data Collector provides a single central point for data collection across

your database servers and applications and, unlike SQL Trace, is not limited to collecting performance data only.

The Data Collector feature consists of the following components:

- ▶ **Data collection sets**—These are the definitions and scheduled jobs for collecting performance data. They are stored in the `msdb` system database.
- ▶ **The Data Collector runtime component**—This standalone process, called `Dcexec.exe`, is responsible for loading and executing the SSIS packages that are part of a collection set.
- ▶ **SQL Server Integration Services (SSIS) packages**—These packages are used to collect and upload the data.
- ▶ **The management data warehouse database**—This is a relational database where the collected data is stored. It also contains the views and stored procedures needed for collection management.
- ▶ **MDW Reports**—These reports are built in to SSMS for viewing the collected performance data.

Figure 39.2 provides an overview of the Data Collector architecture and how the various components interact.

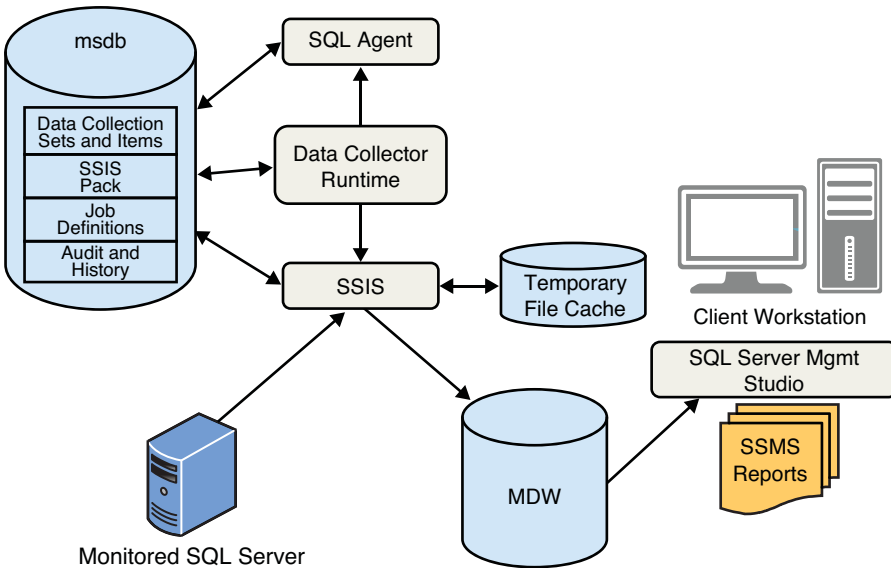

FIGURE 39.2 Data Collector architecture.

NOTE

The Data Collector is not a zero-impact monitoring solution. It incurs approximately a 2% to 5% performance hit on the servers where it's collecting data. This performance hit is mainly on the CPU.

Data Collection Sets

A *data collection set* is a group of collection items. A *collection set* is the unit of data collection that a user can interact with through the user interface. Data collection sets are defined and deployed on a SQL Server 2008 instance and can be run independently of each other. Each collection set is run by a SQL Server Agent job or jobs, and data is uploaded to the management data warehouse on a predefined schedule.

Out of the box, SQL Server 2008 provides the following built-in system data collection sets and reports:

- ▶ **Disk Usage**—Collects local disk usage information for all the databases of the SQL Server instance. This information can help you determine current space utilization and future disk space requirements for disk capacity planning.
- ▶ **Server Activity**—Collects SQL Server instance-level resource usage information like CPU, memory, and I/O. This information can help you monitor short-term to long-term resource usage trends and identify potential resource bottlenecks on the system. It can also be used for resource capacity planning.
- ▶ **Query Statistics**—Collects individual statement-level query statistics, including query text and query plans. This information can help you identify the top resource-consuming queries that may need performance tuning.

The definition of the system collection sets cannot be modified. However, you can define your own collection sets or define your own custom reports for this data.

Data Collector Runtime Component

The Data Collector runtime component is invoked by a standalone process called `Dcexec.exe`. This component manages data collection based on the definitions provided in a collection set. The Data Collector runtime component is responsible for loading and executing the SSIS packages that are part of a collection set.

A collection set can be run in one of the following collection and upload modes:

- ▶ **Noncached mode**—Data collection and upload are executed on the same schedule. The packages collect data as scheduled and then immediately upload data.
- ▶ **Cached mode**—Data collection and upload are performed on different schedules. The collection package continues to collect and cache data until stopped. Data is uploaded from the local cache according to the schedule specified by the user.

NOTE

The Data Collector runtime component can perform only data collection or data upload. It cannot run these tasks concurrently.

SSIS Packages

The Data Collector is implemented as SSIS packages that are invoked by the Data Collector runtime component. These packages can be configured to run manually, continuously, or scheduled as SQL Server Agent jobs to periodically collect and upload data to the management data warehouse.

The two most important tasks for the SSIS packages are data collection and data upload. These tasks are carried out by separate packages. A collection package gathers data from a data provider and keeps it in temporary storage. An upload package reads the data in temporary storage, processes the data as required (for example, removing unnecessary data points, normalizing the data, and data aggregation) and then uploads the data to the management data warehouse. The upload is done as a bulk insert to minimize the impact on server performance. The separation of data collection and data upload into separate packages provides more flexibility and efficiency. This design supports scenarios in which snapshots of the data are captured at frequent intervals (for example, every 15 seconds), but the collected data needs to be uploaded only every hour. Data collection and upload frequency should be determined by the monitoring requirements of a particular SQL Server installation.

The Management Data Warehouse

The management data warehouse is a relational database where the Data Collector stores its data. A single MDW database can serve as the central repository for data collectors running on one or more target SQL Server instances. A data collector is configured on each target server, and it collects and uploads data to the MDW database, which may be on a remote server. Between the time the data is captured and the time it is uploaded, the Data Collector may write temporary data into cache files on the target server.

NOTE

You can install the MDW on the same instance of SQL Server that is running the Data Collector. However, if server resources or performance are an issue on the server that is being monitored, you might want to install the management data warehouse on a different computer to avoid additional CPU and I/O contention.

The MDW can become quite large, growing at approximately 250–500MB per day. This is roughly around 2GB of database storage per server each week. You need to decide how long you want to retain the data based on your performance monitoring needs and your storage availability. For the most part, you can probably stick with the default retention settings, which are 14 days for Query Statistics and Server Activity History data collections and two years for Disk Usage Summary collections.

The required schemas and the objects to support the predefined system collection sets are created when you run the wizard to create the MDW. Two schemas are created: core and snapshots. The core schema describes the tables, stored procedures, and views used to organize and identify collected data. These tables are shared among all the data tables created for individual collector types. The snapshots schema describes the objects needed to store and maintain the data collected by the collector types that are provided.

A third schema, custom_snapshots, is created if you create your own user-defined collection sets that include collection items that use the Generic T-SQL Query collector type.

CAUTION

You should not directly modify any data stored in the management data warehouse. Changing the data that you have collected invalidates the legitimacy of the collected data. Also, instead of directly accessing the MDW tables, you should always use the documented stored procedures and functions provided with the Data Collector to access instance and application data.

MDW Reports

The MDW reports included in SSMS present the information gathered by the Data Collector in the following areas:

- ▶ Query performance statistics and use of indexes
- ▶ Server activity information, including waiting processes, memory usage, CPU/scheduler usage, and disk I/O
- ▶ Disk usage information

Each of the reports present a summary of the data at a high level, with the capability to drill down into the details. Sometimes the reports can provide information to help direct you to a solution for a performance problem. For example, if the query performance statistics report shows an extremely slow-running query, you can drill down through the report to expose more details on the query, right down to the query plan. The query plan could indicate that there is a missing index on that table, and creating that index could make a major difference in the query performance.

Installing and Configuring the Data Collector

Before you can use the Data Collector, you must complete the following tasks:

- ▶ Create logins and map them to Data Collector roles.
- ▶ Configure the management data warehouse.

NOTE

The management data warehouse can be installed only on a server running SQL Server 2008 or SQL Server 2008 R2.

The Data Collector has specific roles for data collection and management data warehouse tasks. The logins and roles required for data collection need to be created on the server that performs the data collection. Logins and roles for the MDW need to be created in the server that hosts the MDW. These logins and the MDW are created using the Configure Management Data Warehouse Wizard, which performs the following tasks:

- ▶ Creates the management data warehouse
- ▶ Installs the predefined System Data collection sets
- ▶ Maps logins to management data warehouse roles
- ▶ Enables data collection
- ▶ Starts the System Data collection sets

To invoke the Configure Management Data Warehouse Wizard, perform the following tasks on the SQL Server instance where you want to host the MDW:

1. Ensure that SQL Server Agent is running (for information on starting SQL Server Agent, see Chapter 16, “SQL Server Scheduling and Notification”).
2. In Object Explorer in SSMS, expand the server instance that will host the MDW and expand the Management node for that server.
3. Right-click Data Collection and then click Configure Management Data Warehouse. This starts the Configure Management Data Warehouse Wizard.
4. Click on Next to display the Select Configuration Task window, as shown in Figure 39.3.

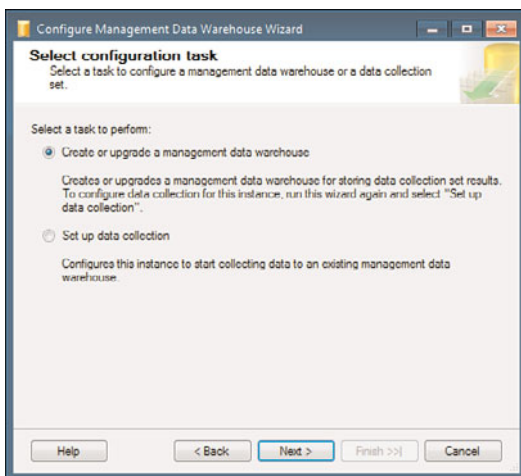

FIGURE 39.3 The Configure Management Data Warehouse Wizard’s Select Configuration Task window.

TIP

If you've already created a repository database for the SQL Server Utility (see the "SQL Server Utility" section later in this chapter), you must use this same database as the MDW for the Data Collector. You can skip the process of creating the MDW and jump right to the configuration of the Data Collector. On the Configure Management Data Warehouse Storage screen (look ahead to Figure 39.6), you specify the name of the server that was set up as the utility control point (UCP) and specify the name of the utility data warehouse database that was set up to collect the SQL Server Utility performance statistics.

In the Select Configuration Task window, make sure the radio button for Create or Upgrade a Management Data Warehouse is selected and click Next. Specify the name of the server instance that will host the MDW and click on New to create the MDW database. This brings up the standard New Database dialog. Enter the name you want to use for the MDW database and specify the location of the database files if you want the database created in different drive or directory than the default data file directory.

TIP

If you are creating the MDW on a server that you will also be monitoring with the Data Collector, it's a good idea to put the MDW on drives separate from where your production databases reside to avoid the potential for any I/O contention between the MDW and your production databases.

Also, because of the anticipated growth of the MDW, you might want to change the default autogrow size of the MDW from 50MB to possibly 250 or 500MB and set the initial size to at least 500MB or 1GB.

Before saving your settings and creating the MDW database, display the Options page and make sure that the database is configured for Simple recovery mode. For the current release of the Data Collector, the management data warehouse should be created using the Simple recovery model, to minimize logging.

When you are satisfied with the database configuration, click on OK to create the MDW database. After the database is created and you are brought back to the Configure Management Data Warehouse Storage screen (see Figure 39.4), click Next to continue to the Map Logins and Users screen. On this screen, assign the appropriate MDW roles to your SQL Server users (see Figure 39.5). Any users who need to view the Data Collector reports need the `mdw_reader` role.

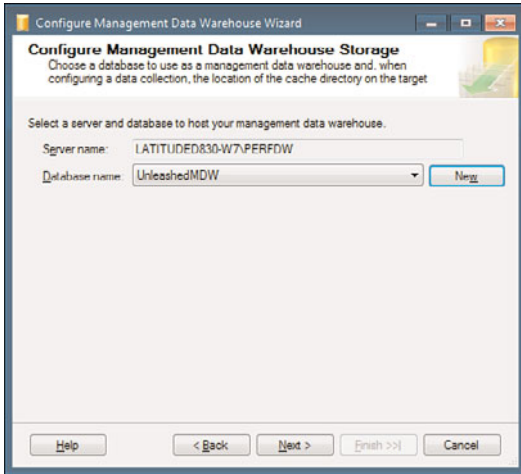

FIGURE 39.4 The Configure Management Data Warehouse Storage screen.

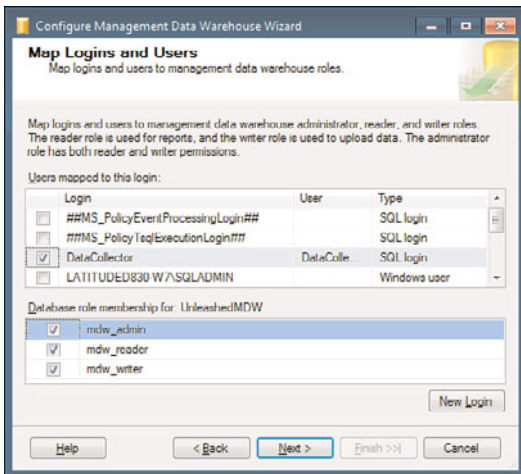

FIGURE 39.5 The Map Logins and Users screen.

By default, no user is a member of the MDW database roles. User membership in these roles must be granted explicitly. Members of the `mdw_admin` role have Read, Write, Update, and Delete access to the management data warehouse. Members of this role can change the management data warehouse schema when required (for example, adding a new table when a new collection type is installed) and run maintenance jobs on the management data warehouse, such as archive or cleanup. Members of the `mdw_writer` role can upload and write data to the management data warehouse; any Data Collector that stores data in the management data warehouse has to be a member of this role. Members of the `mdw_reader` role have Read access to the management data warehouse primarily for the purpose of supporting troubleshooting by providing access to historical data.

It is recommended that you create a new login for data collection and map it as shown in Figure 39.5.

After you map the users, click on Next to bring up the Complete the Wizard screen, which provides a summary of the tasks to be performed. If everything looks okay, click Finish to perform the configuration of the MDW, which includes running the installation script to install the required schema objects in the MDW.

After you have created the MDW and made it available, the next step is to begin data collection for one or more of your SQL Server 2008 instances. Right-click on the Data Collection node in Object Explorer and select the Configure Management Data Warehouse option again. On the Select Configuration Task screen (refer to Figure 39.3), select the Set Up Data Collection radio button and click Next. On the Configure Management Data Warehouse Storage screen (see Figure 39.6), specify the name of the server that hosts the MDW and the name of the MDW database created previously. When specifying the server, you can also specify which directory you want the Data Collector to use for its local file cache (again, if possible, this should be on a different drive than where your database data files reside to minimize I/O contention). If you leave the value blank, it uses the default SQL Agent TEMP directory.

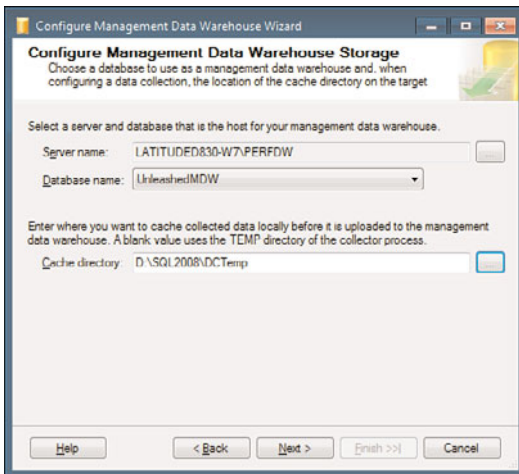

FIGURE 39.6 The Configure Management Data Warehouse Storage screen when configuring data collection.

When you finish making your selections, click Next to bring up the Complete the Wizard screen, which provides a summary of the tasks to be performed. If everything looks okay, click Finish to have the wizard perform the configuration of the system collection sets and enable data collection.

The System Data Collectors

When the Configure Management Data Warehouse Wizard is finished, you should see three additional nodes under the Data Collector node: Disk Usage, Query Statistics,

and Server Activity. You can double-click each node, or right-click and select Properties, to open the Properties window. The Properties window for the Disk Usage Data Collector is shown in Figure 39.7.

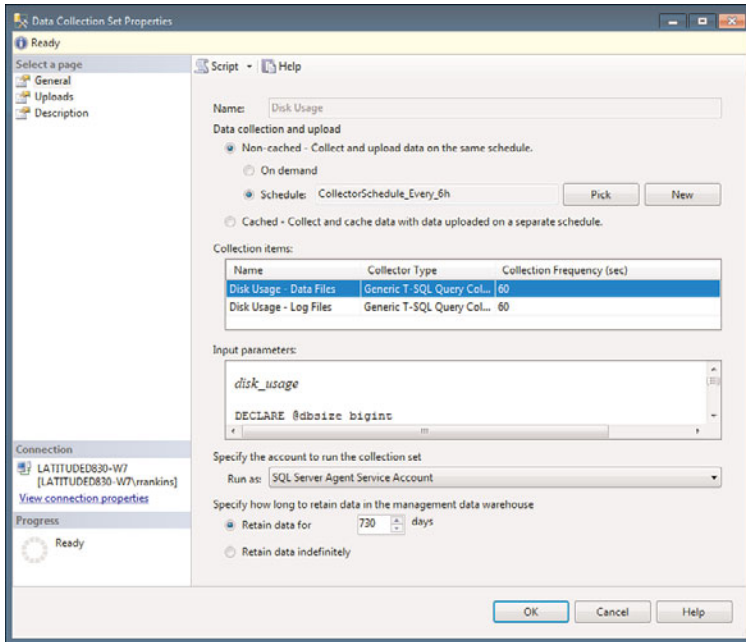

FIGURE 39.7 Data Collection Set Properties window for the Disk Usage Data Collector.

The main item you may want to change in the Data Collection Set Properties window is the data collection and upload schedule. By default, the wizard configures the Disk Usage Collection set to run in noncached mode every six hours. Depending on how active your server is, you might want to increase or decrease the frequency that it runs. You can also configure how long it should retain data in the MDW. By default, it is configured to retain data for two years (730 days). This is probably fine for keeping track of disk usage, but for more active Data Collector Sets, you might want to reduce the retention period to reduce the size of the MDW. For example, the default retention period for the Query Statistics and Server Activity Data Collectors is 14 days.

Both the Query Statistics and Server Activity Data Collectors are configured to cache data and upload to the MDW on a separate schedule. If you look in the General page of the Data Collection Set Properties window for these Data Collectors, you see that the schedule Query Statistics Data Collector is to gather information every 10 seconds, and the Server Activity collector gathers information every 60 seconds. To view the upload schedule, click on the Uploads page (see Figure 39.8). Both Data Collectors, by default, are configured to

upload the cached data to the MDW every 15 minutes. To change the upload schedule, you can either pick from an existing schedule or create a new one (Figure 39.8 shows the Pick Schedule list). The Upload Properties page also displays the last time the cached data was uploaded to the MDW.

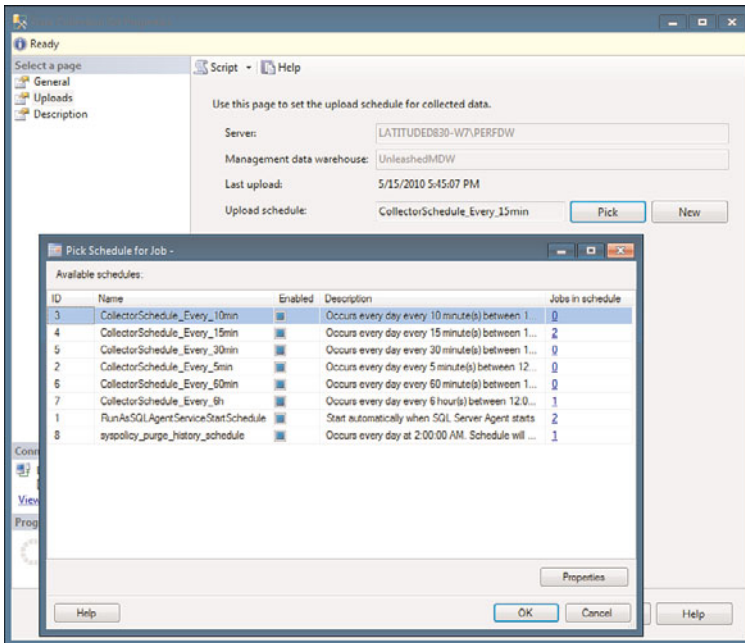

FIGURE 39.8 Data Collection Set upload schedule.

In very active servers, the Data Collector can generate a lot of data, and its storage tables can fill up with millions of rows within hours. You might want to modify the collector job schedules and decrease the frequency of data collections depending on the use of each server and your monitoring requirements.

NOTE

Data collection for the built-in system collection sets begins automatically after the Configure Management Data Warehouse completes. Depending on how active your servers are, it likely will take awhile for some meaningful data to accumulate. You might want to wait an hour or so before looking at the reports.

Data Collector Reports

After you set up data collection, SQL Server Management Studio provides three new reports for viewing data accumulated by the Data Collector: Server Activity History, Disk

Usage Summary and Query Statistics History. You can view these reports by right-clicking on the Data Collection node and selecting Reports, and then select Management Data Warehouse. From there, you can choose one of the three built-in reports:

- ▶ **Disk Usage Summary**—Displays data and log file sizes (starting size and current size) and average daily growth
- ▶ **Query Statistics History**—Displays query execution statistics including the top 10 queries by CPU, Duration, Total I/O, Physical Reads, and Logical Writes
- ▶ **Server Activity History**—Displays performance statistics in four general areas: CPU %, Disk I/O Usage, Memory Usage, and Network Usage, plus SQL Server Wait statistics by wait type and SQL Server activity

Figure 39.9 displays an example of the Disk Usage Summary Report. All the data collection reports provide drill-down capabilities on just about every data element and widget displayed in the main report. For example, in the Disk Usage Summary report, you can click on the database name to display a more detailed breakdown of the disk usage for that specific database. Figure 39.10 shows the Disk Usage details for the AdventureWorks2008R2 database. If you click on the Trend graph or the current database or log size, it displays a more detailed graph showing the growth trends for the database over time since the data collection session started.

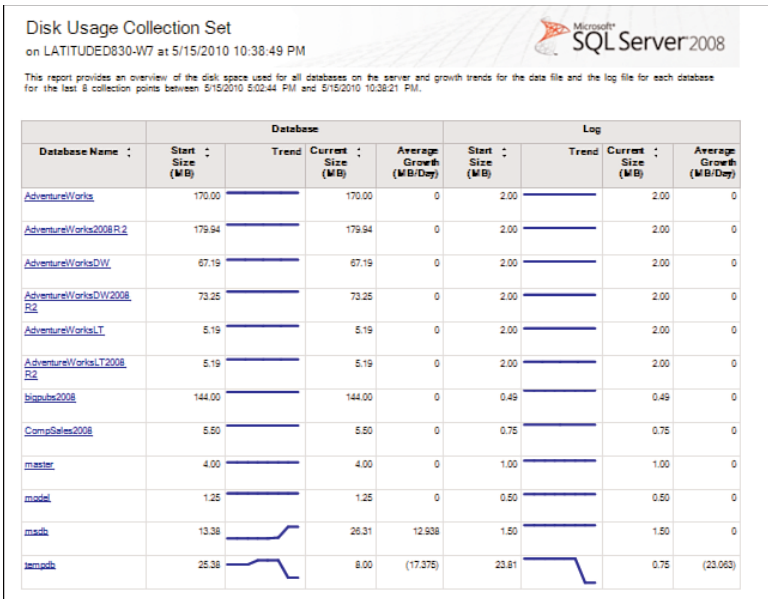

FIGURE 39.9 Disk Usage Summary report.

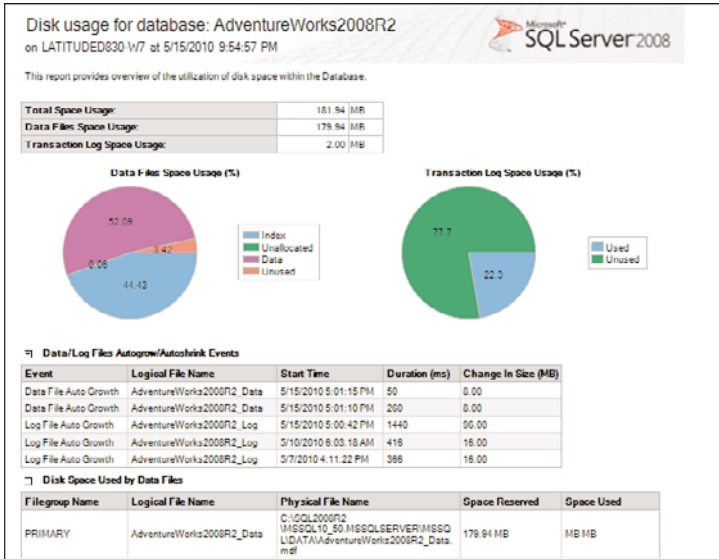

FIGURE 39.10 Disk Usage report for **AdventureWorks2008R2** database.

If you want to run reports for any of the monitored servers without having navigate to the Data Collection node for each server instance, you can open the server instance that hosts the MDW. Browse to the MDW database in the SSMS Object Browser and right-click on that database. Then select Reports and select the the Management Data Warehouse Overview report (see Figure 39.11).

FIGURE 39.11 Management Data Warehouse Overview report.

The Management Data Warehouse Overview report lists which servers the data collection is running on and shows the most recent times data was uploaded for each of the collection sets. You can click on the hyperlinks below each of the listed collection sets to bring up that corresponding report for that server. For example, if you click on the link below Server Activity for the LATITUDE830-W7 server, it displays the Server Activity History report, as shown in Figure 39.12.

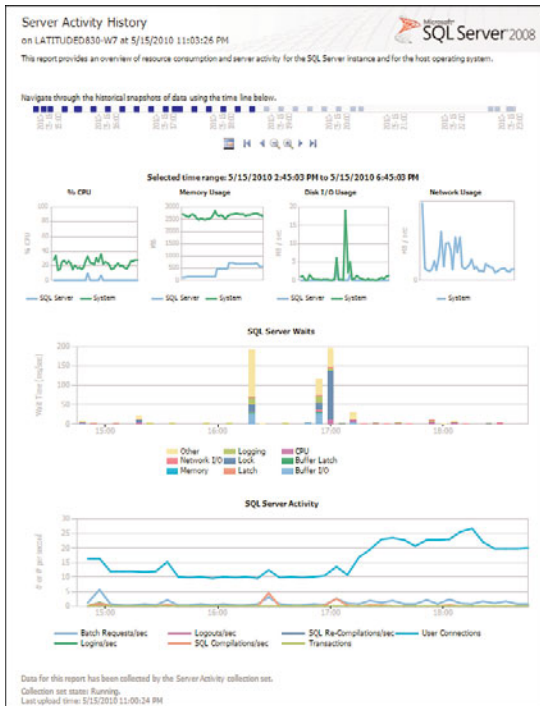

FIGURE 39.12 The Server Activity History report.

Like the Disk Usage report, most of the data elements in the Server Activity History report are hyperlinks that let you drill down into more detail. For example, you can click in the line in the Disk I/O Usage graph to bring up additional detail by disk of the Disk Response Time, Average Disk Queue Length, Disk Transfer Rate, as well as the average, minimum, and maximum I/O reads and writes for the processes running during the data collection session.

If you want to narrow down the report to a specific time frame, you can click on a point in the timeline shown on the report to set the end time of the data displayed. You can click on the magnifying glass to increase or decrease the size of the interval displayed and click the arrow buttons to move to the next or previous interval. For finer control over the time period displayed, click on the calendar icon to bring up the dialog shown in Figure 39.13. Here, you can set the specific start time and choose an interval (15 minutes or 1, 4, 12, or 24 hours) to display from that start time.

The Data Collector reports contain a lot of data, especially if you drill down into the details. There are more details than we have space to get into in this chapter. You should plan to spend some time examining each of these reports by drilling down into the various details and selecting different time frames and so on to get familiar with what they have to offer. For example, you can drill from the Query Statistics History report to the individual query details, including the graphical execution plan.

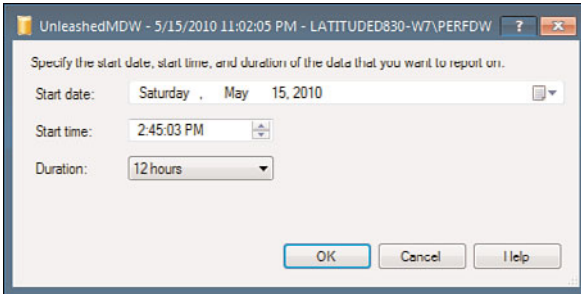

FIGURE 39.13 Defining the time frame to display in a data collection report.

Managing the Data Collector

To stop collecting performance data for a SQL Server instance, right-click on Data Collection in the Management node and click Disable Data Collection. If you want to stop a specific data collection set, expand the Data Collection node and then expand the System Data Collection Sets folder. Right-click on the data collection set you want to stop and select Stop Data Collection Set.

You can also force a collection set to gather data and upload statistics manually by right-clicking on the data collection set and selecting Collect and Upload Now.

To check on the status and history of the Data Collectors, you can right click on the Data Collection node and select View Logs. This launches the log viewer that displays the activity that has occurred for each of the data collection sets, such as which collection sets are active and the collection and upload history of each of the collection sets.

Managing the Data Collector in T-SQL

Much of the Data Collector can be managed effectively within SSMS. However, if you have to perform a number of tasks repeatedly, using the wizards and SSMS dialogs can sometimes become tedious. Fortunately, the Data Collector provides an extensive collection of stored procedures that you can use to perform any data collection task. In addition, you can use functions and views to retrieve configuration data from the `msdb` and management data warehouse databases, execution log data, as well as the performance data stored in the management data warehouse.

TIP

As with most tools in SSMS, when using the GUI, you can click the Script button to generate a script for the actions being performed. This is a great way to become more familiar with the T-SQL commands and procedures for managing the Data Collector.

For example, to enable or disable the Data Collector in a SQL Server instance, you can use the `sp_syscollector_enable_collector` and `sp_syscollector_disable_collector` stored procedures:

```
USE msdb;
GO
EXEC dbo.sp_syscollector_disable_collector;
GO
EXEC dbo.sp_syscollector_enable_collector;
GO
```

To force the running of a noncached collection set and have it upload to the MDW for collection sets configured in noncached collection mode, use the `sp_syscollector_run_collection_set` system procedure:

```
sp_syscollector_run_collection_set
    [ [ @collection_set_id = ] collection_set_id ]
    , [ [ @name = ] 'name' ]
```

You can pass either the collection set ID or the collection name. When you are passing one, the other parameter can be NULL:

```
USE msdb;
GO
EXEC sp_syscollector_run_collection_set @name = 'Disk Usage'
go
```

To force a manual update of a cached mode Data Collector, you can use the `sp_syscollector_upload_collection_set` procedure:

```
USE msdb;
GO
EXEC sp_syscollector_upload_collection_set @name = 'Server Activity'
go
```

To stop or start a specific collector set, you can use the `sp_syscollector_start_collection_set` and `sp_syscollector_stop_collection_set` stored procedures:

```
USE msdb;
GO
EXEC dbo.sp_syscollector_stop_collection_set @name = 'Disk Usage'
GO
EXEC dbo.sp_syscollector_start_collection_set @name = 'Disk Usage'
GO
```

To modify a collection set, you can use the `sp_syscollector_update_collection_set` procedure. The syntax is as follows:

```
sp_syscollector_update_collection_set
    [ [ @collection_set_id = ] collection_set_id ]
    , [ [ @name = ] 'name' ]
    , [ [ @new_name = ] 'new_name' ]
```

```

, [ [ @target = ] 'target' ]
, [ [ @collection_mode = ] collection_mode ]
, [ [ @days_until_expiration = ] days_until_expiration ]
, [ [ @proxy_id = ] proxy_id ]
, [ [ @proxy_name = ] 'proxy_name' ]
, [ [ @schedule_uid = ] 'schedule_uid' ]
, [ [ @schedule_name = ] 'schedule_name' ]
, [ [ @logging_level = ] logging_level ]
, [ [ @description = ] 'description' ]

```

If the collection set is running, the only options you can modify are the *schedule_uid* and *description*. You need to stop the collection set with `sp_syscollector_stop_collection_set` first to change other options like the *collection-mode* or *days_until_expiration*. For example, the following code changes the number of days to retain collection set data to seven days for the Server Activity collection set:

```

USE msdb;
GO
EXEC dbo.sp_syscollector_stop_collection_set @name = 'Disk Usage'
GO
EXEC dbo.sp_syscollector_update_collection_set
@name = N'Server Activity',
@days_until_expiration = 7;
GO
EXEC dbo.sp_syscollector_start_collection_set @name = 'Disk Usage'
GO

```

To view information about the configured collection sets, you can run a query on the `syscollector_collection_sets` table similar to the following:

```

select collection_set_id as ID,
       cast (scs.name as varchar(20)) as name,
       is_running as 'running',
       case collection_mode when 0 then 'cached'
       else 'noncached' end as coll_mode,
       days_until_expiration as retnn,
       cast (s.name as varchar(30)) as schedule
from syscollector_collection_sets scs
     inner join
     sysschedules s
     on scs.schedule_uid = s.schedule_uid
go

```

ID	name	running	coll_mode	retnn	schedule
2	Server Activity	1	cached	7	CollectorSchedule_Every_15min
3	Query Statistics	1	cached	14	CollectorSchedule_Every_15min

```

4 Utility Information 1 noncached 1 CollectorSchedule_Every_30min
1 Disk Usage 1 noncached 730 CollectorSchedule_Every_6h

```

There are other informational views you can use to view the data collection configuration:

```

-- To display the location of the temporary cache and the MDW
select * From syscollector_config_store
go
parameter_name      parameter_value
-----
CacheDirectory      D:\SQL2008\DCTemp
CacheWindow         1
CollectorEnabled    1
MDWDatabase         UnleashedMDW
MDWInstance         LATITUDE830-W7\PERFDW

```

```

-- To display the data collection capture and upload
-- information from the execution log
select * From syscollector_config_store
go
select csc.name as collection_set, start_time
  From syscollector_execution_log sel
      inner join
      syscollector_collection_sets csc
      on sel.collection_set_id = csc.collection_set_id
order by csc.name, start_time
go

```

You can also use the stored procedures, functions, and views that are provided to create your own end-to-end data collection scenarios.

Creating a Customized Data Collection Set

Although you cannot change or delete the built-in system Data Collectors, you can define your own custom data collection sets. However, currently, you can define them only in T-SQL. There are four different collector types that you can use to build a collector set:

- ▶ **T-SQL query**—Executes a user-provided T-SQL statement as an input parameter, saves the output from the query, and then uploads the output to the management data warehouse.
- ▶ **SQL Trace**—Uses SQL Trace to monitor the SQL Server Relational Engine, with trace data coming from the system default trace or from one or more custom traces.
- ▶ **Performance counters**—Collects specific performance counter information from Windows Performance Monitor on the computer running SQL Server 2008.
- ▶ **Query activity**—Collects query statistics and query activity information along with the query plan and query text for queries that meet predefined criteria. Essentially, this collector type collects the same information as the Query Statistics collection

set, so it is recommended that you simply use the predefined Query Statistics collection set.

One of the reasons you might create a customized data collection set is that the default system Data Collector for Query Statistics does not store all the statements. It captures only the worst-performing queries based on the algorithms specified in the collection set. You might want to collect more queries than the top three worst performing ones. However, if you create your own data collection for query statistics, you should probably disable the default system collector to reduce data collection overhead.

This chapter shows how to create a custom collection set to monitor a few Performance Monitor counters.

TIP

To see an example of a collection set based on performance counters, DMVs, and T-SQL queries, you can look at the definition of the default Server Activity collection set. You can easily see this definition by right-clicking on Server Activity in the System Data Collection Sets folder in SSMS and selecting Script Data Collection.

There is also GUI support for creating a collection set based on a SQL Server Profiler trace. After you define a trace in SQL Server Profiler with the events you want to capture, select Export from the File menu; then choose Script Trace Definition and select For SQL Trace Collection Set. Doing so generates a T-SQL script that you can use to create a custom Data Collector Set based on a SQL Server Profiler Trace definition.

Assuming you've already set up your MDW, you can begin by creating the data collection set and adding the collection items you want it to contain. To create the data collection set, use the `sp_syscollector_create_collection_set` procedure. Next, you need to create the `collection_items` to indicate what information you want the collection set to collect. If you are creating collection items for Performance Monitor counters, The Performance Counter collector type takes three input parameters:

- ▶ **Objects**—The SQL Server objects running in an instance of SQL Server
- ▶ **Counters**—The counters associated with a SQL Server object
- ▶ **Instances**—The instances of the specified object

Some input parameters support wildcard characters, which enable you to include multiple counters in a single statement. However, you can use wild cards only at the Counters and Instances levels and, even then, only at the beginning of the string (for example, '* Processor') or at the end of the string (for example, 'Memory *').

An example of the creation of custom collection set for capturing information for the Logical Disk and Process Performance Monitor counters is shown in Listing 39.1.

LISTING 39.1 Creating a Custom Collection Set

```

Use msdb
go

Declare @collection_set_id_1 int
Declare @collection_set_uid_2 uniqueidentifier
EXEC [dbo].[sp_syscollector_create_collection_set]
    @name=N'Disk I/O Perf and SQL CPU',
    @collection_mode=1, -- non-cached
    @description=
        N'Collects logical disk performance counters and SQL Process CPU',
    @target=N'',
    @logging_level=0,
    @days_until_expiration=7,
    @proxy_name=N'',
    @schedule_name=N'CollectorSchedule_Every_5min',
    @collection_set_id=@collection_set_id_1 OUTPUT,
    @collection_set_uid=@collection_set_uid_2 OUTPUT
Select collection_set_id_1=@collection_set_id_1,
        collection_set_uid_2=@collection_set_uid_2

/*****
** Now, create the desired collection items
*****/

Declare @collector_type_uid_3 uniqueidentifier
Select @collector_type_uid_3 = collector_type_uid
    From [dbo].[syscollector_collector_types]
    Where name = N'Performance Counters Collector Type';
Declare @collection_item_id_4 int
EXEC [dbo].[sp_syscollector_create_collection_item]
@name=N'Logical Disk Collection and SQL Server CPU',
@parameters=N'<ns:PerformanceCountersCollector xmlns:ns="DataCollectorType">
    <PerformanceCounters Objects="LogicalDisk"
        Counters="Avg. Disk Bytes/Read"
        Instances="*" />
    <PerformanceCounters Objects="LogicalDisk"
        Counters="Avg. Disk Bytes/Write"
        Instances="*" />
    <PerformanceCounters Objects="LogicalDisk"
        Counters="Avg. Disk sec/Read"
        Instances="*" />
    <PerformanceCounters Objects="LogicalDisk"

```

```

        Counters="Avg. Disk sec/Write"
        Instances="*" />
<PerformanceCounters Objects="LogicalDisk"
    Counters="Disk Read Bytes/sec"
    Instances="*" />
<PerformanceCounters Objects="LogicalDisk"
    Counters="Disk Write Bytes/sec"
    Instances="*" />
<PerformanceCounters Objects="Process"
    Counters="% Privileged Time"
    Instances="sqlservr" />
<PerformanceCounters Objects="Process"
    Counters="% Processor Time"
    Instances="sqlservr" />
</ns:PerformanceCountersCollector>',
@collection_item_id=@collection_item_id_4 OUTPUT,
@frequency=5,
@collection_set_id=@collection_set_id_1,
@collector_type_uid=@collector_type_uid_3
Select @collection_item_id_4
Go

```

After you create the collection set, you can start this data collection, either through SSMS (your user-defined collection sets will be listed directly within the Data Collection node) or with the following stored procedure call:

```

Declare @collection_set_id int
select @collection_set_id = collection_set_id
from syscollector_collection_sets
where name = 'Disk I/O Perf and SQL CPU'

EXEC sp_syscollector_start_collection_set
    @collection_set_id = @collection_set_id
go

```

Because there aren't any custom reports available for displaying the results of the custom collection set just defined, you need to run a query in the MDW database to view the collected Performance Monitor counter values. A sample query (which could serve as the basis for a customer report) is provided in Listing 39.2.

LISTING 39.2 Querying the MDW for Custom Data Collection Values

```

Use UnleashedMDW
Go
select spci.path as 'Counter Path', spci.object_name as 'Object Name',
spci.counter_name as 'counter Name', spci.instance_name,
spcv.formatted_value as 'Formatted Value',
spcv.collection_time as 'Collection Time',
sii.instance_name as 'SQL Server Instance'
from snapshots.performance_counter_values spcv
    inner join
    snapshots.performance_counter_instances spci
        on spcv.performance_counter_instance_id = spci.performance_counter_id
    inner join
    core.snapshots_internal si
        on si.snapshot_id = spcv.snapshot_id
    inner join
    core.source_info_internal sii
        on sii.source_id = si.source_id
where
    sii.collection_set_uid = '5D9849BE-1526-4159-99EB-6B0E690C31EA'
order by spcv.collection_time desc

```

It is possible to create your own custom reports using SQL Server Reporting Services that query the information for your custom collection sets in the MDW database. For more information on creating custom reports, see Chapter 53, “SQL Server 2008 Reporting Services.”

Data Collector Limitations and Recommendations

Although the Data Collector is a great start to a built-in performance monitoring tool, it does have some limitations still, which are not wholly unexpected in a product that’s still early in its release cycle. One key limitation is the limited number of built-in data providers and the reports available. It is hoped that future versions will make it easier to extend the Data Collector to add additional collection sets and reports.

If you are defining your own custom Data Collectors, consider these recommendations:

- ▶ Combine multiple performance counter or query collection items into a single collection item wherever possible.
- ▶ Combine collection items into a single collection set whenever possible unless you need separate data retention periods or different collection schedules for the collection items.
- ▶ If you collect data frequently, it is more efficient to run the collection set in cached collection mode than starting and stopping a new process every time new data must be collected. In cached collection mode, the collection process runs continuously. As a general rule, if you will be capturing data every five minutes or less, consider using a collection set that runs in cached collection mode.

- ▶ If you are collecting data less frequently than every five minutes, using noncached mode is more efficient than leaving a generally idle process running all the time.
- ▶ Although the collection frequency for cached collection sets can be set to run as frequently as every five seconds, be aware that more frequent collection has correspondingly high overhead. Always choose the lowest collection frequency that will meet your needs.

Currently, removing data collection after it has been configured is not supported. You can disable data collections but cannot remove them or the SSIS packages and jobs associated with them after they have been defined. Attempting to manually remove data collection may lead to errors if you try to re-implement data collection in the future. In addition, you should not drop or change the name of the MDW database because all the jobs are based on the original database name.

Another key limitation in the Data Collector is the lack of built-in alerting in the event that certain performance thresholds are crossed while monitoring the system. In contrast, the SQL Server Utility, which performs more limited monitoring and data capture than the Data Collector, does provide a threshold and alerting mechanism.

SQL Server Utility

SQL Server 2008 R2 introduces a new multiserver management tool named the SQL Server Utility. This new tool takes performance monitoring in SQL Server to the next level by providing the capability to monitor specific performance metrics for one or more SQL Server instances in a single view from a single SQL Server instance. The performance information is captured in a database, and you can view this information in one convenient place from within the SSMS environment.

Some basic setup is required to start using the SQL Utility. You accomplish this basic setup by using the new Utility Explorer available in SSMS. You click View on the SSMS menu bar and then select Utility Explorer. This Utility Explorer has a tree-like structure similar to the Object Explorer, and it integrates into the SSMS environment in much the same way.

NOTE

The option to view the Utility Explorer is not available if you are running a version of SQL Server prior to SQL Server 2008 R2.

The first page displayed when you launch the Utility Explorer is shown in Figure 39.14. This screen outlines all the utility configuration steps and is a handy launch point into wizards that guide you through the setup process. You can also click on the Video link next to each step to obtain further help on configuring that step.

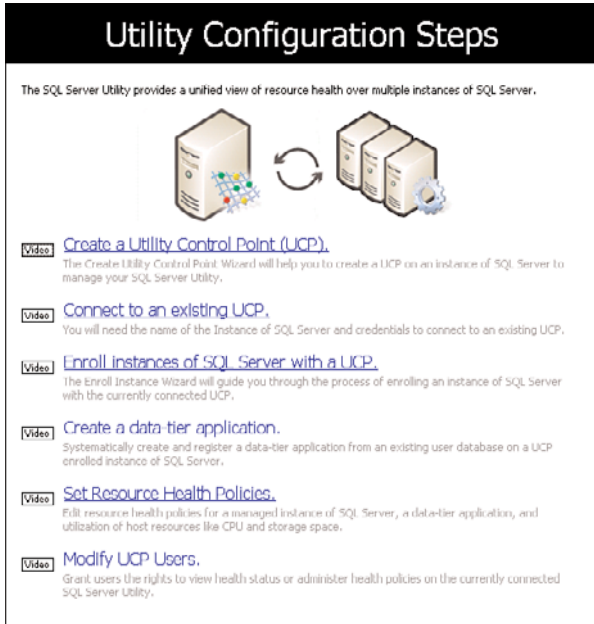

FIGURE 39.14 Utility Configuration Steps.

These steps and the details related to configuring the Utility Explorer are covered in more depth in Chapter 4. This chapter focuses on the performance monitoring capabilities of the SQL Server Utility and the specific metrics available for collection. To enable these capabilities, you only need to do the following:

1. Create a utility control point.
2. Connect to an existing UCP.
3. Enroll instances of SQL Server into the UCP.

The UCP is a central repository for storing configuration information and performance data for all the instances that have been enrolled in the SQL Server Utility. Each SQL Server Utility has only one UCP that you define by clicking on the first link listed in the Utility Configurations Steps. A wizard guides you through the creation.

NOTE

The SQL Server Utility collection set can work side by side with non-SQL Server Utility collection sets, such as those set up for data collection in the MDW. In other words, a managed instance of SQL Server can be monitored by other collection sets while it is a member of a SQL Server Utility. However, you must disable data collection while the instance of SQL Server is being enrolled into the SQL Server Utility.

In addition, after the instance is enrolled with the UCP, when you restart the non-SQL Server Utility collection sets, all collection sets on the managed instance upload their data to the utility management data warehouse (UMDW), `sysutility_mdw`.

After you create the UCP, a new tab named Utility Explorer Content is displayed within the Utility Explorer (see Figure 39.15). This Utility Explorer window is also called the SQL Server Utility *dashboard*. This dashboard is the main window for viewing performance metrics captured by the SQL Server Utility. The information displayed on this screen immediately after creating the UCP is the performance information for the UCP itself. Each UCP is automatically a managed instance and thus has performance data collected for it.

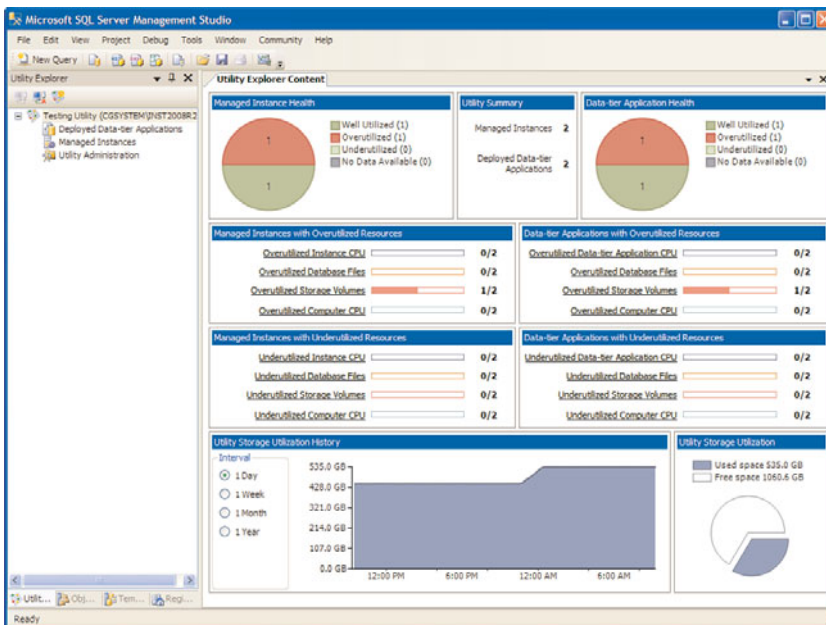

FIGURE 39.15 SQL Server Utility dashboard.

The following four performance utilization metrics are captured by the SQL Server Utility and displayed on the Utility Explorer Content screen:

- ▶ CPU utilized by the SQL Server instance
- ▶ Database file utilization
- ▶ Storage volume utilization

► CPU utilized by the computer running the instance

This performance data is broken down based on utilization thresholds and displayed in the dashboard window based on whether the specific metric is overutilized, underutilized, or well utilized. This breakdown is created for each managed instance as well as data-tier applications, a discussion of which is beyond the scope of this chapter.

The key to making this performance information valuable for you is defining the thresholds for each one of these metrics. Overutilization or underutilization, to some degree, is a matter of personal preference. A CPU that is at 70% utilization may be considered overutilized for some but not for others. The thresholds for these metrics can be defined using the Utility Administration node in the Utility Explorer. Figure 39.16 shows the policy screen where the global policies for the managed instances can be defined. These policies are essentially the thresholds for each of the four performance categories displayed in the SQL Server Utility dashboard.

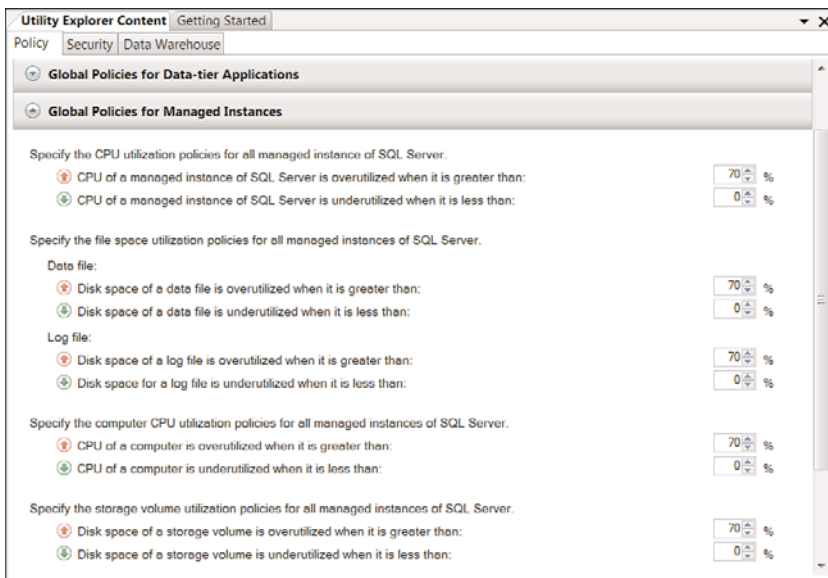

FIGURE 39.16 Global policies for managed instances.

The real power of the SQL Server Utility lies in its capability to collect the kind of performance data that we have been talking about for other SQL Server instances. This multi-server management capability is easy to implement and simply requires that you enroll the other SQL Server instances with a UCP. As mentioned earlier, you can do this by using the third link on the Utility Configuration Steps page. You can also right-click on the Managed Instances node in the Utility Explorer and select Enroll Instance. The Enroll Instance Wizard guides you through the enrollment steps. Upon completion of the wizard, the new instance appears in the Utility Explorer Content tab, as shown in Figure 39.17.

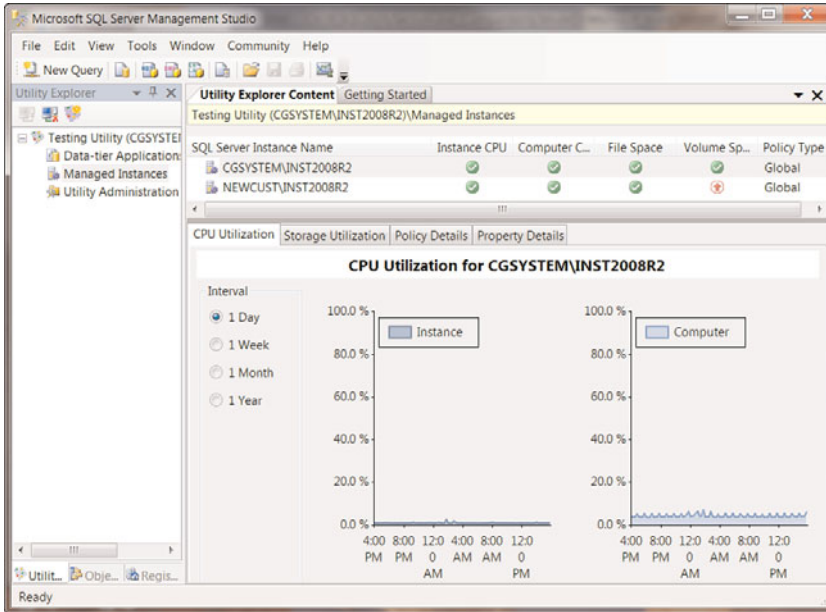

FIGURE 39.17 Managed instances.

The performance data collected by the SQL Server Utility is stored in the utility management data warehouse. The UMDW is a database named `sysutility_mdw` that is automatically created on the UCP instance when the UCP is created. It can be viewed in the list of databases in Object Explorer. By default, each managed instance enrolled in the UCP sends configuration and performance data to the UCP database every 15 minutes. The frequency of data collections provides for a comprehensive set of historical information. This data can be viewed in the Utility Explorer across different intervals, including daily, weekly, monthly, and yearly views. These views provide a sound foundation for identifying problems or identifying trends that can lead to problems in the enrolled SQL Server instances.

CAUTION

The frequency of collection of data in the UMDW database can also lead to a large database. Make sure that you monitor the size of the `sysutility_mdw` database over time. You can manage the data retention period through the SQL Server Utility Explorer. Click on Utility Administration and then select the Data Warehouse tab. You can drag the slider to change the retention period from the default value of one year to one, three, or six months if the UMDW database is becoming too large.

SQL Server Extended Events

SQL Server Extended Events (SSEE) are truly the future event-oriented framework that all SQL Server-based systems and applications will be using going forward. Extended Events are highly flexible to define, are able to capture almost any action or event within your

reach, are lightweight in their implementation, and are flexible enough to create simple or complex monitoring across multiple systems and environments. In other words, SSEE is a unified approach to handling events across SQL Server systems, while at the same time enabling users to isolate specific events for troubleshooting purposes.

The Extended Events framework can be utilized to help SQL Server implementations in many ways. Some approaches might include the following:

- ▶ Isolating excessive CPU utilization
- ▶ Looking for deadlocks/locking
- ▶ Locating long-running SQL queries

One of the key features of Extended Events is that events are not bound to a general set of output columns like SQL Trace events. Instead, each Extended Event publishes its data using its own unique schema. This makes the system as flexible as possible for what can be returned from Extended Events. The Extended Event system was engineered from the ground up with performance in mind, so events should have minimal impact on system performance.

SSEE currently is T-SQL based (there is no GUI tool available for SSEE yet). However, it has several predefined SQL Server catalog and dynamic management views and also is integrated with the Event Tracing for Windows (ETW) tools. Figure 39.18 shows the overall makeup of the new SSEE framework.

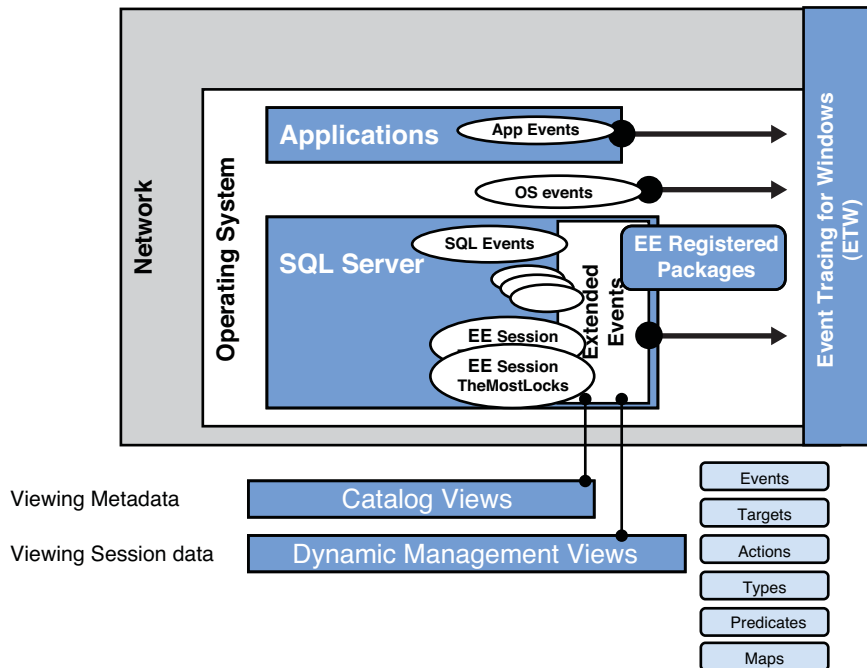

FIGURE 39.18 SQL Server Extended Event framework.

There is basically an Extended Event engine that runs within SQL Server and drives the event gathering for active sessions. This capability essentially provides a standard and powerful way to dynamically monitor active processes, while at the same time having minimal effect on those processes.

Looking a little closer at Figure 39.18, you can see the concept of Extended Events packages (a package), which contain one or more Extended Events objects. The Extended Events engine allows any event to be bound to any target. In other words, events can push their results to any location for consumption (like the ETW) or can be exposed via Views in SMSS, and so on.

Predicates are used to filter what events (that are firing) get pushed to the target (consumer). This capability greatly adds to the flexibility of the Extended Events infrastructure.

The next sections examine the main elements of Extended Events.

Packages

A *package* is a container for SQL Server Extended Events objects. It is the basic unit within which all other Extended Event objects ship. Four kinds of Extended Events packages are included in SQL Server 2008:

- ▶ **package0**—Extended Events system objects. This is the default package.
- ▶ **sqlserver**—SQL Server–related objects.
- ▶ **sqlos**—SQL Server Operating System (SQLOS)–related objects.
- ▶ **SecAudit**—Security Audit events.

You can see these four packages by running the following query:

```
select * from sys.dm_xe_packages
```

Packages can interact with one another to avoid having to provide the same code in multiple contexts. In other words, if one package exposes an action that can be bound to an event, any number of other events in other packages can also use it. For example, the **package0** package that ships with SQL Server 2008 contains objects designed to be used by all the other packages.

A package can contain any or all of the following objects:

- ▶ Events
- ▶ Targets
- ▶ Actions
- ▶ Types
- ▶ Predicates
- ▶ Maps

Events

Events are monitoring points of interest in the execution path of a program, such as SQL Server. An event firing indicates that the point of interest was reached and provides state information from the time the event was fired. Events can be used solely for tracing purposes or for triggering actions. These actions can either be synchronous or asynchronous. There can be one or more events in an event session package.

To see a list of the events provided with SQL Server, you can run the following query:

```
select * from sys.dm_xe_objects where object_type = 'event'
```

As stated previously, events have a schema that defines their contents. This schema is composed of event columns with well-defined types. You can view the event schema by querying `sys.dm_xe_object_columns`, as in the following example:

```
select name, column_id, type_name, column_type
from sys.dm_xe_object_columns
where object_name = 'page_split'
go
```

name	column_id	type_name	column_type
ID	0	uint16	readonly
UUID	1	guid_ptr	readonly
VERSION	2	uint8	readonly
CHANNEL	3	etw_channel	readonly
KEYWORD	4	keyword_map	readonly
file_id	0	uint16	data
page_id	1	uint32	data

Columns marked with `column_type` data are the values that will be filled in at runtime. The read-only columns provide metadata about the event. Notice that one of the columns in the output is the channel for the event; this indicates the category of the event. The available event channels in SQL Server 2008 are as follows:

- ▶ **Admin**—Admin events are primarily targeted to the end users, administrators, and support. They include events such as error reports and deprecation announcements.
- ▶ **Operational**—Operational events are used for analyzing and diagnosing a problem or occurrence. They can be used to trigger tools or tasks based on the problem or occurrence. An example of an operational event is one in which a database is attached or detached.
- ▶ **Analytic**—Analytic events are those that fire on a regular basis, often in high volume. They describe program operation such as lock acquisition and SQL Server statement execution. They are typically aggregated to support performance analysis.
- ▶ **Debug**—Debug events are used solely by DBAs and support engineers to help diagnose and solve engine-related problems.

Targets

Targets are event session consumers and indicate where output is located, such as a file, ring buffer, or a bucket with aggregation. Targets can process events synchronously or asynchronously. Extended Events provides several predefined targets you can use as appropriate for directing event output. An example of one of our favorites is provided later in this chapter.

You can find a list of available targets in SQL Server 2008 by running the following query:

```
select * from sys.dm_xe_objects where object_type = 'target'
```

Predicates

Predicates are a set of logical evaluation rules for events when they are processed that serve to filter events. They help reduce the volume of captured data and tailor down the output for analysis. In effect, they enable the Extended Events user to selectively capture event data based on specific criteria.

There are two different types of predicates in SQL Server 2008: `pred_compare` and `pred_source`. The `pred_compare` predicates are comparison functions, such as `>=`.

To view a list of the `pred_compare` predicates available in SQL Server 2008, you can run the following query:

```
select * from sys.dm_xe_objects where object_type = 'pred_compare'
```

If you run this query, you'll notice that there are a number of similar `pred_compare` predicates with the same comparison function but for different data types (for example, `greater_than_int64` and `greater_than_float64`).

The `pred_source` predicates are extended attributes that can be used within predicates to filter on attributes not carried by the event's own schema (such as `transaction_id` or `database_id`). The available `pred_source` predicates can be listed by using the following query:

```
select * from sys.dm_xe_objects where object_type = 'pred_source'
```

Actions

Actions are programmatic responses or series of responses to an event. Actions are bound to an event, and each event may have a unique set of actions. Actions are performed synchronously in association with bound events. They can be used to accomplish certain tasks or simply provide more information relevant to the events.

There are many types of actions, and they have a wide range of capabilities:

- ▶ Receive a stack dump and inspect data.
- ▶ Store state information in a variable.
- ▶ Bring event data from multiple places together.

- ▶ Append new data to existing event data.

To view a list of the actions available in SQL Server 2008, you can run the following query:

```
select * from sys.dm_xe_objects where object_type = 'action'
```

Types and Maps

Two kinds of data types can be defined in an event: scalar types and maps. *Scalar types* are single values, like integers. *Maps* are tables that map internal object values to static, predefined, user-friendly descriptions. They help you see what the internal values stand for (making them human consumable) but allow the event to more efficiently store the internal map value rather than the actual text.

Like all the other elements discussed thus far, types and maps can also be viewed by querying the `sys.dm_xe_objects` catalog view:

```
select * from sys.dm_xe_objects
where object_type in ('type', 'map')
```

Although types are relatively self-explanatory, maps require a lookup to expose the associated human-readable text when appropriate. The map values are stored in the DMV called `sys.dm_xe_map_values`. To list the `map_keys` and `map_values` for lock types, for example, you can run the following query:

```
select * from sys.dm_xe_map_values where name = 'lock_mode'
```

Extended Events Catalog Views and DMVs

To get metadata information about what events, actions, fields, and targets have been defined, you can use the catalog views supplied with SQL Server.

NOTE

Examples of the queries presented in this section are provided in the file named `Extended Events Views.sql` on the CD for this book.

For catalog views, the following short list shows the `SELECT` statements and their purposes (that use the predefined SSEE catalog views).

To see event sessions, you use the following:

```
SELECT * FROM sys.server_event_sessions;
```

To see actions on each event (of an event session), run this:

```
SELECT * FROM sys.server_event_session_actions;
```

To see events in an event session, run the following:

```
SELECT * FROM sys.server_event_session_events;
```

To see columns of events and targets, use this statement:

```
SELECT * FROM sys.server_event_session_fields;
```

And, to see event targets for an event session, you use the following:

```
SELECT * FROM sys.server_event_session_targets;
```

You use the dynamic management views to obtain session metadata and session data itself (as it is being gathered during execution). The metadata is obtained from the catalog views, and the session data is created when you start and run an event session.

To see session dispatcher pools, you use the following statement:

```
SELECT * FROM sys.dm_os_dispatcher_pools;
```

To see event package objects, use this:

```
SELECT * FROM sys.dm_xe_objects;
```

To see the schema for all objects, run this statement:

```
SELECT * FROM sys.dm_xe_object_columns;
```

To see the registered packages in the Extended Events engine, use this:

```
SELECT * FROM sys.dm_xe_packages;
```

To see the active Extended Events sessions, run the following:

```
SELECT * FROM sys.dm_xe_sessions;
```

To see session targets, run this statement:

```
SELECT * FROM sys.dm_xe_session_targets;
```

To see session events, use this:

```
SELECT * FROM sys.dm_xe_session_events;
```

To see event session actions, use this:

```
SELECT * FROM sys.dm_xe_session_event_actions;
```

To see the mapping of internal keys to readable text, use the following:

```
SELECT * FROM sys.dm_xe_map_values;
```

Specific variations might be as follows:

```
SELECT map_value Keyword from sys.dm_xe_map_values
where name = 'keyword_map';
```

```
SELECT map_key, map_value from sys.dm_xe_map_values
where name = 'lock_mode';
```

And finally, to see the configuration values for objects bound to a session, you use the following:

```
SELECT * FROM sys.dm_xe_session_object_columns;
```

Creating an Extended Events Session

Microsoft uses the same common paradigm (CREATE, ALTER, DROP) for most of its newer capabilities, such as `Create Audit..` (for SQL Auditing), `Create Endpoint..` (for database mirroring), and many others. SSEE follows the same path in that you basically create an Extended Events session, alter it to start the monitoring session, alter it again to stop the monitoring, and then leverage the catalog and dynamic management views before, during, and after the session monitoring to view the event information.

Creating events (event sessions) is fairly easy to do using the CREATE, ALTER and DROP EVENT statements. These Data Definition Language (DDL) statements completely control the creation and activation of Extended Events. All the SSEE objects are created in the `msdb` database. Only those users with `CONTROL SERVER` permissions can create, alter, or drop SSEE objects. To use the catalog and dynamic management views, you need at least `VIEW SERVER STATE` permission.

In this section, you quickly set up and define a new Extended Events session object that includes operating system IO requests and SQL Server lock-acquired counts. The purpose is to isolate the database objects (tables) that are being hit hardest with locks to better understand the behavior of the database design.

Included on the CD for this book is a SQL script file named `TheMostLocks.sql`. Locate this SQL script now; then start SSMS and open a new query connection with the `CREATE EVENT SESSION` script in it. Figure 39.19 shows a current connection to SQL Server with `TheMostLocks.sql` file open and the event session named `TheMostLocks` ready to be created.

As you examine the `CREATE EVENT SESSION` T-SQL code, notice that two events are being created with the `ADD EVENT` statements. One will gather `async IO` requests, and the other will retrieve SQL Server-acquired locks on an object's information. Also, notice the `TARGET` statement, which uses a predefined target location that allows you to retrieve the results within SQL Server during execution and that filters on showing only the lock's acquired information.

The `CREATE EVENT SESSION` T-SQL code is as follows:

```
IF EXISTS(SELECT * FROM sys.server_event_sessions WHERE name='TheMostLocks')
DROP EVENT session TheMostLocks ON SERVER;
```

```
CREATE EVENT SESSION TheMostLocks
ON SERVER
```

```

ADD EVENT sqllos.async_io_requested,
ADD EVENT sqlserver.lock_acquired
ADD TARGET package0.synchronous_bucketizer (
    SET filtering_event_name='sqlserver.lock_acquired',
source_type=0, source='resource_0')
WITH (MAX_MEMORY=4MB, MAX_EVENT_SIZE=4MB);

```

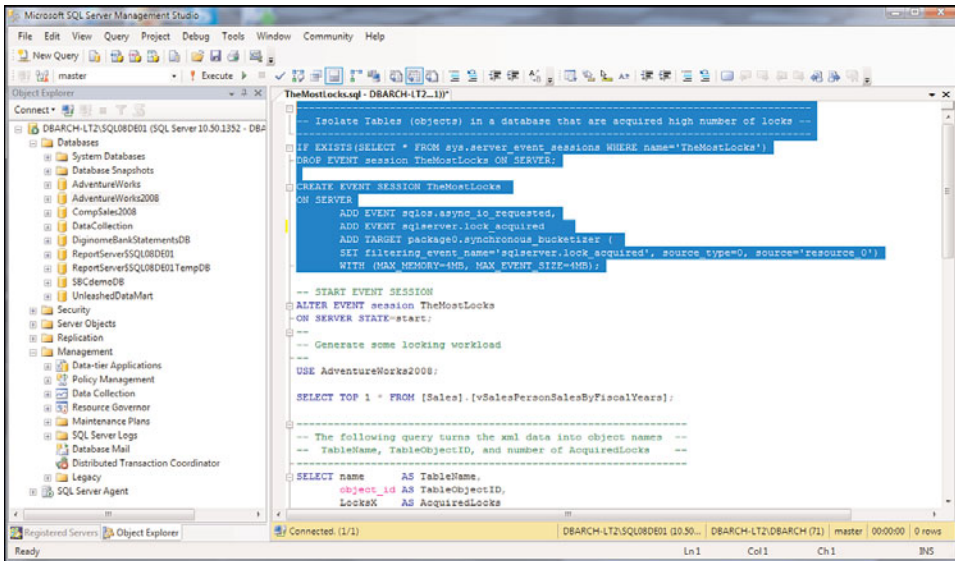

FIGURE 39.19 SSMS creating an event session named **TheMostLocks**.

Alternatively, you can direct the TARGET output to a file by using the following TARGET statement, for example:

```

ADD TARGET package0.etw_classic_sync_target
    (SET default_etw_session_logfile_path = N'C:\TEMP\EESessionFile.etl' )

```

You could then use the resulting file with the ETW to assemble this and other events from other portions of your environment.

After the event session is created, you are able to start it by using the ALTER EVENT SESSION command, generate some activity on your server that will be captured by the event session, view the dynamic results during the execution of the activity, and then stop the event session.

Go ahead and create the event session as it is listed now. Simply highlight the CREATE EVENT SESSION T-SQL statements shown previously and execute this code from SSMS. When it is complete, you are ready to start the event session by using the following command:

```

-- START EVENT SESSION
ALTER EVENT SESSION TheMostLocks ON SERVER STATE=start;

```

Using the AdventureWorks2008 database, you can generate some simple activity that is known to acquire share locks on tables. Use the following T-SQL that references the [Sales].[vSalesPersonSalesByFiscalYears] view:

```
--
-- Generate some lock acquiring workload
--
USE AdventureWorks2008;

SELECT TOP 1 * FROM [Sales].[vSalesPersonSalesByFiscalYears];
```

As soon as the preceding SELECT statement is generated, the Extended Event begins doing its job of collecting information. As you can see in Figure 39.20, this fairly complex join statement grabs the results of this Extended Event and displays them in a very nice readable fashion. This SELECT statement uses the dynamic management views previously identified in this chapter during the Extended Events active session.

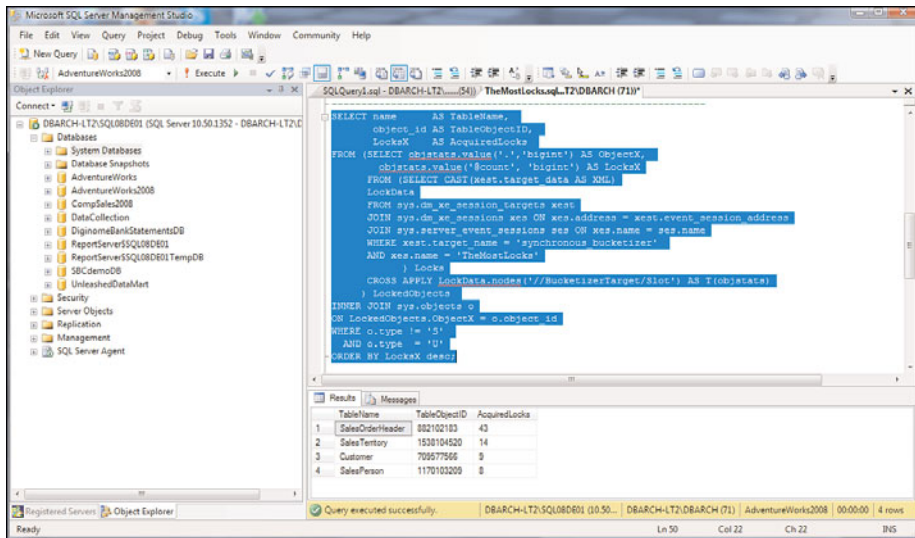

FIGURE 39.20 Displaying the results of acquired locks from the Extended Events session. As you can see, this session isolates the table objects that have the most acquired locks on them during execution. This capability is very powerful.

The T-SQL code is as follows:

```
.....
-- The following query turns the xml data that is accumulating --
-- from the Extended Event Session and displays it more clearly --
-- TableName, TableObjectID, and number of AcquiredLocks --
.....

SELECT name AS TableName,
```

```

        object_id AS TableObjectID,
        LocksX     AS AcquiredLocks
FROM (SELECT objstats.value('.', 'bigint') AS ObjectX,
        objstats.value('@count', 'bigint') AS LocksX
FROM (SELECT CAST(xest.target_data AS XML)
LockData
FROM sys.dm_xe_session_targets xest
JOIN sys.dm_xe_sessions xes ON xes.address = xest.event_session_address
JOIN sys.server_event_sessions ses ON xes.name = ses.name
WHERE xest.target_name = 'synchronous_bucketizer'
AND xes.name = 'TheMostLocks'
) Locks
CROSS APPLY LockData.nodes('//BucketizerTarget/Slot') AS T(objstats)
) LockedObjects
INNER JOIN sys.objects o
ON LockedObjects.ObjectX = o.object_id
WHERE o.type != 'S'
AND o.type = 'U'
ORDER BY LocksX desc;

```

To turn off the Extended Events session, you simply issue another `ALTER EVENT SESSION` command with the `STATE` equal to `stop`, as shown here:

```

-- STOP EVENT SESSION
ALTER EVENT SESSION TheMostLocks
ON SERVER STATE=stop ;

```

Various Extended Events can be defined for monitoring purposes within the SQL Server environment, your application environment, and at the operating system level. You will likely build up a complete library of Extended Events that represent what you are most interested in monitoring about your environment. They will then become valuable tools for years to come. We also expect forums and Microsoft to create many templates of Extended Events to aid you in creating this extensive library of monitoring capability.

Windows Performance Monitor

Windows Performance Monitor is a graphical tool that provides a visual display of built-in Windows performance counters, either in real-time or as a way to review historical data. It is supplied as part of the installation of any Windows server or workstation (in Windows Server 2008 it is called *Reliability and Performance Monitor*). Hundreds of performance counters are available. These counters can be monitored on the local machine or remotely over the network, and they can be set up to monitor any object and counter on multiple systems at once from one session. A small subset of performance information is also available via the Windows Task Manager Performance tab. However, all this information and more is available using the Performance Monitor facility.

NOTE

This chapter covers the version of Performance Monitor available in Windows Server 2008, Windows Server 2008 R2, Windows Vista, and Windows 7. If you are running on Windows XP, Windows Server 2003, or earlier versions of Windows, the interface and functionality of Performance Monitor are a bit more limited than the version presented here. However, many of the concepts of using Performance Monitor and performance counters are still similar.

Performance Monitor features multiple graph views that enable you to visually review performance log data. You can add performance counters to Performance Monitor individually or by creating custom Data Collector Sets. The recent version of Windows Performance Monitor combines the functionality of previous standalone tools including Performance Logs and Alerts (PLA), Server Performance Advisor (SPA), and System Monitor.

You can use Windows Performance Monitor to examine how programs you run affect your computer's performance, both in real-time and by collecting log data for later analysis. When you install SQL Server, additional performance counters are installed that you can use to monitor SQL Server performance elements such as cache utilization, locking, wait states, and I/O performance. Performance Monitor can be launched from many different points. From SQL Profiler, choose the Tools menu option and choose the Performance Monitor item. Figure 39.21 shows this menu option from SQL Profiler. You can also launch it from the Administrative Tools folder in the Windows Start menu.

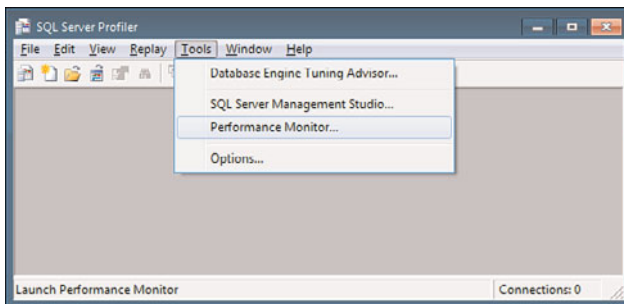

FIGURE 39.21 Launching Performance Monitor from SQL Profiler.

Performance Monitor Views

When you first launch Performance Monitor, you are presented with the welcome screen (in Windows 2008, the welcome screen is the Resource Overview). Click on Performance Monitor in the Monitoring Tools folder to bring up the Performance Monitor main display. In the Performance Monitor main display, you can view the performance information in one of three different modes:

- ▶ **Graphic chart**—This view, the default, shows the selected counters as colored lines over a timeline with the y-axis representing the value and the x-axis representing

time. You can also add gridlines (horizontal and vertical). This view lets you view performance trends over time.

- ▶ **Histogram chart**—This view shows the selected counters as colored horizontal bars (as in a histogram). These histogram bars change dynamically to reflect the data sampling values. With this view, you see a current snapshot of the performance counters rather than the trend of activity over time.
- ▶ **Report display**—In this mode, you see the current values for counters collected under their parent object in a textual display format. Like the histogram view, this view does not show you the activity trends, just the current sampling value, but it is great for showing what counters you are collecting data with.

Figure 39.22 shows the basic graphic chart view interface for Performance Monitor displaying several useful system counters that are explained later in this chapter. These counters are added to Performance Monitor through the creation of Performance Monitor Data Collector Sets.

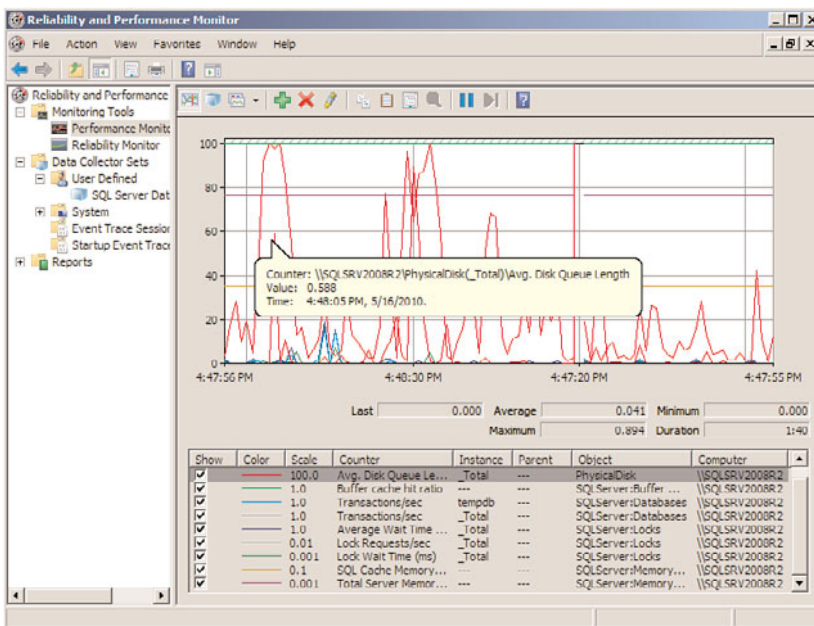

FIGURE 39.22 Performance Monitor chart view, with various counters.

When you open the Performance Monitor view, depending on the OS version you are running, you see up to three default performance counters: Memory: Pages/sec, PhysicalDisk:Avg.Disk Queue Length, and Processor:% Processor Time. These counters provide a good start, but you really want to see many other counters that reflect the complete picture of how your server is behaving. This chapter explains the recommended ones to use for SQL Server in the “SQL Server Performance Counters” section.

You add a counter by clicking the large plus sign toolbar button near the top. The Add Counters dialog that appears (see Figure 39.23) allows you to select the computer to monitor (this can be a remote server), a performance object, any specific counters, and an instance of the counter, if applicable. You can select the Show Description check box to get a simple explanation of the currently selected counter. When you are done making your selections of counters to add, click OK to return to the Performance Monitor screen.

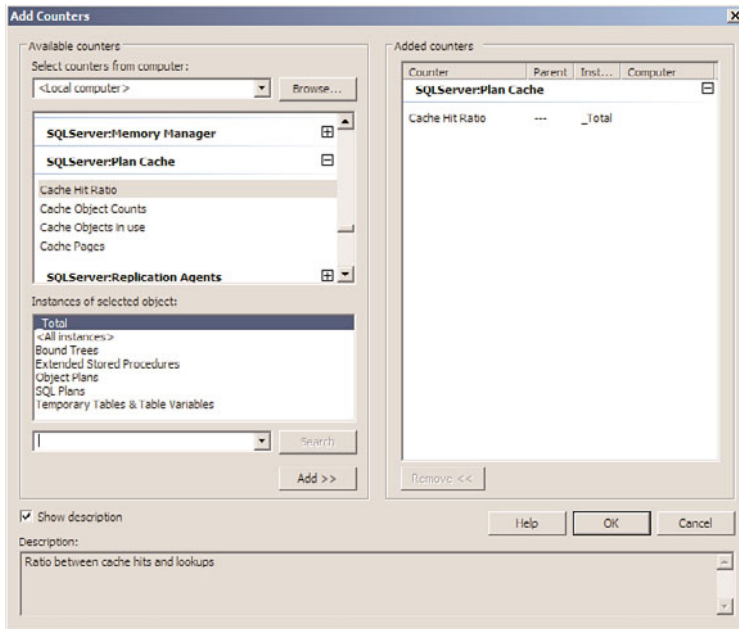

FIGURE 39.23 Adding a counter in Performance Monitor.

You can customize the look of the lines in the chart view by right-clicking and selecting Properties. On the Data tab of the System Monitor Properties dialog, you can specify the color, width, and style of line for each of your counters. You can also change the scale of a counter's value as well so that the line appears within the graph's scale of 1 to 100.

TIP

To quickly rescale all the counters, select all the counters in the bottom panel of the Chart view window, right-click, and select Scale Selected Counters. Performance Monitor automatically selects a scale for each counter such that all lines appear within the display.

To remove a counter, you simply highlight the line in the bottom area of the Chart view window and press the Delete key or click on the X button in the toolbar. If you just want

to temporarily hide a counter to make the display a little less busy, you can right-click a counter in the bottom area of the Chart view and select Hide Selected Counters.

The Chart view also provides a way to make a specific counter or set of counters stand out in the display by making the line or lines black and bold. This capability can help you focus on the trend of a specific counter. To turn on highlighting, select one or more counters in the bottom area of the Chart view and click on the Highlight button on the toolbar (the one that looks like highlighter pen just to the right of the big red X).

Adding counters like this in an ad hoc manner is fine for a quick monitoring session. However, after you close the Performance Monitor tool, you lose the counters you have selected, so they are not available the next time you open Performance Monitor. Typically, you need to set up those counters you want to reuse or to have running continuously or on a schedule that captures the performance counters to a log file. To do this, you create one or more Data Collector Sets.

Creating Data Collector Sets in Performance Monitor

A *Data Collector Set* is the building block of performance monitoring and reporting in Windows Performance Monitor. It organizes multiple data collection points into a single component that can be used for review or to log performance counters. A Data Collector Set can be created and then recorded individually, grouped with other Data Collector Sets and incorporated into logs, viewed in Performance Monitor, or configured to generate alerts when thresholds are reached. You can set up schedules on your Data Collector Sets to have them run the data collection at specific times.

Data collector sets can contain the following types of Data Collectors:

- ▶ Performance counters
- ▶ Event trace data
- ▶ System configuration information (Registry key values)

Performance counters are measurements of system state or activity. They can be included in the operating system or can be part of individual applications. When you install SQL Server, a number of SQL Server–specific performance counters are installed (a number of the more useful ones are described later in this chapter). Windows Performance Monitor requests the current value of performance counters at specified time intervals.

Event trace data is collected from trace providers, which are components of the operating system or of individual applications that report actions or events. Output from multiple trace providers can be combined into a trace session.

Configuration information is collected from key values in the Windows Registry. Windows Performance Monitor can record the value of a Registry key at a specified time or interval as part of a log file.

The easiest way to create a Data Collector Set is to create a custom view of counters in Performance Monitor (similar to what was shown in the previous section). When you are satisfied with the counters and settings you have configured, right-click on the Performance Monitor node in the Monitoring Tools folder, select New, and then select

Data Collector Set. This starts the Create Data Collector Set Wizard, which walks you through the following steps:

1. The wizard prompts for a name for the Data Collector Set. Enter a name and click Next.
2. Specify the root directory where the Performance Monitor log files will be written and click Next.
3. Specify if you want the Data Collector to run under a different user ID and if you want to start the Data Collector immediately or to just save the Data Collector Set. Click Finish to return to Performance Monitor.

The newly created Data Collector Set is listed under the User Defined folder in the Data Collector Sets node in Performance Monitor.

You can also create a Data Collector Set manually or from a template by right-clicking on the User Defined folder in the Data Collector Sets node and selecting New, Data Collector Set. This launches a modified version of the Create New Data Collector Set Wizard, as shown in Figure 39.24.

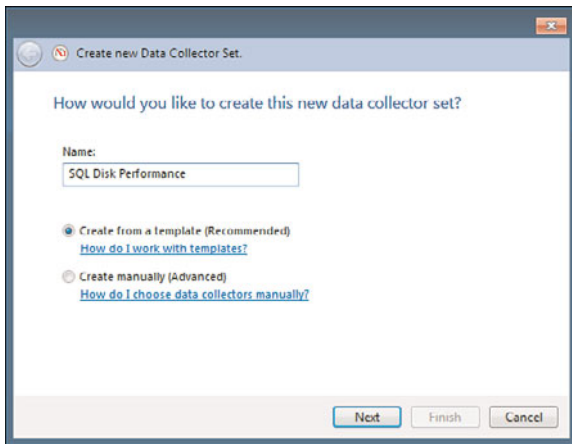

FIGURE 39.24 The Create New Data Collector Set Wizard.

You first specify a name for the collector set and then choose whether to create it from a template or manually. Then you click Next.

If you choose to create from a template, the next screen displays the built-in templates provided with Windows; these standard templates focus on general system performance or diagnostics. You can also choose to import your own templates by clicking on the Browse button.

NOTE

Creating your own Data Collector Set templates in Performance Monitor is relatively easy. If you have a Data Collector Set that you've set up with the performance counters and settings that you would like to reuse, simply right-click the Data Collector Set you want to export and click Save Template. Select a directory in which to store the collector set as an XML file and click Save. You can now copy this template for use on other computers.

After selecting the template, navigate to the next screen to specify the root directory for the log files. On the final screen, you have the option again to start the collector immediately, save it, or open the properties for the Data Collector Set so you can make further modifications to it, such as specifying a schedule or how it should handle.

If you choose to create a new Data Collector Set manually instead of using a template, you are presented with the screen shown in Figure 39.25. You have the option to create a Data Collector Set that generates data logs or to create a Performance Counter Alert. If you are creating data logs, you can specify what sort of information you want to include in the collector set (in this example, we're logging performance counters only).

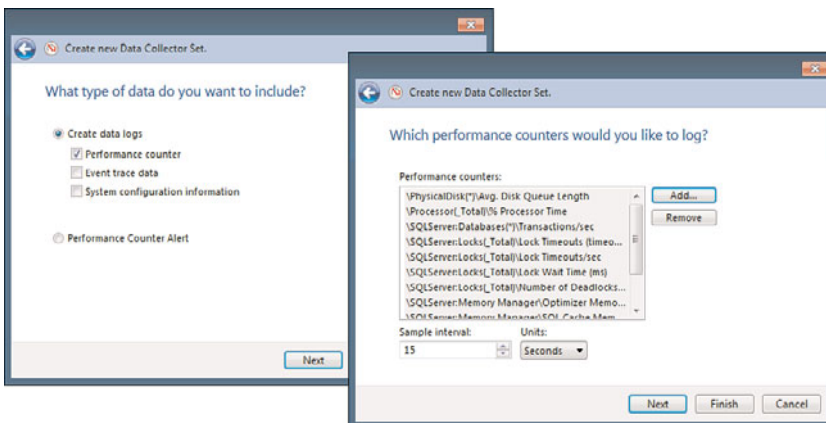

FIGURE 39.25 Creating a new Data Collector Set manually to capture performance counters.

Depending on the Data Collector types you select, you are presented with dialogs to add Data Collectors to your Data Collector Set. In this example, you are presented with the dialog to add performance counters, as shown in Figure 39.25.

After defining the counters, and so on, you are presented with the familiar options to specify the root directory and whether to save, run, or edit the properties of the Data Collector Set.

After you create a Data Collector Set, you can add additional Data Collectors to it as desired. They can be additional performance counter event traces, configuration Data Collectors, or performance counter alerts.

Running a Data Collector Set in Performance Monitor

The easiest way to run a Data Collector Set is to right-click on it and choose Start. When you are done capturing, right-click again and choose Stop. However, this is probably not the most effective way to execute your Data Collector Sets. A more effective approach is to set up a schedule for data collection.

During Data Collector Set creation, you can configure the schedule by selecting Open Properties for this Data Collector Set at the end of the Create New Data Collector Set Wizard. After a Data Collector Set is created, you can access the schedule options by right-clicking the Data Collector Set name in the Microsoft Management Console (MMC) navigation pane and selecting Properties. When the Properties dialog is displayed, click the Schedule tab to specify the schedule when you want the Data Collector to run. You can specify the start date, time, or day for data collection. If you do not want to collect new data after a certain date, select Expiration Date and choose a date from the calendar. You can create multiple schedules for a single Data Collector Set.

The Data Collector runs continuously unless you specify a Stop condition for a Data Collector Set. The Stop condition can be set in the Stop Condition tab. To stop collecting data after a period of time, select Overall Duration and choose the quantity and units. On the Stop Condition tab, you can also specify limits to segment data collection into separate logs. Select the Restart the Data Collector Set at Limits option to continue running the Data Collector after the limit is reached. You can select Duration to configure a time period for data collection to write to a single log file, or select Maximum Size to restart the Data Collector Set or to stop collecting data when the log file reaches a specific size. If you select both limits, data collection stops or restarts when the first limit is reached.

TIP

If you are running a Data Collector continuously, you should set a limit so that the Data Collector breaks the log file into multiple segments. In addition to preventing the file from becoming exceedingly large, breaking up the log file also enables you to view the log file segments prior to the current one while the Data Collector Set is running. Unfortunately, you cannot directly open the currently active log file for a Data Collector Set to view the live data collection. However, if you have a previous report available, you can open the report in the Performance Monitor window. When this report is open, click the View Current Activity button (or press Ctrl+T) and you can view the current activity in real-time as it's being captured.

Viewing Data Collector Set Results in Performance Monitor

To view a Data Collector Set report in Windows Performance Monitor, expand Reports and click User Defined or System. Then expand the Data Collector Set that you want to view as a report. Simply click the report that you want to view from the list of available reports. The report opens in the console pane.

If you want to open one or more log files in Performance Monitor (perhaps you have a set of log files copied from another server), in the Windows Performance Monitor navigation pane, expand Monitoring Tools and click Performance Monitor. In the console pane toolbar, click the Add Log Data button (or press Ctrl+L). The Performance Monitor Properties page opens with the Source tab active (see Figure 39.26). In the Data Source section, follow these steps:

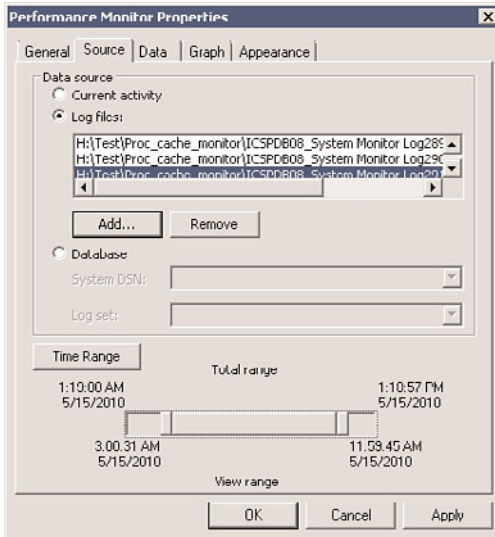

FIGURE 39.26 Importing log files into Performance Monitor.

1. Select Log Files and click Add.
2. Browse to the log file you want to view and click Open.
3. To add multiple log files to the Performance Monitor view, click Add again.
4. Click Time Range to see times included in the log or logs you selected.
5. When you are finished selecting log files, click OK.
6. Right-click in the Performance Monitor display and click Add Counters to select the counters you want to display in Performance Monitor. Only the counters included in the log file or files you selected in step 4 are made available.

For a single log file, you can move the beginning and ending time sliders to view only a portion of the log file in Performance Monitor.

For multiple log files, you can move the beginning and ending time sliders to choose the time period (from all the selected log files) to view in Performance Monitor. If a log has data from the time period you select, it is available in the display.

Why Use Performance Monitor?

You might be asking, “With all the new performance monitoring tools provided with SQL Server, is there a need to continue to use Performance Monitor?”

Even though many of the performance counters and relevant information are now available in the SQL Server Data Collector, as mentioned previously, the Data Collector does incur some overhead on SQL Server. Performance Monitor, on the other hand, incurs significantly less impact on SQL Server performance.

In addition, the SQL Server Data Collector currently doesn't have a built-in alerting capability. As mentioned previously, you can set up performance counter alerts in Performance Monitor. In addition, Performance Monitor enables you to monitor more than what is provided with SQL Server Data Collector, including all aspects of the operating system as well as other applications.

One other feature that's very useful with Performance Monitor logs is the capability to import performance counter logs into SQL Server Profiler.

NOTE

For more information on importing and viewing performance counter logs in SQL Server Profiler, see Chapter 6.

SQL Server Performance Counters

For each SQL Server instance installed, Performance Monitor has a number of SQL Server–specific performance objects added to it, each with a number of associated counters. Each SQL Server instance has its own set of monitoring objects because you certainly wouldn't want to mix monitoring values across multiple instances. Performance counters for named instances use the naming convention `MSSQL$` followed by the instance name (for example, `MSSQL$SQL2008DEV:General Statistics`). Performance counters for the default instance of SQL Server use the naming convention of `SQLSERVER` followed by the counter name (for example, `SQLServer:General Statistics`).

Table 39.1 provides a list of the SQL Server performance counters available for SQL Server 2008

TABLE 39.1 SQL Server Performance Objects

Performance Object	Description
<code>SQLServer:Access Methods</code>	Information on searches and allocations of SQL Server database objects (for example, the number of index searches or number of pages allocated to indexes and data).
<code>SQLServer:Backup Device</code>	Information about backup devices, such as the throughput of the backup device.
<code>SQLServer:Buffer Manager</code>	Information about the memory buffers used by SQL Server.
<code>SQLServer:Buffer Partition</code>	Information about buffer free page accesses.

TABLE 39.1 SQL Server Performance Objects

Performance Object	Description
SQLServer:CLR	Information about common language runtime (CLR)
SQLServer:Cursor Manager by Type	Information about cursors.
SQLServer:Cursor Manager Total	
SQLServer:Database Mirroring	Information about database mirroring.
SQLServer:Databases	Database-specific information such as the amount of free log space available or the number of active transactions in the database.
SQL Server:Deprecated Features	Information on the number of times deprecated features are used.
SQLServer:Exec Statistics	Execution statistics information.
SQLServer:General Statistics	General server-wide activity, such as the number of logins per second.
SQLServer:Latches	Information about the latches on internal resources, such as database pages.
SQLServer:Locks	Information about the individual lock requests made by SQL Server, such as lock timeouts and deadlocks.
SQLServer:Memory Manager	Information about SQL Server memory usage, such as the total number of lock structures currently allocated.
SQLServer:Plan Cache	Information about the SQL Server cache used to store objects such as stored procedures, triggers, and query plans.
SQLServer: Resource Pool Stats	Information about Resource Governor resource pool statistics.
SQLServer:SQL Errors	Information about SQL Server errors.
SQLServer:SQL Statistics	Query statistics, such as the number of batches of T-SQL statements received by SQL Server.
SQLServer:Transactions	Transaction statistics, such as the overall number of transactions and the number of snapshot transactions.
SQLServer>User Settable	Custom counters that can be a custom stored procedure or any T-SQL statement that returns a value to be monitored.

TABLE 39.1 SQL Server Performance Objects

Performance Object	Description
SQLServer: Wait Statistics	Information about waits.
SQLAgent:Alerts	Information about SQL Server Agent alerts.
SQLAgent:Jobs	Information about SQL Server Agent jobs.
SQLAgent:JobSteps	Information about SQL Server Agent job steps.
SQLAgent:Statistics	General information about SQL Server Agent.
SQLServer:Replication Agents	Information about replication agent activity.
SQLServer:Replication Snapshot	
SQLServer:Replication Logreader	
SQLServer:Replication Dist.	
SQLServer:Replication Merge	

User-Defined Counters

You can extend the range of information that Performance Monitor displays by creating up to 10 of your own counters. These user-defined counters appear under the `SQLServer\User Settable:Query` object, which contains the 10 counters as instances, starting with User Counter 1. You define your own counters by calling stored procedures with the names `sp_user_counter1` through `sp_user_counter10`, which are located in the master database.

These counters work differently than they did under previous versions of SQL Server and require you to call the stored procedures to update the information they return to Performance Monitor. To make any real use of these stored procedures, you now need to call them within a loop or as part of a job that is scheduled on some recurring basis.

Using these counters allows you to monitor any information you want, whether it is system, database, or even object specific. The only restriction is that the stored procedure can take only a single integer value argument.

The following sample user-defined counter procedure sets the counter value to the average connection time for all user connections. Processes that have a `session_id` less than 50 are internal system processes (checkpoint, Lazy Writer, and so on):

```
DECLARE @value INT

SELECT @value = AVG( DATEDIFF( mi, login_time, GETDATE()))
FROM sys.dm_exec_sessions
WHERE session_id > 50

EXEC sp_user_counter1 @value
```

You could further extend this information by creating additional user procedures for returning the minimum and maximum times connected, as well as database usage. Your only limitation is that you can monitor only a maximum of 10 pieces of information at one time.

Accessing Performance Counters via T-SQL

Most of the SQL Server–oriented performance counter values can also be seen at any point in time via the system catalog view named `sys.sysperfinfo`:

```
SELECT * from sys.sysperfinfo
```

This view shows the performance object name, counter name, and current counter value as of the time the system view is executed.

You should keep in mind that many of the performance counters are accumulation counters, and you have to run them at intervals and determine the difference (change) from one interval to the next. Others are current values of aspects such as transaction rates, memory usage, and hit ratios.

A Performance Monitoring Approach

If you take a closer look at the performance monitoring areas depicted in Figure 39.1, you can see that SQL Server spans them all. SQL Server must process requests submitted to it via the network, service those requests with one or more processors, and rely on accessing a request's data from both memory/cache and the disk system. If you maximize utilization on these resources from the point of view of SQL Server and the operating system, you end up with a well-tuned database server. However, an optimally tuned system doesn't guarantee good performance. It's still important to have a good database design and to implement optimal index strategies. The whole picture is important to tuning your SQL Server implementation, but the database, table designs, indexing strategy, and SQL statement tuning are described in much more detail in other chapters. This section focuses on the SQL Server instance as it sits on the OS and the hardware, along with the major monitoring capabilities available to you.

One area of interest is the amount of network traffic handled by SQL Server and the size of these network requests. Another area of interest is the capability of the available processors to service the load presented to them by SQL Server without exceeding the CPU capacity of the system. This section also looks at SQL Server memory utilization of the available system memory and how effectively SQL Server is utilizing the disk system.

In general, you want to start from the bottom, with the network, and work your way up into the SQL Server–specific elements. This allows you to quickly isolate certain issues that are paramount in performance tuning. In each of these areas, this section provides a list of minimum detail performance handles or counters that can be examined. This approach can be summarized into the following steps:

1. Understand and monitor network request characteristics as they relate to SQL Server and the machine on which SQL Server has been installed. This means a

complete profile of what is coming into and being sent back out over the network from SQL Server.

2. Understand processor utilization. Processing power might be the biggest issue affecting performance. You need to get a handle on this aspect of performance early.
3. Understand and monitor memory and cache utilization. This is the next step, monitoring the overall memory usage from the operating system level point of view and monitoring the memory that SQL Server is using for data buffers, plan cache, and so on.
4. Understand and monitor disk system utilization. You are often rewarded for implementing a simple (and less expensive) disk configuration or data storage approach. However, a simple configuration may not provide the best performance for your system. And you often don't know you have a problem unless you look for it. Techniques that are often used to alleviate disk performance issues include disk striping, isolation of logs from data, and so on.

You need to repeat steps 1 through 4 on a regular basis. Your continued success (and, it is hoped, salary increases) will reflect your diligence here. For each step, certain tools and facilities are available for you to use that gather the information needed to identify and monitor performance issues. Let's look now at how to use these tools to monitor and analyze the network, processor, memory, and disk utilization and performance.

Monitoring the Network Interface

One area of possible congestion is the network card or network interface; it does not matter how fast the server's work is if it has to queue up to go out through a small pipe. Remember that any activity on the server machine might be consuming some of the bandwidth of the network interface card. With the increasing implementations of gigabit networks and the increases in network bandwidth over wide area networks (WANs), network throughput is not as much of a bottleneck as it used to be. That's not to say network performance issues do not arise. For example, a bad or misconfigured router can cause all sorts of network performance issues, especially if your users and your SQL Server are on different sides of the router. If you are not detecting query performance issues in SQL Server but users are still complaining about slow query performance, the network is a likely culprit.

You can monitor network activity via Performance Monitor. Table 39.2 shows the typical network performance object and counters you can use to monitor network interface activity.

TABLE 39.2 Network Interface Performance Objects and Counters

Performance Monitor Object	Description
Network Interface: Bytes Received	The rate at which bytes are received on the interface.
Network Interface: Bytes Sent	The rate at which bytes are sent on the interface.

TABLE 39.2 Network Interface Performance Objects and Counters

Performance Monitor Object	Description
Network Interface: Bytes Total	The rate at which all bytes are sent and received on the interface.
Network Interface: Current Bandwidth	The bits per second (bps) of the interface card.
Network Interface: Output Queue Length	The length of the output packet queue (in packets). If this is longer than two, delays are occurring, and a bottleneck exists.
Network Interface: Packets Received	The rate at which packets are received on the network interface.
Network Interface: Packets Sent	The rate at which packets are sent on the network interface.
Network Interface: Packets	The rate at which packets are sent and received on the network interface.
Server: Bytes Received	The number of bytes the server has received from the network. This is the big-picture indicator of how busy the server is.
Server: Bytes Transmitted	The number of bytes the server has sent/transmitted to the network. Again, this is a good overall picture of how busy the server is.

In general, if the SQL Server packet sends or receives are grossly lower than the overall server's packet sends and receives, other activity on the server is occurring that is potentially bogging down this server or not allowing SQL Server to be used optimally. The rule of thumb here is to isolate all other functionality to other servers if you can and let SQL Server be the main application on a machine.

The `sp_monitor` system stored procedure, as well as several SQL Server system variables, can be used to see how many requests are queuing up, waiting to make use of the network interface. The following `SELECT` statement retrieves a current picture of what is being handled by SQL Server from a network packet's point of view:

```
SELECT @@connections as Connections,
       @@pack_received as Packets_Received,
       @@pack_sent as Packets_Sent,
       getdate() as 'As of datetime'

go
Connections Packets_Received Packets_Sent As of datetime
-----
39407      395569      487258      2010-05-16 22:34:19.650
```

The `sp_monitor` system stored procedure provides packets sent and received as a running total and since the last time it was run (difference in seconds). Here's an example of what would result (the network- and packets-related results):

```
EXEC sp_monitor
GO
last_run                current_run                seconds
-----
2010-04-02 17:34:58.817 2010-05-16 22:35:08.940 3819610

cpu_busy    io_busy    idle
-----
318(318) -0% 62(62) -0% 182952(182928) -4%

packets_received packets_sent    packet_errors
-----
395781(395753) 487483(487455) 1(1)

total_read    total_write    total_errors connections
-----
8084(8084)    69921(69921) 0(0)          39432(39418)
```

The values within the parentheses are the amounts since the last time `sp_monitor` was run, and the seconds column shows how long that period was. You can actually see the rate at which traffic is coming into and out of SQL Server.

Monitoring the Processors

The main processors of a server do the majority of the hard work, executing the operating system code and all applications. This is the next logical place to start looking at the performance of a system. With SQL Server 2008, you can identify the number of CPUs you want to utilize on your physical machine. If your physical machine has 32 CPUs, you might not necessarily want to make all 32 CPUs available to SQL Server. In fact, in some cases, this would be a detriment; some CPU processing should be reserved for the OS and the network management on heavily loaded servers (5% of the CPUs). SQL Server allows you to identify how many CPUs it can use from what is available on the physical machine. In Figure 39.27, you can see the number of CPUs available to SQL Server on a typical server from the SSMS Server Properties page. In this example, all CPUs are being made available to SQL Server.

In a 32-CPU server example and using the 5% number just mentioned, you should let SQL Server use 30 of the CPUs and reserve 2 CPUs for dedicated network- and OS-related activity ($0.05 \times 32 = 1.6$, rounded up to 2 CPUs). This also allows SQL Server to utilize SQL parallelism effectively.

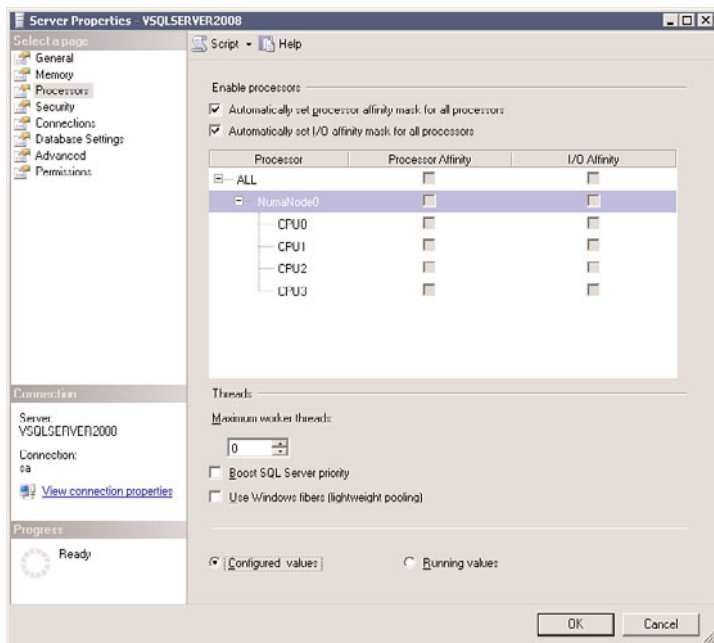

FIGURE 39.27 Processor (CPU) properties of a SQL Server instance.

Keep in mind that from a multitasking point of view, Windows servers often move process threads among different processors. This process thread movement activity can reduce Microsoft SQL Server performance under heavy system loads because each processor cache is repeatedly reloaded with data. It is possible to assign processors to specific threads, which can improve performance under these types of conditions by eliminating processor reloads. This association between a thread and processor is called *processor affinity*. SQL Server 2008 supports processor affinity by means of two affinity mask options: affinity mask (also known as CPU affinity mask) and affinity I/O mask. If you do nothing, SQL Server is allowed to use each CPU for all its processing, with no affinity whatsoever. The operating system distributes threads from instances of SQL Server evenly among these CPUs.

The affinity I/O mask option binds SQL Server disk I/O to a specified subset of CPUs. In high-end SQL Server online transaction processing (OLTP) environments, this extension can enhance the performance of SQL Server threads issuing a high number of I/Os. This enhancement does not support hardware affinity for individual disks or disk controllers, though. Perhaps this will be a future enhancement to SQL Server.

NOTE

A side effect of specifying the affinity mask option is that the operating system does *not* move threads from one CPU to another. Most systems obtain optimal performance by letting the operating system schedule the threads among the available CPUs, but there are exceptions to this approach. The only time we have used this affinity setting was to isolate CPUs to specific SQL Server instances on the same box that had numerous CPUs to utilize. Typically, you should leave the settings to have SQL Server automatically set processor and I/O affinity as needed unless your processor monitoring indicates manually configuring the affinity may be necessary.

Monitoring Processors in Performance Monitor

From a Performance Monitor point of view, the emphasis is on seeing if the processors that are allocated to the server are busy enough to maximize performance but not so saturated as to create a bottleneck. The rule of thumb here is to see whether your processors are working at between 20% and 50%. If this usage is consistently above 80% to 95%, you should consider splitting off some of the workload or adding processors. Table 39.3 indicates some of the key Performance Monitor objects and counters for measuring processor utilization.

TABLE 39.3 Processor-Related Performance Objects and Counters

Performance Monitor Object	Description
Processor: % Processor Time	The rate at which bytes are received on the interface.
System: Processor Queue Length	The number of threads in the processor queue. A sustained processor queue of greater than two threads indicates a processor bottleneck.
System: Threads	The number of threads executing on the machine. A thread is the basic executable entity that can execute instructions in a processor.
System: Context Switches	The rate at which the processor and SQL Server has to change from executing on one thread to executing on another. This costs CPU resources.
Processor: % Interrupt Time	The percentage of time that the processor spends receiving and servicing hardware interrupts.
Processor: Interrupts/sec	The average number of hardware interrupts the processor is receiving and servicing.

The counters System: % Total Processor Time, System: Processor Queue Length, and Processor: % Processor Time are the most critical to watch. If the percentages are consistently high (above that 80% to 95% level), you need to identify which specific

processes and threads are consuming so many CPU cycles. The ideal Windows setup is to run SQL Server on a standalone member server to the Windows domain. You should not install SQL Server on a primary domain controller (PDC) or backup domain controller (BDC) because the PDC and BDC run additional services that consume memory, CPU, and network resources.

Before you upgrade to the latest processor just because the % Processor Time counter is constantly high, you might want to check the load placed on the CPU by your other devices. By checking Processor: % Interrupt Time and Processor: Interrupts/Sec, you can tell whether the CPU is interrupted more than normal by devices such as disk controllers.

The % Interrupt Time value should be as close to 0 as possible; controller cards should handle any processing requirements.

The System: Context Switches counter can reveal when excessive context switching occurs, which usually directly affects overall performance. In addition, the System: Threads counter can give a good picture of the excessive demand on the CPU of having to service huge numbers of threads. In general, you should look at these counters only if processor queuing is happening.

By upgrading inefficient controllers to bus-mastering controllers, you can take some of the load from the CPU and put it back on the adapter. You should also keep the controller patched with the latest drivers from the hardware vendor.

Monitoring Processor Performance in SSMS

The Activity Monitor in SSMS provides some basic information on processor performance, such as the % Processor Time that SQL Server is consuming and a list of the current user connections into SQL Server.

If you've enabled the SQL Server Utility for your SQL Server instance, you can get a high-level view of CPU utilization on the CPU Utilization page of the Utility Explorer (see Figure 39.28). This view displays CPU utilization for the SQL Server instance and the overall CPU utilization for the server.

If you are collecting performance data into the MDW using the Data Collector for a SQL Server instance, you can view more detailed CPU utilization and CPU wait information in the Server Activity History report (refer to Figure 39.12). If you see high CPU utilization, you can click on the CPU Usage graph to drill down and examine the details of the top 10 processes consuming CPU resources.

If there is an indication of excessive CPU waits, you can click on the SQL Server Waits graph to drill down into the details regarding the queries experiencing high CPU waits.

Dynamic Management Views or System Views for Monitoring Processor Items

Within SQL Server, you can execute a simple SELECT statement that yields the SQL Server processes and their corresponding threads:

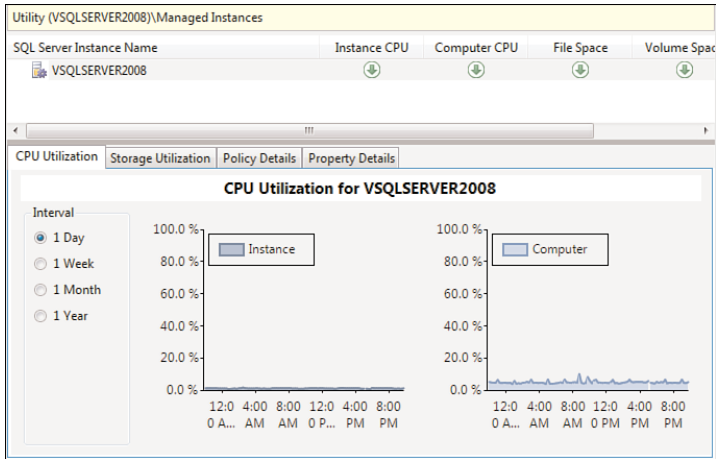

FIGURE 39.28 Viewing CPU utilization in the Utility Explorer.

```
SELECT top 10 spid, lastwaittype, dbid, uid, cpu, physical_io, memusage, status,
    loginame, program_name
from sys.sysprocesses
ORDER BY cpu desc
```

This statement lists the top 10 CPU resource hogs active in SQL Server. After you identify which processes are causing a burden on the CPU, you can check whether they can be either turned off or moved to a different server. If they cannot be turned off or moved, you might want to consider upgrading the processor. The same information is available via the new DMV:

```
SELECT top 10 session_id, command, database_id, user_id,
    cpu_time, reads, writes, logical_reads
from sys.dm_exec_requests
order by cpu_time desc
```

Taking a peek at the SQL Server schedulers (using the `sys.dm_os_schedulers` DMV) also shows whether the number of runnable tasks is getting bogged down. If the `runnable_tasks_count` values are nonzero, there aren't enough CPU time slices available to run the current SQL Server workload. The following example shows how you query the `dm_os_schedulers` view for this information:

```
SELECT scheduler_id, current_tasks_count, runnable_tasks_count
FROM Sys.dm_os_schedulers
```

And finally, to get an idea of the top CPU hogs in SQL Server cached SQL and stored procedures, you can query the `sys.dm_exec_query_stats` DMV and aggregate on `total_worker_time` to get the total CPU consumption, as follows:

```

SELECT top 50 sum(total_worker_time) as Total_CPU,
              sum(execution_count) as Total_Count,
              count(*) as Total_Statements,
              plan_handle
FROM sys.dm_exec_query_stats
GROUP BY plan_handle
Order by 1 desc
GO

```

To actually see the SQL code that is behind the `plan_handle`, you can execute the `dm_exec_sql_text` function to get your “hog” list:

```

SELECT total_worker_time, b.text
FROM sys.dm_exec_query_stats A
CROSS APPLY sys.dm_exec_sql_text (A.plan_handle) AS B
order by 1 desc

```

Monitoring Memory

Memory, like a processor, is divided into segments for each process running on the server. If there is a demand for more memory than is available, the operating system has to use virtual memory to supplement the physical memory. Virtual memory is storage allocated on the hard disk; it is named `PAGEFILE.SYS` under Windows.

It is important to remember that when the operating system or SQL Server isn't able to use memory to find something and has to use virtual memory stored on the disk, performance degrades. You need to work on minimizing this situation, known as *swapping* or *page faulting*.

Monitoring Memory with Performance Monitor

Table 39.4 reflects the main performance objects and counters that are best utilized to monitor memory for SQL Server.

TABLE 39.4 Memory-Related Performance Objects and Counters

Performance Monitor Object	Description
Process: Working Set\sqlservr	The set of memory pages touched recently by the threads in the process (SQL Server, in this case).
SQLSERVER:Buffer Manager: Buffer cache hit ratio	The percentage of pages that were found in the buffer pool without having to incur a read from disk.
SQLSERVER:Buffer Manager: Total Pages	The total number of pages in the buffer pool, including database pages, free pages, and stolen pages.
SQLSERVER:Memory Manager: Total Server Memory(KB)	The total amount of dynamic memory the server is currently consuming.
SQLSERVER:Memory Manager: SQL Cache Memory(KB)	The total amount of dynamic memory the SQL Server cache is currently consuming.

TABLE 39.4 Memory-Related Performance Objects and Counters

Performance Monitor Object	Description
SQLSERVER:Plan Cache: Cache hit ratio	The ratio between lookups and cache hits for query plans in the plan cache.
SQLSERVER:Buffer Manager: Total Pages	The total number of pages in the plan cache.
Memory: Pages/sec	The number of pages read from or written to disk to resolve hard page faults. This value usually gives a direct indication of memory issues.
Memory: Pages Read/sec	The number of times the disk was read to resolve hard page faults.
Memory: Page Faults/sec	The overall rate at which faulted pages are handled by the processor.
Process: Page Faults/sec\sqlservr	The rate of page faults occurring in the threads associated with a process (SQL Server, in this case).

To observe the level of the page faulting, you can look at the `Memory: Page Faults/sec` and `Process: Page Faults` (for a SQL Server instance) counters. Next in line are the `MSSQL Buffer Manager: Buffer Cache hit ratio` and `MSSQL Buffer Manager: Total Pages` counters. They directly indicate how well SQL Server is finding data in its controlled memory (cache). You want to achieve a near 90% or higher ratio here.

If the `Memory: Pages/sec` counter is greater than 0 or the `Memory: Page Reads/sec` counter is greater than 5, the operating system is being forced to use the disk to resolve memory references. These are called *hard faults*. The `Memory: Pages/sec` counter is one of the best indicators of the amount of paging that Windows is doing and the adequacy of SQL Server's current memory configuration.

Because the memory used by SQL Server 2008 dynamically grows and shrinks, you might want to track the exact usage by using either `Process: Working Set: SQLServer` or `MSSQL: Memory Manager: Total Server Memory (KB)` counters. These counters indicate the current size of the memory used by the SQL Server process. If these numbers are consistently high, compared to the amount of physical memory in the machine, you are probably ready to install more memory on the server. If you see a performance degradation because SQL Server must continually grow and shrink its memory, you should either remove some of the other services or processes running or configure SQL Server to use a fixed memory allocation.

Monitoring Memory in SSMS

If you are collecting performance data into the MDW using the Data Collector for a SQL Server instance, you can view more detailed memory usage and memory wait information in the Server Activity History report (refer to Figure 39.12). You can click on the Memory Usage graph to drill down and examine the details of the total memory usage in SQL

Server and the cache and page ratios. It also displays a list of all processes in the server and the total working set size. You can use this information to see if other running processes may be using memory that should be left available for SQL Server.

DMVs or System Views for Monitoring Memory

The DMVs associated with memory are numerous. The ones you'll most likely utilize are memory clerks, memory pools, and cache counters.

You can find memory allocations by type by using the `sys.dm_os_memory_clerks` DMV view:

```
SELECT type, sum(multi_pages_kb) from sys.dm_os_memory_clerks
WHERE multi_pages_kb <> 0
GROUP BY type
order by 2 desc
```

To see how the cache is being used, you can query `sys.dm_os_memory_cache_counters`:

```
SELECT substring(name,1,25) AS Name, single_pages_kb,
       single_pages_in_use_kb
FROM sys.dm_os_memory_cache_counters
order by single_pages_kb desc
```

Finally, when you want to see the total pages allocated to the different objects in memory, you use the `sys.dm_os_memory_objects` DMV:

```
SELECT substring(type,1,25) as Type,
       sum(pages_allocated_count) as Total_Memory_Allocated
FROM sys.dm_os_memory_objects
group by type
order by 2 desc
```

Several new DMVs were introduced in SQL Server 2008 to simplify retrieval of information that can be helpful with memory troubleshooting. In some cases, the newly introduced DMVs provide information that was previously available only in DBCC MEMORYSTATUS output. Table 39.5 provides a summary of the new DMVs available for memory troubleshooting.

TABLE 39.5 New Memory-Related DMVs in SQL Server 2008

DMV	Description
<code>sys.dm_os_memory_brokers</code>	Provides information about memory allocations using the internal SQL Server memory manager. The information provided can be useful in determining very large memory consumers.

TABLE 39.5 New Memory-Related DMVs in SQL Server 2008

DMV	Description
sys.dm_os_memory_nodes and sys.dm_os_memory_node_access_stats	Provide information about physical nonuniform memory access (NUMA) memory nodes and node access statistics grouped by the type of the page. (sys.dm_os_memory_node_access_stats is populated only if dynamic trace flag 842 is enabled due to its performance impact.)
sys.dm_os_nodes	Provides information about CPU node configuration for SQL Server. This DMV also reflects software NUMA (soft-NUMA) configuration.
sys.dm_os_process_memory	Provides overview information about SQL Server memory usage, including the total physical memory in use and the memory utilization percentage
sys.dm_os_sys_memory	Provides overview information about the system memory usage including total physical memory on the system and the available physical memory.
sys.dm_resource_governor_configuration, sys.dm_resource_governor_resource_pools, and sys.dm_resource_governor_workload_groups	Provide information about the state of the Resource Governor feature of SQL Server 2008. Some of the configuration parameters of Resource Governor affect how SQL Server allocates memory; you should check these parameters during memory troubleshooting. For more information on using Resource Governor and its impact on memory allocation, see Chapter 40, “Managing Workloads with the Resource Governor.”

Monitoring the Disk System

SQL Server performance depends heavily on the I/O subsystem. SQL Server is constantly reading pages from and writing pages to disk via the data cache. It is also constantly writing to disk via the transaction log. Focusing on the database data files, transaction log files, and especially tempdb can yield great performance for your SQL Server platform. Table 39.6 lists the essential performance objects and counters related to monitoring the disk system.

TABLE 39.6 Disk Usage-Related Performance Objects and Counters

Performance Monitor Object	Description
Physical Disk: Current Disk Queue Length	The number of outstanding requests (read/write) for a disk.
Physical Disk: Avg. Disk Queue Length	The average number of both read and write requests queued for disks.
Physical Disk: Disk Read Bytes	The rate at which bytes are transferred from the disk during read operations.
Physical Disk: Disk Write Bytes	The rate at which bytes are transferred to the disk during write operations.
Physical Disk: % Disk Time	The percentage of elapsed time that the selected disk drive is busy servicing read or write requests.
Logical Disk: Current Disk Queue Length	The number of outstanding requests (read/write) for a disk.
Logical Disk: Avg. Disk Queue Length	The average number of both read and write requests queued for disks.
Logical Disk: Disk Read Bytes	The rate at which bytes are transferred from the disk during read operations.
Logical Disk: Disk Write Bytes	The rate at which bytes are transferred to the disk during write operations.
Logical Disk: % Disk Time	The percentage of elapsed time that the selected disk drive is busy servicing read or write requests.

Slow disk I/O causes a reduction in the transaction throughput. To identify which disks are receiving all the attention, you should monitor both the Physical Disk and Logical Disk performance objects. You have many more opportunities to tune at the disk level than with other components, such as processors. This has long been the area where database administrators and system administrators have been able to get better performance. You can start by looking at the behavior of the Physical Disk: Current Disk Queue Length and Physical Disk: Avg. Disk Queue Length counters for all disks or for each particular disk. This way, you can identify where most of the activity is, from a disk-usage point of view.

As you monitor each individual disk, you might see that some drives are not as busy as others. You can relocate heavily used resources to minimize these long queue lengths that you have uncovered and spread out the disk activity. Common techniques for this are to relocate indexes away from tables, isolate read-only tables away from volatile tables, and so on. You need to take special care with tempdb. The best practice is to isolate it away from all other disk I/O processing.

The **Physical Disk: % Disk Time** counter for each physical disk drive shows the percentage of time that the disk is active; a continuously high value could indicate an underperforming disk subsystem.

Of course, the monitoring up to this point shows only half the picture if drives are partitioned into multiple logical drives. To see the work on each logical drive, you need to examine the logical disk counters; in fact, you can monitor read and write activity separately with **Logical Disk: Disk Write Bytes/sec** and **Logical Disk: Disk Read Bytes/sec**. You should be looking for average times below 20ms. If the averages are over 50ms, the disk subsystem is in serious need of replacement, reconfiguration, or redistribution.

If you use RAID, you need to know how many physical drives are in each RAID array to figure out the monitored values of disk queuing for any one disk. In general, you just divide the disk queue value by the number of physical drives in the disk array. This calculation gives you a fairly accurate number for each physical disk's queue length.

Monitoring SQL Server's Disk Activity

In the preceding section, we looked at monitoring overall disk activity. In this section, we examine what SQL Server's contribution is to all this disk activity. Disk activity can be categorized into reads and writes. SQL Server carries out writes to the disk for the following processes:

- ▶ Logging records
- ▶ Writing dirty cache pages at the end of a transaction
- ▶ Freeing space in the page cache

Logging is a constant occurrence in any database that allows modifications, and SQL Server attempts to optimize this process by batching a number of writes together. To see how much work is done on behalf of the database logs, you can examine the **SQLServer:Databases:Log Bytes Flushed** and **SQLServer:Databases:Log Flushes/sec** counters. The first tells you the quantity of the work, and the second tells you the frequency.

The third kind of write occurs to make space within the page cache. This is carried out by the Lazy Writer process, which you can track with the counter **SQLServer:Buffer Manager:Lazy Writes**.

You also can easily monitor the amount of reading SQL Server is doing by using the counter **SQLServer:Buffer Manager:Page Reads**.

Monitoring Disk Performance in SSMS

If you are collecting performance data into the MDW using the Data Collector for a SQL Server instance, you can view more detailed disk performance in the Server Activity History report (refer to Figure 39.12). You can click on the Disk Usage graph to drill down and examine the details on Disk Response Time, Average Disk Queue Length, and Disk

Transfer Rate. In addition, the System Disk Usage detail report also lists the top 20 processes with the highest I/O writes or highest I/O reads per second. This information can help you determine which processes besides SQL Server are performing a large number of disk reads and/or writes that could be affecting the I/O performance of SQL Server.

DMVs or System Views for Monitoring Disk System Items

There are several I/O-related DMVs and functions. They cover backup tape I/O, pending I/O requests, I/O on cluster shared drives, and virtual file I/O statistics.

The best of these is the `sys.dm_io_virtual_file_stats` function, which allows you to see the file activity within a database allocation. You supply the database ID as the first parameter, along with the file ID of the database file as the second parameter. This yields an accumulating set of statistics that can be used to isolate and characterize heavy I/O:

```
SELECT cast(db_name(database_id) as varchar(12)) as dbname,
       file_id,
       num_of_reads as numreads,
       num_of_bytes_read as bytesread,
       num_of_bytes_written as byteswritten,
       size_on_disk_bytes as size
FROM sys.dm_io_virtual_file_stats (5,1)
GO
dbname      file_id numreads bytesread byteswritten size
-----
UnleashedMDW 1      7022      411140096 759291904 1048576000
```

In addition, the OS wait stats for I/O latch waits are great for identifying when reading or writing of a page is not available from the data cache. These latch waits account for the physical I/O waits when a page is accessed for reading or writing. When the page is not found in the cache, an asynchronous I/O gets posted. If there is any delay in the I/O, the `PAGEIOLATCH_EX` or `PAGEIOLATCH_SH` latch waits are affected. An increased number of latch waits indicates that an I/O bottleneck exists. The following query reveals this latch wait information:

```
SELECT substring(wait_type,1,15) AS Latch_Waits, waiting_tasks_count, wait_time_ms
FROM sys.dm_os_wait_stats
WHERE wait_type like 'PAGEIOLATCH%'
ORDER BY wait_type
GO
Latch_Waits      waiting_tasks_count  wait_time_ms
-----
PAGEIOLATCH_DT   0                    0
PAGEIOLATCH_EX  2871                 61356
PAGEIOLATCH_KP   0                    0
PAGEIOLATCH_NL   0                    0
PAGEIOLATCH_SH  7305                 98120
PAGEIOLATCH_UP  1372                 7318
```

Monitoring Other SQL Server Performance Items

In addition to the main system items that affect performance which have been covered already, there are other items in SQL Server that affect system performance that you should include in your performance monitoring approach.

Monitoring Locks

One of the often-overlooked areas of performance degradation is locking. You need to ensure that the correct types of locks are issued and that the worst kind of lock, a blocking lock, is kept to a minimum. A *blocking lock*, as its name implies, prevents other users from continuing their own work. An easy way to identify the level of blocking locks is to use the counter `SQLServer:Memory Manager:Lock Blocks`. If this counter frequently indicates a value greater than 0, you need to examine the queries being executed or even revisit the database design.

For a more detailed discussion on monitoring locking in SQL Server and minimizing locking contention, see Chapter 37, “Locking and Performance.”

Monitoring Users

Even though you cannot always trace performance problems directly to the number of users connected, it is a good idea to occasionally monitor how this number fluctuates. It is fairly easy to trace one particular user who is causing a massive performance problem.

The leverage point here is to see the current number of user connections with the `SQLServer:General Statistics>User Connections` counter in conjunction with other objects and counters. It is easy to say that the disk subsystem is a bottleneck, but how many users is SQL Server supporting at the time?

Summary

Attacking SQL Server performance is not a simple task because so many variables are involved. Tuning queries and proper database design are a huge part of this, but dealing with SQL Server as an engine that consumes resources and the physical machine is equally important. This is why it is so critical to take an orderly, methodical approach when undertaking this task. As pointed out in this chapter, you need to basically peel apart the box on which SQL Server has been installed, one component at a time (network, CPU, memory, and disk). This way, you can explore the individual layer or component in a clear and concise manner. Within a short amount of time, you will be able to identify the biggest performance offenders and resolve them.

The next chapter, “Managing Workloads with Resource Governor,” discusses the new feature in SQL Server 2008 that lets you control the allocation of resources to SQL Server sessions. This feature can help avoid situations in which a runaway query consumes excessive resources in SQL Server.

CHAPTER 40

Managing Workloads with the Resource Governor

If you have ever had a user kick off a runaway report that brought the system to its knees, effectively halting your production online transaction processing (OLTP) activity, you might have wished for a mechanism in SQL Server that would limit the amount of hardware resources allocated to ad hoc reporting requests so that normal production activity was not affected. Such a mechanism could prevent certain processes from consuming too many of the available SQL Server resources, ensuring that your more critical, higher-priority processes would consistently have access to the resources they need.

Fortunately, SQL Server 2008 now provides such a mechanism: Resource Governor. Resource Governor allows you to classify different types of sessions on your server, which in turn allows you to control how server resources are assigned to a given activity. In SQL Server 2005 and earlier, queries fought among themselves to decide which one would grab the necessary resources first, and it was hard to predict who would win out. By using Resource Governor, you are able to instruct SQL Server to limit the resources a particular session can access. This capability can help ensure that your OLTP processes continue to provide predictable performance that isn't adversely affected by unpredictable activity. For example, with Resource Governor, you can specify that no more than 20% of CPU and/or memory resources should be allocated to running reports. When this feature is enabled, no matter how many reports are run, they can never exceed their designated resource allocation. Of course, this reduces the performance of the reports, but at least your production OLTP performance isn't as negatively affected by runaway reports anymore.

IN THIS CHAPTER

- ▶ Overview of Resource Governor
- ▶ Resource Governor Components
- ▶ Configuring Resource Governor
- ▶ Monitoring Resource Usage
- ▶ Modifying Your Resource Governor Configuration

NOTE

Resource Governor is available only in the Enterprise, Datacenter, and Developer Editions of SQL Server 2008 and SQL Server 2008 R2.

Overview of Resource Governor

Resource Governor works by controlling the allocation of resources according to workloads. When a connection request is submitted to the Database Engine, the request is classified based on a classification function. The classification function is a scalar function that you define via T-SQL. The classification function evaluates information about the connection (for example, login ID, application name, hostname, server role) to determine how it should be classified. After the connection request is classified, it is routed to a workload group defined for that classification (or if the connection cannot be classified, it is routed to the default workload group). Each workload group is associated with a resource pool. A resource pool represents the physical resources of SQL Server (currently in SQL Server 2008, the only physical resources available for configuration are CPU and memory) and specifies the maximum amount of CPU and/or memory resources that are to be allocated to a specific type of workload. When a connection is classified and put into the correct workload group, the connection is allocated the CPU and memory resources assigned to it, and then the query is passed on to the query optimizer for execution. This process is illustrated in Figure 40.1.

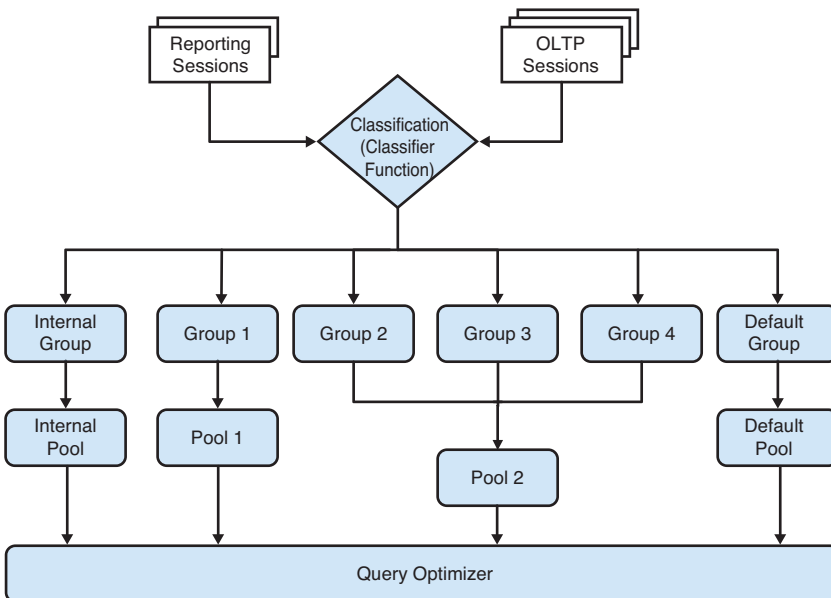

FIGURE 40.1 Overview of the Resource Governor.

Resource Governor is designed to address the following types of resource issues, which are commonly found in a database environment:

- ▶ **Runaway queries**—These resource-intensive queries can take up most or all of the server resources.
- ▶ **Unpredictable workload execution**—This situation occurs when you have concurrent applications on the same server that are not isolated from each other, and the resulting resource contention causes unpredictable performance.
- ▶ **Workload prioritization**—You might want to ensure that a critical workload is given priority to the system resources so it can process faster than other workloads or is guaranteed to complete if there is resource contention.

In addition to enabling you to classify incoming connections and route their workloads to a specific group, Resource Governor also enables you to do the following:

- ▶ Monitor resource usage for each workload in a group
- ▶ Pool resources and set pool-specific limits on CPU usage and memory allocation, which can prevent or minimize the probability of runaway queries
- ▶ Associate grouped workloads with a specific pool of resources
- ▶ Identify and set priorities for workloads

The current release of Resource Governor has the following limitations:

- ▶ Resource allocation is only for CPU and memory usage. There is no support for managing network and disk I/O resource utilization.
- ▶ Resource Governor manages only resource consumption of the Database Engine. You cannot use Resource Governor to manage workloads within SSAS, SSIS, or SSRS.

In the following sections, you learn how to set up and configure Resource Governor for use, how Resource Governor works under the hood, and how you can use Resource Governor to better prioritize and manage a SQL Server's workload.

Resource Governor Components

Resource Governor consists of three main components: classification, workload groups, and resource pools. Understanding these three components and how they interact is important to understanding and using Resource Governor.

Classification

Classification is the process of evaluating incoming user connections and assigning them to a workload group. Classification is performed by logic contained in a user-defined function. The function returns the workload group name, which Resource Governor uses to route the sessions into the appropriate workload groups.

When Resource Governor is configured, the login process for a session consists of the following steps:

1. Login authentication
2. LOGON trigger execution
3. Classification

Workload Groups

Workload groups are the containers for similar connections, which are grouped together as similar according to the classification criteria applied to each connection. A workload group also provides the mechanism for aggregate monitoring of resource consumption.

Resource Governor has two predefined workload groups: the internal group and default group. The internal workload group is used solely by internal Database Engine processes. You cannot change the classification criteria for the internal group, and you also cannot classify any user requests for assignment to the internal group. You can, however, monitor the internal group.

Connection requests are automatically classified into the default group when the following conditions exist:

- ▶ There are no criteria to classify a request.
- ▶ There is an attempt to classify the request into a nonexistent group.
- ▶ There is a general classification failure.

Resource governor supports a total of 20 workload groups. Because two of them are reserved for the internal and default workload groups, a total of 18 user-defined workload groups can be defined.

Resource Pools

A *resource pool*, or *pool*, represents the allocation of physical resources of the SQL Server. A resource pool has two parts:

- ▶ The first part specifies the minimum resource reservation. This part of the resource pool does not overlap with other pools.
- ▶ The other part specifies the maximum possible resource reservation for the pool. The resource allocation is shared with other pools.

In SQL Server 2008 and SQL Server 2008 R2, the pool resources are set by specifying a MIN or MAX allocation for CPU and a MIN or MAX allocation for memory. The MIN setting specifies the minimum guaranteed resource availability of the pool. The MAX setting sets the maximum size of the pool for each of the resources.

Because there cannot be any overlap in the minimum resource reservation, the sum of the MIN values across all pools cannot exceed 100% of the total server resources. This ensures that each pool is guaranteed the specified resource allocation.

The MAX value can be set anywhere in the range between the MIN value and 100% inclusive. The MAX setting represents the maximum amount of resources a session can consume, as long as the resources are available and not in use by another pool that is configured with a nonzero MIN value. When a pool has a nonzero MIN percentage defined, the effective MAX value of other pools is readjusted down, as necessary, to the existing MAX value minus the sum total of the MIN values of other pools.

For example, consider you have two user-defined pools. One pool, Pool1, is defined with a MIN setting of 20% and a MAX setting of 100%. The other pool, Pool2, is defined with a MIN setting of 50% and a MAX setting of 70%. The resulting effective MAX setting for Pool1 is 50% (100% minus the MIN 50% of Pool2). The effective MAX setting of Pool2, however, remains at 70% rather than 80% because 70% is the configured MAX value of Pool2.

The shared part of the pool (the amount between the MIN and effective MAX values) is used to determine the amount of resources that can be consumed by the pool if the resources are available and not being consumed by another pool. When resources are consumed by a pool, they are assigned to the specified pool and are not shared until processing completes in that pool.

To illustrate this further, consider a scenario in which there are three user-defined resource pools:

- ▶ PoolA is defined with a MIN % of 10 and MAX % of 100.
- ▶ PoolB is defined with a MIN % of 35 and a MAX % of 90.
- ▶ PoolC is defined with a MIN % of 30 and a MAX % of 80.

The effective MAX of PoolA would be calculated as follows:

MAX % of PoolA	100
minus MIN % of PoolB	35
minus MIN % of PoolC	30
equals EFF MAX of PoolA	35

The total Shared % of resources of PoolA would then be calculated as follows:

Effective MAX % of PoolA	35
minus MIN % of PoolA	10
equals Shared % of PoolA	25

Table 40.1 illustrates the calculated effective MAX and Shared % values for all pools in this configuration.

TABLE 40-1 Effective **MAX** and **Shared** % Values for Multiple Pools

ResourcePool	MIN %	MAX %	Effective MAX %	Shared %
Internal	0	100	100	100
Default	0	100	25	25
PoolA	10	100	35	25
PoolB	35	90	50	15
PoolC	30	80	35	5

To coincide with the predefined workload groups, Resource Governor also has two predefined resource pools: the internal pool and default pool.

The internal pool represents the resources consumed by the internal processes of the Database Engine. This pool always contains only the internal group, and the pool is not alterable in any way. The Internal Pool has a fixed MIN % of 0 and a MAX % of 100, and resource consumption by the internal pool is not restricted or reduced by any settings in other pools. In other words, the effective MAX of the Internal Pool is always 100%. Any workloads in the internal pool are considered critical for server function, and Resource Governor allows the internal pool to consume 100% of available resources if necessary, even if it means the violation of the resource requirements of the other pools.

The default pool is the first predefined user pool. Prior to any configuration, the default pool contains only the default group. The default pool cannot be created or dropped, but it can be altered. The default pool can contain user-defined groups in addition to the default group.

Now that you have an understanding of the Resource Governor components, let's put them into use by enabling and setting up some resource groups.

Configuring Resource Governor

To begin using Resource Governor for managing the resources of your workloads, follow these steps:

1. Enable Resource Governor.
2. Create your user-defined resource pools.
3. Define your workload groups and assign them to pools.
4. Create the classifier function.
5. Register the classifier function with the Resource Governor.

NOTE

Resource Governor can be set up and managed using either SQL Server Management Studio (SSMS) or via T-SQL commands. In the following sections, we first show you how to perform the tasks in SSMS and how the same actions can be implemented using T-SQL.

Enabling Resource Governor

Before you can begin creating your resource pools, you need to enable the Resource Governor first. To enable Resource Governor in SSMS, in Object Explorer, expand the Management node, right-click on the Resource Governor node, and select Enable (see Figure 40.2).

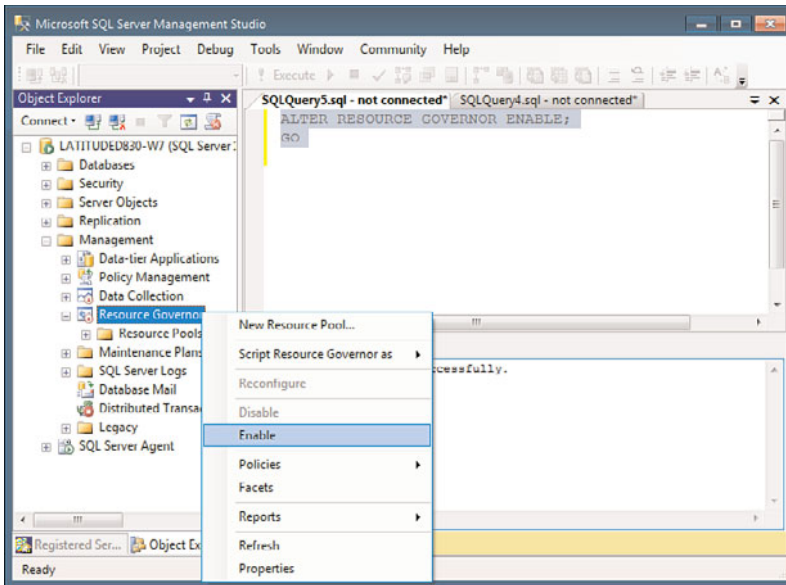

FIGURE 40.2 Enabling Resource Governor in SSMS.

Alternatively, you can also enable Resource Governor by using the `ALTER RESOURCE GOVERNOR` command in T-SQL:

```
ALTER RESOURCE GOVERNOR RECONFIGURE
```

When Resource Governor is not enabled, the `RECONFIGURE` option enables Resource Governor. Enabling Resource Governor has the following results:

- ▶ The classifier function, if defined, is executed for new connections so that their workload can be assigned to workload groups.
- ▶ The resource limits specified in the Resource Governor configuration are honored and enforced.
- ▶ Any connections that existed before Resource Governor was enabled are now affected by any configuration changes made when Resource Governor was disabled.

When Resource Governor is already enabled, the `RECONFIGURE` option must be executed to apply any configuration changes made using the `CREATE|ALTER|DROP WORKLOAD GROUP` or `CREATE|ALTER|DROP RESOURCE POOL` statements.

To determine whether Resource Governor is currently enabled, you can run a SELECT statement against the `sys.resource_governor_configuration` system catalog table to view the `is_enabled` column:

```
select is_enabled from sys.resource_governor_configuration
go

is_enabled
-----
1
```

To determine whether any RESOURCE GOVERNOR configuration changes are pending, you can use the `sys.dm_resource_governor_configuration` dynamic management view (DMV):

```
select is_reconfiguration_pending
       from sys.dm_resource_governor_configuration
go

is_reconfiguration_pending
-----
0
```

To disable Resource Governor, right-click on the Resource Governor node and select Disable or execute the following command in T-SQL:

```
ALTER RESOURCE GOVERNOR DISABLE
```

Defining Resource Pools

When setting up a Resource Pool, you have to specify a name for the pool and set its properties. The properties available for a resource pool are

- ▶ **Name**—The name used to refer to the resource pool
- ▶ **Minimum CPU %**—The guaranteed average CPU bandwidth for all requests to the resource pool *when there is CPU contention*
- ▶ **Maximum CPU %**—The maximum average CPU bandwidth for all requests to the resource pool *when there is CPU contention*
- ▶ **Min Memory %**—The guaranteed minimum amount of memory reserved for the resource pool that *cannot be shared with other resource pools*
- ▶ **Max Memory %**—The total server memory that can be used by requests to the resource pool

Creating a Resource Pool in SSMS

The following steps walk you through using SSMS to create a resource pool named ReportPool that you'll configure for handling report query workloads:

1. In Object Explorer, expand the Management node for a SQL Server Instance and expand the Resource Governor node.
2. Right-click on Resource Pools and select New Resource Pool to open the Resource Governor Properties page (see Figure 40.3).

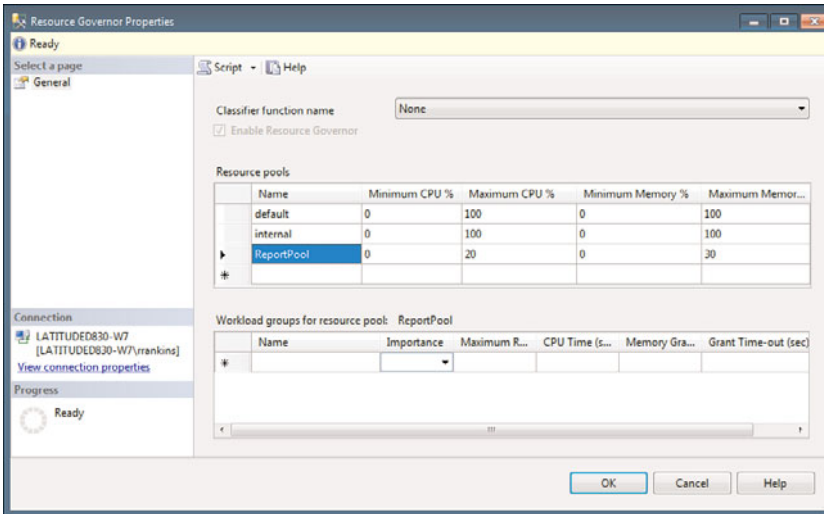

FIGURE 40.3 Creating a resource pool in SSMS.

3. In the Resource Pools grid, click the first column in the empty row. This row is labeled with an asterisk (*).

NOTE

If the Resource Pools grid does not have a row labeled with an asterisk, Resource Governor has not been enabled yet. You can enable Resource Governor without leaving the Resource Governor Properties page by putting a check mark in the Enable Resource Governor check box.

4. Double-click the empty cell in the Name column. Type in the name that you want to use for the resource pool. For this example, use the name ReportPool.
5. Set the CPU and Memory resource values. In this example, leave the Min CPU % and Min Memory % values at 0 and configure the Max CPU % and Max Memory % values at 20 and 30, respectively.
6. To create the pool and exit the dialog, click OK.

To verify that the new pool was created, you expand the Resource Pools folder under the Resource Governor node and look for a node named ReportPool. Alternatively, you can

run a query against the `sys.resource_governor_resource_pools` dynamic management view, similar to the following, which also displays the resource pool configuration:

```
select name,
       min_cpu_percent as MinCPU,
       max_cpu_percent as MaxCPU,
       min_memory_percent as 'MinMEM%' ,
       max_memory_percent as 'MaxMEM%'
from sys.resource_governor_resource_pools
go
```

name	MinCPU	MaxCPU	MinMEM%	MaxMEM%
internal	0	100	0	100
default	0	100	0	100
ReportPool	0	20	0	30

Creating a Resource Pool in T-SQL

Now that you've set up the `ReportPool` resource pool in SSMS, you are able to set up a second resource pool, `OLTPPool`, using T-SQL. The command to create a resource pool, `CREATE RESOURCE POOL`, takes four arguments: `MIN_CPU_PERCENT`, `MAX_CPU_PERCENT`, `MIN_MEMORY_PERCENT`, and `MAX_MEMORY_PERCENT`. After creating the resource pool, you need to run `ALTER RESOURCE GOVERNOR RECONFIGURE` to apply the new resource pool:

```
CREATE RESOURCE POOL OLTPPool
WITH
    (min_cpu_percent=80,
     max_cpu_percent=100,
     min_memory_percent=75,
     max_memory_percent=100)
GO
ALTER RESOURCE GOVERNOR RECONFIGURE;
GO
```

Now that you've defined the resource pools needed, the next step is to define your workload groups and associate them with a resource pool.

Defining Workload Groups

After you define your resource pools, the next step is to create the workload groups and associate them with the appropriate resource pools. Multiple workgroups can be assigned to that same pool, but a workgroup cannot be assigned to multiple resource pools.

Creating Workload Groups in SSMS

To create a workload group in SSMS, perform the following steps:

1. In Object Explorer, expand the Management node, right-click the Resource Governor node, and then click Properties to bring up the Resource Governor Properties page.
2. In the Resource Pools grid, click the row for the resource pool you want to create a workload group for (in this example, the ReportPool resource pool). This creates a new empty row in the Workload Groups for Resource Pool grid for that pool.
3. Double-click the empty cell in the Name column for the empty workload group row and type in the name you want to use for the workload group (for this example, ReportWG1) and any other properties you want to specify (see Figure 40.4)

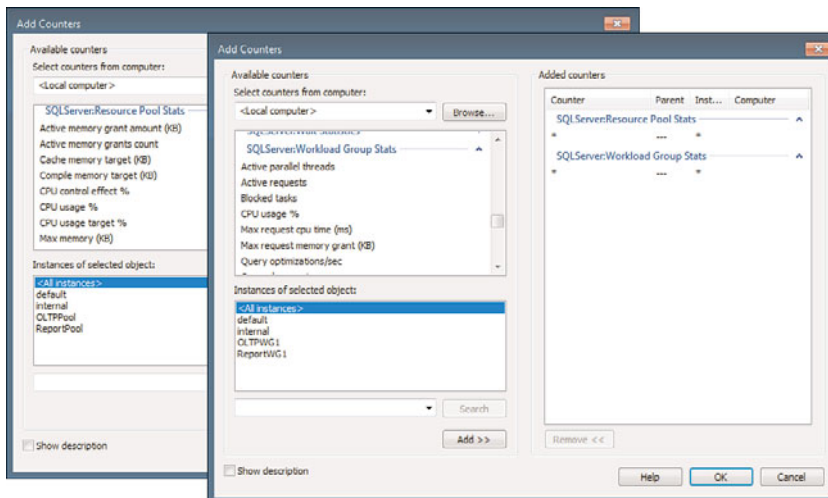

FIGURE 40.4 Creating a Workload Group in SSMS.

4. Click OK to exit the Properties page and create the workload group.

The additional, optional properties available for workload groups let you set a finer level of control over the execution of queries within a workload group. The options available are

- **Importance**—Specifies the relative importance (LOW, MEDIUM, or HIGH) of the workload group within the resource pool. If you define multiple workload groups in a

resource pool, this setting determines whether requests within one workload group run at a higher or lower priority than other workload groups within the same resource pool. MEDIUM is the default setting. Currently, the weighting factors for each setting is LOW=1, MEDIUM=3, and HIGH=9. This means that the scheduler will attempt to execute sessions in workgroups with importance of HIGH three times more often than workgroups with MEDIUM importance, and nine times more often workgroups with LOW importance.

NOTE

Try to avoid having too many sessions in groups with high importance or assigning high importance to too many groups because the sessions will likely end up getting only equal time on the scheduler as your medium and low priority sessions.

- ▶ **Maximum Requests**—Specifies the maximum number of simultaneous requests allowed to execute in the workload group. The default setting, 0, allows unlimited requests.
- ▶ **CPU Time**—Specifies the maximum amount of CPU time, in seconds, that a request within the workload group can use. The default setting is 0, which means unlimited.
- ▶ **Memory Grant %**—Specifies, as a percentage, the maximum amount of execution grant memory that a single request can take from the resource pool. This percentage is relative to the amount of memory allocated to the resource pool. The allowed range of values is from 0 through 100. The default setting is 25. *Execution grant memory* is the amount of memory used for query execution, not for data buffers or cached plans, which can be shared by many sessions, regardless of resource pool or workload group. Note that setting this value to 0 prevents queries with SORT and HASH JOIN operations in user-defined workload groups from running. It is also not recommended that this value be set greater than 70 because the server may be unable to set aside enough free memory if other concurrent queries are running.
- ▶ **Grant Time-out**—Specifies the maximum time, in seconds, that a query waits for a resource to become available. If the resource does not become available, the process may fail with a time-out error. Note that a query does not always fail when the grant time-out is reached. A query fails only if there are too many concurrent queries running. Otherwise, the query may run with reduced resources, resulting in reduced query performance. The default setting is 0, which means the server calculates the time-out using an internal calculation based on query cost to determine the maximum time.
- ▶ **Degree of Parallelism**—Specifies the maximum degree of parallelism (DOP) for parallel queries. This values takes precedence over the global max degree of parallelism configuration setting, as well as any query hints. The allowed range of values is from 0 through 64. The default setting is 0, which means that processes use the global setting. Be aware that MAX_DOP specifies an upper limit only. The actual degree

of parallelism is determined by the server based on the actual number of schedulers and available number of parallel threads, which may be less than the specified MAX_DOP. To better understand how the MAX_DOP setting is handled, consider the following:

- ▶ MAX_DOP as a query hint is considered only if it does not exceed the workload group MAX_DOP setting.
- ▶ MAX_DOP as a query hint always overrides the max degree of parallelism server configuration option.
- ▶ Workload group MAX_DOP always overrides the max degree of parallelism server configuration option
- ▶ If a query is marked as serial at compile time, it cannot be changed back to parallel at runtime regardless of the workload group or server configuration setting.
- ▶ When the degree of parallelism is decided, it can be lowered only when memory pressure occurs. Workload group reconfiguration is not seen for tasks already waiting in the grant memory queue.

To verify that the new workload group was created, in SSMS Object Explorer, expand the Resource Governor node, expand the Resource Pools folder, expand the ReportPool node, and finally, expand the Workload Groups folder. You should then see a folder named ReportWG1.

Creating Workload Groups in T-SQL

Now that you've set up the ReportWG1 workload group in SSMS, you are able to set up a second workload group, OLTPWG1, using T-SQL. The command to create a resource pool, CREATE RESOURCE POOL, takes five optional arguments:

REQUEST_MAX_MEMORY_GRANT_PERCENT, REQUEST_MAX_CPU_TIME_SEC, GROUP_MAX_REQUESTS, REQUEST_MEMORY_GRANT_TIMEOUT_SEC, and MAX_DOP, which were described in the preceding section.

```
CREATE WORKLOAD GROUP OLTPWG1
    WITH ( IMPORTANCE = HIGH )
    USING OLTPPool
ALTER RESOURCE GOVERNOR RECONFIGURE
GO
```

To view the workload groups in T-SQL, you can run a query against the sys.resource_governor_workload_groups system catalog view, similar to the following, which also displays the workload group settings:

```
select wg.name,
       p.name as 'pool',
       group_max_requests as max_req,
       request_max_cpu_time_sec as max_cpu,
       request_max_memory_grant_percent as max_mem,
```

```

        request_memory_grant_timeout_sec as grant_timeout,
        max_dop
from sys.resource_governor_workload_groups wg
    inner join
    sys.resource_governor_resource_pools p
    on wg.pool_id = p.pool_id
go

```

name	pool	max_req	max_cpu	max_mem	grant_timeout	max_dop
internal	internal	0	0	25	0	0
default	default	0	0	25	0	0
ReportWG1	ReportPool	0	0	25	0	0
OLTPWG1	OLTPPool	0	0	25	0	0

Creating a Classification Function

After you define your resource pools and workload groups, you need to create a classification function that contains the logic to evaluate the connections and assign them to the appropriate workload group. The classification function applies to each new session connection to SQL Server. Each session stays in the assigned workload group until it terminates, unless it is reassigned explicitly to a different group. There can be only one classification function active at any given time. If no classifier function is defined or active, all connections are assigned to the default workload group.

The classification function is a scalar function created with the `CREATE FUNCTION` statement, which must return a workgroup name as value of type `SYSNAME` (`SYSNAME` is a data type alias for `nvarchar(128)`). If the user-defined function returns `NULL`, `'default'`, or the name of nonexistent group, the session is assigned to the default workload group. The session is also assigned to the default context if the function fails for any reason.

The logic of the classification function is typically based on connection properties and often determines the `workload_group` the connection should be assigned to based on values returned by system functions such as `SUSER_NAME()`, `SUSER_SNAME()`, `IS_SRVROLEMEMBER()`, `IS_MEMBER()`, `HOST_NAME()`, or `APP_NAME()`. In addition to these functions, you can use other available property functions when making classification decisions. The `LOGINPROPERTY()` function now includes two properties (`DefaultDatabase` and `DefaultLanguage`) that can be used in classification functions. In addition, the `CONNECTIONPROPERTY()` function provides access to the network transport and protocol being used for the connection, as well as details of the authentication scheme, the local IP address and TCP port, and the client's IP address. For example, you could assign a connection to a workload group based on which subnet a connection is coming in from.

TIP

If you decide to use either `HOST_NAME()` or `APP_NAME()` in your classifier function, be aware that it's possible for the values returned by these functions to be altered by users. In general, however, the `APP_NAME()` function tends to work very well for classifying connections.

TIP

A client session may time out if the classification function does not complete within the specified time-out for the login. Login time-out is a client property, and as such, the server is unaware of a time-out. A long-running classifier function can leave the server with orphaned connections for long periods. It is important that you create efficient classifier functions that finish execution before a connection time-out.

If you are using the Resource Governor, it is recommended that you enable the dedicated administrator connection (DAC) on the server. The DAC is not subject to Resource Governor classification and can be used to monitor and troubleshoot a classification function.

For simplicity, the example presented in this chapter uses the `SUSER_NAME()` function. Listing 40.1 first creates a couple of SQL Server logins (`report_user` and `oltp_user`), which will be used within the classification function to identify which workload group session connections should be assigned to. After adding the logins as users in the AdventureWorks2008R2 database, it then creates the classification function in the master database.

LISTING 40.1 Classification Function Example

```
use master;
create login report_user with password='Rep0rter1'
create login oltp_user with password='01tPus3r1'
go

use AdventureWorks2008R2;
create user report_user
create user oltp_user
EXEC sp_addrolemember N'db_datawriter', N'report_user'
EXEC sp_addrolemember N'db_datareader', N'report_user'
EXEC sp_addrolemember N'db_datawriter', N'oltp_user'
EXEC sp_addrolemember N'db_datareader', N'oltp_user'
go
```

```

use master
go
CREATE FUNCTION dbo.WorkgroupClassifier ()
    RETURNS SYSNAME WITH SCHEMABINDING
AS
BEGIN
    DECLARE @WorkloadGroup SYSNAME = N'Unidentified';
    SET @WorkloadGroup = CASE suser_name()
        WHEN N'report_user' THEN
            N'ReportWG1'
        WHEN N'oltp_user' THEN
            N'OLTPWG1'
        ELSE N'Unidentified'
    END;
    RETURN @WorkloadGroup;
END;
Go
GRANT EXECUTE on dbo.WorkgroupClassifier to public
go

```

Before you put the classification function into use, it's a good idea to test it. A poorly written classification function could cause your system to become unresponsive. For example, you can test the `WorkgroupClassifier()` function in SSMS by executing the following commands under different login IDs:

```

-- Executed logged in as report_user
select dbo.WorkgroupClassifier()
go
-----
ReportWG1
-- Executed logged in as report_user
select dbo.WorkgroupClassifier()
go
-----
OLTPWG1
-- Executed Logged in as another user
select dbo.WorkgroupClassifier()
go
-----
Unidentified

```

After you verify the classification function works as expected, you can then configure it as the classification function using the `ALTER RESOURCE GOVERNOR` command:

```
ALTER RESOURCE GOVERNOR
  WITH (CLASSIFIER_FUNCTION = dbo.WorkgroupClassifier);
ALTER RESOURCE GOVERNOR RECONFIGURE;
```

After you create the function and apply the configuration changes, the Resource Governor classifier will use the workload group name returned by the function to send new requests to the appropriate workload group.

NOTE

You can also set the classification function for Resource Governor on the Resource Governor Properties page, as shown in Figure 40.4. Click the Classifier Function Name drop-down list and choose from the list of available functions presented. Click OK to save the changes and reconfigure Resource Governor.

You can verify which classification function Resource Governor is currently using by running the following query against the `sys.resource_governor_configuration` system catalog view:

```
select object_name(classifier_function_id) AS 'Classifier UDF name',
       is_enabled
from sys.resource_governor_configuration
go
```

```
Classifier UDF name  is_enabled
-----
WorkgroupClassifier  1
```

At this point, your Resource Governor configuration is complete. You then should monitor the system to make sure it's working as it should.

TIP

To help make setting up and configuring Resource Governor easy and make sure you get all the pieces together in the right sequence, you can configure Resource Governor by using a template provided in SQL Server Management Studio. From the View menu in SSMS, select Template Explorer to display the Template Explorer. In the Template Explorer, expand Resource Governor and then double-click Configure Resource Governor. Provide the connection information, and the template `Configure Resource Governor.sql` opens in a query editor window. This template contains template code to create and configure a resource pool, workload group, and classifier function.

Monitoring Resource Usage

SQL Server provides three dynamic management views you can use to view and monitor your Resource Governor configuration:

- ▶ **sys.dm_resource_governor_workload_groups**—Returns workload group statistics along with the current in-memory configuration of the workload groups.

- ▶ **sys.dm_resource_governor_resource_pools**—Returns information about current state of your resource pools and resource pool statistics.
- ▶ **sys.dm_resource_governor_configuration**—Returns the in-memory configuration state of the Resource Governor. Output is the same as the `sys.resource_governor_configuration` system catalog view.

For example, the following query against the `sys.dm_resource_governor_resource_pools` DMV returns the configuration settings for each of the pools along with the actual memory allocated:

```
select name,
       min_cpu_percent as MinCPU,
       max_cpu_percent as MaxCPU,
       min_memory_percent as 'MinMEM%' ,
       max_memory_percent as 'MaxMEM%',
       max_memory_kb as 'MaxMemKB',
       used_memory_kb as 'UsedMemKB',
       target_memory_kb as 'TgtMemKB'
from sys.dm_resource_governor_resource_pools
GO
```

name	MinCPU	MaxCPU	MinMEM%	MaxMEM%	MaxMemKB	UsedMemKB	TgtMemKB
internal	0	100	0	100	1556232	8296	1556232
default	0	100	0	100	389064	8336	389064
ReportPool	0	20	0	30	389064	280	389064
OLTPPool	80	100	75	100	1556232	40	1556232

The following example displays statistics on the requests received within the defined workgroups:

```
select
  cast(g.name as nvarchar(10)) as wg_name,
  cast(p.name as nvarchar(10)) as pool_name,
  total_request_count as totreqcnt,
  active_request_count as actreqcnt,
  g.total_cpu_usage_ms as tot_cpu_use,
  total_cpu_limit_violation_count as tot_clvc,
  g.request_max_cpu_time_sec as req_mcts,
  g.total_reduced_memgrant_count as tot_rmc
from sys.dm_resource_governor_workload_groups g
  inner join
  sys.dm_resource_governor_resource_pools p
  on p.pool_id = g.pool_id
go
```

wg_name	pool_name	totreqcnt	actreqcnt	tot_cpu_use	tot_clvc	req_mcts	tot_rmc
internal	internal	0	0	37314	0	0	0
default	default	784	2	97938	0	0	0
ReportWG1	ReportPool	170	1	476016	0	0	0
OLTPWG1	OLTPPool	161	0	1834	0	0	0

Six other DMVs in SQL Server 2008 contain information related to Resource Governor:

- ▶ **sys.dm_exec_query_memory_grants**—Returns information about the queries that have acquired a memory grant or that still require a memory grant to execute. Resource Governor–related columns in this table are the `group_id`, `pool_id`, `is_small`, and `ideal_memory_kb` columns.
- ▶ **sys.dm_exec_query_resource_semaphores**—Returns information about the current `query_resource` semaphore status, providing general query-execution memory status information. The `pool_id` column provides a link to Resource Governor information.
- ▶ **sys.dm_exec_session**—Returns one row per session on SQL Server. The `group_id` column relates the information to Resource Governor workload groups.
- ▶ **sys.dm_exec_requests**—Returns information about each request currently executing within SQL Server. The `group_id` column relates the information to Resource Governor workload groups.
- ▶ **sys.dm_exec_cached_plans**—Returns a row for each query plan cached by SQL Server in the plan cache. The `pool_id` column relates the information to Resource Governor resource pools.
- ▶ **sys.dm_os_memory_brokers**—Returns information about internal allocations within SQL Server that use the Memory Manager. This information includes the following columns for the Resource Governor: `pool_id`, `allocations_db_per_sec`, `predicted_allocations_kb`, and `overall_limit_kb`.

The following query joins between `sys.dm_exec_session` and `sys.dm_resource_governor_workload_groups` to display which sessions are in which workload group:

```
SELECT
    CAST(g.name as nvarchar(10)) as poolname,
    s.session_id as 'session',
    s.login_time,
    CAST(s.host_name as nvarchar(15)) as host_name,
    CAST(s.program_name AS nvarchar(20)) as program_name
    FROM sys.dm_exec_sessions s
    INNER JOIN sys.dm_resource_governor_workload_groups g
        ON g.group_id = s.group_id
where g.name in ('default', 'ReportWG1', 'OLTPWG1')
```

```

go
poolname      session login_time          host_name      program_name
-----
default      51      2010-05-02 14:31:18.530  LATITUDE830-W7 Microsoft SQL Server
default      52      2010-05-02 14:31:21.990  LATITUDE830-W7 SQLAgent - Generic R
default      53      2010-05-02 14:31:23.533  LATITUDE830-W7 SQLAgent - TSQL JobS
default      55      2010-05-02 14:47:27.250  LATITUDE830-W7 Microsoft SQL Server
ReportWG1    60      2010-05-02 19:06:21.100  LATITUDE830-W7 Microsoft SQL Server
OLTPWG1     54      2010-05-02 21:03:03.020  LATITUDE830-W7 Microsoft SQL Server

```

You can also monitor CPU and memory resources allocated by the Resource Governor through the Windows Performance Monitor via a couple of new performance counters:

- ▶ SQLServer: Resource Pool Stats
- ▶ SQLServer: Workload Stats

An instance of the SQLServer: Resource Pool Stats counter is available for each of the configured resource pools. Likewise, an instance of the SQLServer: Workload Stats counter is available for each of the configured workload groups (see Figure 40.5). These performance counters return the same information as that returned by the `sys.dm_resource_governor_workload_groups` and `sys.dm_resource_governor_resource_pools` DMVs but enable you to monitor these statistics over time.

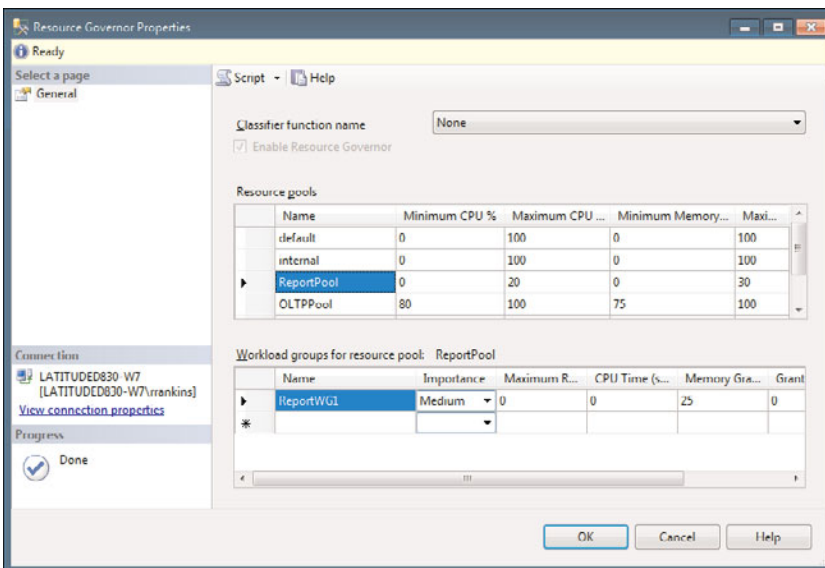

FIGURE 40.5 Monitoring resource pool and workload group statistics in Performance Monitor.

Modifying Your Resource Governor Configuration

You can modify settings for resource pools or workload groups in SQL Server Management Studio via the Resource Governor Properties page, as shown previously in Figure 40.4. You simply make the changes desired (for example, a Resource Pool Maximum CPU% or Workload Group Importance) and click OK to save the changes.

Alternatively, you can modify the resource pool using the `ALTER RESOURCE POOL` command. With this command, you can modify the minimum and maximum CPU and memory percentages for a resource pool. The syntax is as follows:

```
ALTER RESOURCE POOL { pool_name | "default" }
[WITH
    ( [ MIN_CPU_PERCENT = value ]
      [ [ , ] MAX_CPU_PERCENT = value ]
      [ [ , ] MIN_MEMORY_PERCENT = value ]
      [ [ , ] MAX_MEMORY_PERCENT = value ] )
]
```

You can modify workload group settings using the `ALTER WORKLOAD GROUP` command. You can change the workload group settings as well as move the workload group to another resource pool. The syntax is as follows:

```
ALTER WORKLOAD GROUP { group_name | "default" }
[ WITH
    ( [ IMPORTANCE = { LOW | MEDIUM | HIGH } ]
      [ [ , ] REQUEST_MAX_MEMORY_GRANT_PERCENT = value ]
      [ [ , ] REQUEST_MAX_CPU_TIME_SEC = value ]
      [ [ , ] REQUEST_MEMORY_GRANT_TIMEOUT_SEC = value ]
      [ [ , ] MAX_DOP = value ]
      [ [ , ] GROUP_MAX_REQUESTS = value ] )
]
[ USING { pool_name | "default" } ]
```

NOTE

After executing your `ALTER WORKLOAD GROUP` or `ALTER RESOURCE POOL` commands, you need to run the `ALTER RESOURCE GOVERNOR RECONFIGURE` command to apply the changes.

The following example moves the ReportWG1 workload group from the ReportPool1 resource pool to the default resource pool:

```
ALTER WORKLOAD GROUP ReportWG1
USING [default];
GO
```

ALTER RESOURCE GOVERNOR RECONFIGURE
GO

You can also move a workload group to another resource pool in SSMS using the Resource Governor Properties page. Click the Resource Pool name in the Resource Pools grid; then right-click on Workload Group in the Workload Groups grid and select Move To (see Figure 40.6). This brings up the Move Workload Group dialog, which lists the available resource pools the workload group can be moved to. Select the desired resource pool and click OK.

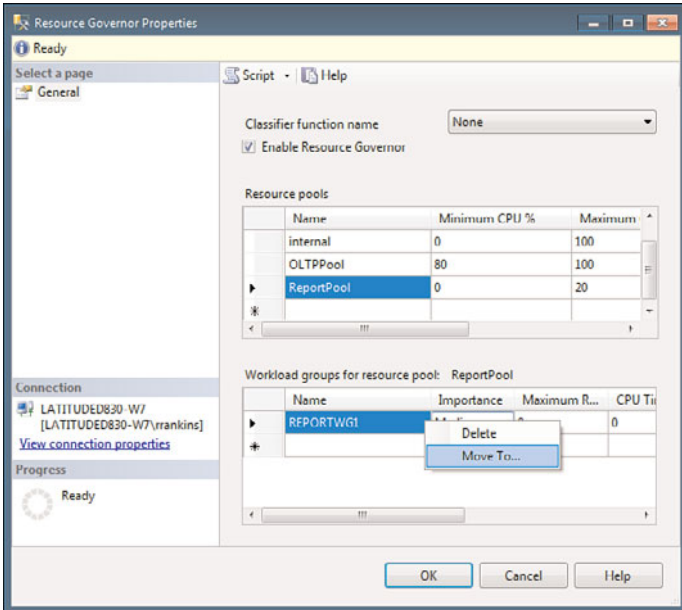

FIGURE 40.6 Moving a workload group in SSMS.

Why move a workload group to a different resource pool? You might decide that a workload group should be in a resource pool that has different configuration settings, or you might want to move workload groups out of a resource pool so that you can drop the resource pool.

Deleting Workload Groups

You can delete a workload group or resource pool by using SQL Server Management Studio or T-SQL. To drop a workload group in SSMS, follow these steps:

1. Expand the Management node in Object Explorer and expand the Resource Governor node to display the Resource Pools folder.
2. Expand the node of the resource pool where the workload group is defined to display the Workload Groups folder.

3. Expand the `Workload Groups` folder to list the workload groups.
4. Right-click the workload group you want to drop and select `Delete`.
5. In the `Delete Object` window, the `Workload Group` is listed in the `Object to Be Deleted` list. Click `OK` to confirm the deletion.

To drop a workload group using T-SQL, use the `DROP WORKLOAD GROUP` command:

```
DROP WORKLOAD GROUP OLTPWG1
ALTER RESOURCE GOVERNOR RECONFIGURE
go
```

You cannot drop a workload group if there are any active sessions assigned to it. If a workload group contains active sessions, deleting the workload group or moving it to a different resource pool will fail when the `ALTER RESOURCE GOVERNOR RECONFIGURE` statement is called to apply the change. The following options provide a way to work around this problem:

- ▶ Wait until all the sessions from the affected group have disconnected and then rerun the `ALTER RESOURCE GOVERNOR RECONFIGURE` statement.
- ▶ Explicitly stop sessions in the affected group by using the `KILL` command and then rerun the `ALTER RESOURCE GOVERNOR RECONFIGURE` statement.
- ▶ Restart SQL Server. When the restart process is complete, the deleted group will not be created, and a moved group will automatically use the new resource pool assignment.

NOTE

If an attempt to reconfigure Resource Governor fails after dropping a workload group because of active sessions and you change your mind about dropping the workload group, you can restore it by rerunning the `CREATE WORKLOAD GROUP` command for that workgroup. After re-creating the workload group, run the `ALTER RESOURCE GOVERNOR RECONFIGURE` command again, and the workload group is restored.

Deleting Resource Pools

To drop a resource pool in SSMS, follow these steps:

1. Expand the `Management` node in `Object Explorer` and expand the `Resource Governor` node to display the `Resource Pools` folder.
2. Expand the `Resource Pools` folder to list the resource pools defined.
3. Right-click the resource pool you want to drop and select `Delete`.
4. In the `Delete Object` window, the resource pool is listed in the `Object to Be Deleted` list. Click `OK` to confirm the deletion.

To drop a workload group using T-SQL, use the `DROP RESOURCE POOL` command:

```
DROP RESOURCE POOL OLTPPOOL
ALTER RESOURCE GOVERNOR RECONFIGURE
go
```

You cannot drop a resource pool if any workload groups are still assigned to the resource pool. You need to drop the workload group or move it to another resource pool first.

Modifying a Classification Function

If you need to make a change to the classification function, it's important to note that the function cannot be dropped or altered while it is marked as the classification function for the Resource Governor. Before you can modify or drop the classification function, you first need to disable Resource Governor. Alternatively, you can replace the classification function with another by running the `ALTER RESOURCE GOVERNOR` command and passing it a different `CLASSIFIER_FUNCTION` name. You can also simply disable the current classifier function by executing the following command:

```
ALTER RESOURCE GOVERNOR
    WITH (CLASSIFIER_FUNCTION = NULL);
ALTER RESOURCE GOVERNOR RECONFIGURE;
```

The sample classification function shown in Listing 40.1 uses a simple case expression to determine the workload group based on only two login IDs. If you have a more complex set of rules to apply or want to be able to make changes more dynamically than having to replace the classification function each time you need to make a change, you can define your classifier function to look up the workload group names from a database table, rather than hard-coding the workload group names and matching criteria into the function. Performance should not be greatly affected when accessing the table to look up the workload group. The reason is that the table likely won't be very large and should remain cached in the buffer pool because it's being accessed repeatedly every time a connection is made to SQL Server.

Summary

Resource Governor offers many potential benefits, primarily the capability to prioritize SQL Server resources for critical applications and users and preventing “runaway” or unexpected queries from adversely impacting SQL Server performance significantly. It fits in with Microsoft’s goal of providing predictable performance for your SQL Server applications.

Resource Governor also offers some potential pitfalls, however. For example, a misconfigured Resource Governor can not only hurt a server’s overall performance, but can potentially lock up your server, requiring you to use the dedicated administrator connection to attach to the locked-up SQL Server to troubleshoot and fix the problem. Therefore, it is recommended that you implement Resource Governor only if you are an experienced DBA and have a good understanding of, and familiarity with, the workloads executed against your SQL Server databases. Even then, it’s imperative that you test your configuration on a test server before rolling it out into production.

Also, after implementing a Resource Governor configuration, you should monitor your SQL Server performance to make sure the configuration has the desired effect. The next chapter, “A Performance and Tuning Methodology,” provides guidelines for monitoring and tuning the performance of your SQL Server environment.

CHAPTER 41

A Performance and Tuning Methodology

Yes, you can tune your SQL Server implementation to perform optimally for you. However, random jabs at bleeding arteries may stop immediate bleeding, but the patient will die before too long. Forgive the graphic analogy, but all too often, performance and tuning is crudely attempted with extremely serious oversights and very often extremely poor results. Usually, you can avoid this outcome if you follow basic, orderly steps when tuning your SQL Server platform and understand the complete SQL Server ecosystem. This chapter describes a repeatable performance and tuning methodology that has been refined over the past decade during hundreds of performance and tuning consulting engagements on SQL Server implementations running at some of the largest companies on the planet.

Good performance really starts when you design it into your implementation from the beginning. Even the best-designed applications require fine-tuning over time. Unfortunately, dealing with performance is very often put off or not considered at all until it becomes a problem in production!

As a part of introducing a formal performance and tuning approach, we describe the overall architectural landscape of most applications and how SQL Server sits within this environment. You should keep in mind that addressing performance and tuning of your SQL Server implementation is a layered exercise and all layers must be considered; all layers factor into your results. We also discuss an assortment of design considerations (guidelines) that you should incorporate into your designs from the beginning. And lastly, we outline several tools of the trade when focusing on performance and tuning. Some are out-of-the-box from Microsoft;

IN THIS CHAPTER

- ▶ The Full Architectural Landscape
- ▶ Primary Performance and Tuning Handles
- ▶ A Performance and Tuning Methodology
- ▶ Performance and Tuning Design Guidelines
- ▶ Tools of the Performance and Tuning Trade

others are from third-party providers that allow you to visualize and rapidly isolate your performance issues as they are happening. A number of other chapters in this book are dedicated to the actual performance tuning of a SQL Server instance, SQL tables, and SQL statements. This chapter provides you with a framework and ordered process to attack a SQL Server-based environment from top to bottom that will yield thorough and complete results. No more just stopping the bleeding artery. We want to cure the patient!

The Full Architectural Landscape

As mentioned previously, understanding all layers of your implementation is critical to performance and tuning of your SQL Server application. Even the smallest aspect, such as locking, could be at the heart of your poor performing system. You just don't truly know until you have evaluated all layers and all interactions that come into play in your SQL Server application. Figure 41.1 provides an overall perspective of all the layers of the architecture that you need to better understand and potentially tune.

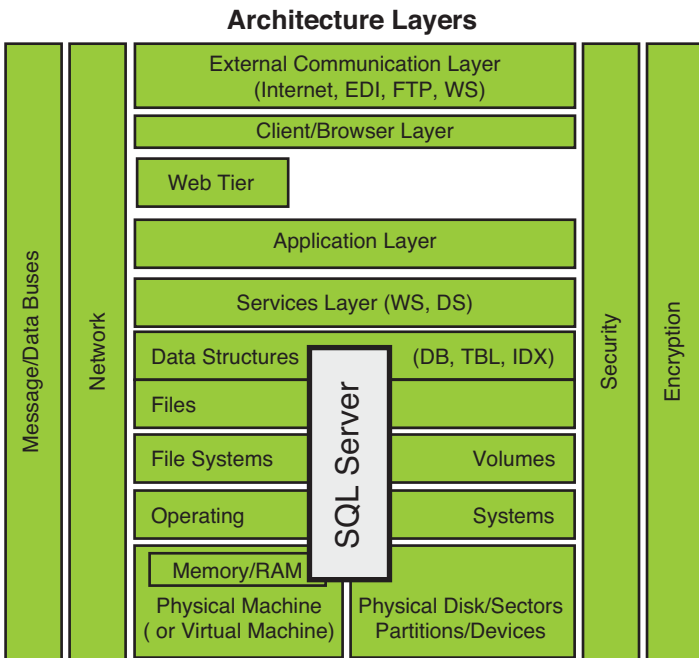

FIGURE 41.1 The overall architectural landscape of a SQL Server implementation.

As you can see in Figure 41.1, your SQL Server environment sits at the heart of many different layers. They include the hardware (either physical or virtual footprint), memory, physical disks/devices, operating system, file systems, and database, to name a few. Quite often, a combined effort is needed between the infrastructure, application, database, and network teams to deliver the final, well-tuned SQL Server environment. If you can under-

stand that you have not just a database problem or just an application design problem, you will likely be more successful at delivering “optimal” results when tuning your environment. You can treat Figure 41.1 as a checklist that you make sure you cover when doing performance and tuning. Then, when you make a change in one layer, you can make sure you test the full impact throughout all the other layers. Often, when you solve one issue in one layer, other issues bubble up to the surface of another layer.

Primary Performance and Tuning Handles

Now, let’s peel the onion a little more into the core architecture of SQL Server itself. Figure 41.2 shows the primary components within a SQL Server instance. The major issues to worry about at the instance level are the caches that comprise the memory pool and the number of CPUs available for processing to SQL Server itself (shown as white boxes, not dark ones). Of course, the disk I/O subsystem and files have to be carefully evaluated and used effectively as well. All other darker boxed items such as the SQL Server kernel are not within your control.

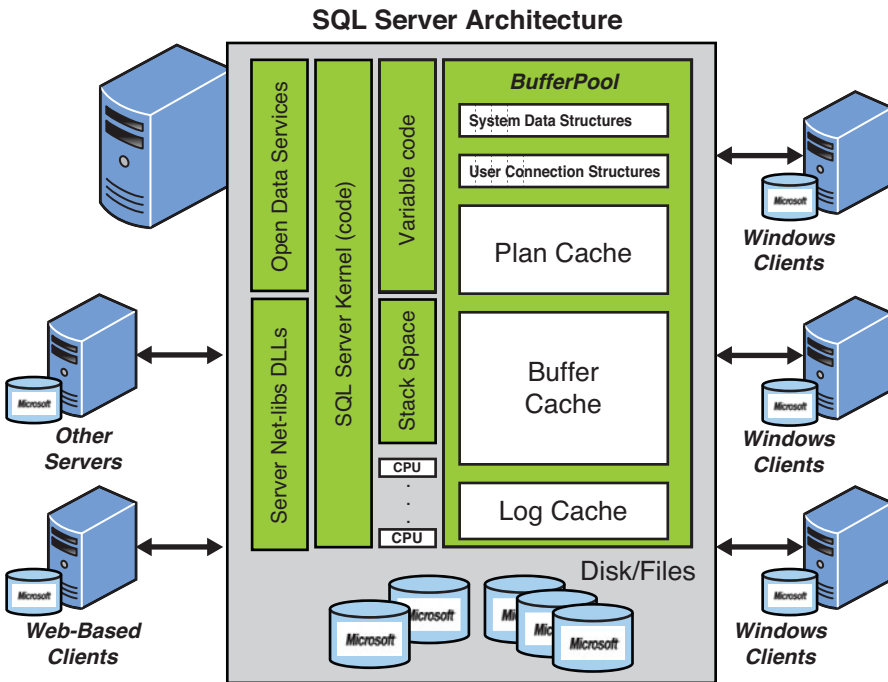

FIGURE 41.2 SQL Server instance architecture (memory, CPU, I/O).

The rule of thumb here is to treat these instance-level resources as “scarce” resources and monitor the CPU and disk I/O for their saturation levels (never exceeding 80%) and memory for its hit ratio and capability to service the desired amount of concurrent work

at or better than the service-level requirements of your end users (even during peak usage times).

Figure 41.3 shows a more readily recognizable combination of “handles” that are the major areas a human can adjust to achieve optimal performance.

FIGURE 41.3 SQL Server handles available for performance tuning.

We’ve already mentioned CPU, cache/memory, and disk I/O; these and all the other handles listed in Figure 41.3 work together and must be considered together when doing performance and tuning. A change in a SQL statement affects what the optimizer (which makes decisions regarding how data is accessed in SQL Server) will do to satisfy the query. The correct index allows the query to get data the most effective way. The correct table design drastically affects updates, deletes, inserts, and reads. The number of CPUs available to SQL Server can invoke parallelism. What work is done in tempdb (and where tempdb is located) can improve performance by 1000%. The index and table level fill factor (free space), number of page splits, and page allocations being done within your databases can hurt you by 1000%. Hints to the optimizer can change the way execution is handled. And other issues such as materialized views, partitions, and file placement (at the disk subsystem level) directly contribute to the overall performance of every SQL execution. Even something as simple as locking (or deadlocks) and the consistent order of update operations within transactions can make or break an entire SQL Server implementation.

We explain a bit more of what to look for with the primary handles in the guideline section later. For most development or production support teams, tackling performance and tuning for SQL Server can truly be overwhelming. The next section describes an orderly performance and tuning methodology that most should be able to follow and use to yield great results.

A Performance and Tuning Methodology

A *methodology* is a process or procedure, for example, designed for repeatability that has been proven to work for a certain paradigm. In our case, it is a repeatable and thorough SQL Server–focused performance and tuning process. We generalized this focused process into a repeatable methodology and identified two possible paths that can be taken through it: one for a *new* SQL Server implementation that will have performance and tuning designed into it from the start and another for performance and tuning of an

existing SQL Server implementation (one that needs to be scaled out or rescued—or in other words, “optimized”).

Figure 41.4 illustrates this overall performance and tuning methodology within a traditional waterfall development methodology context. But, as you will see, it is very iterative in nature and can be followed within any organization’s formal development methodology.

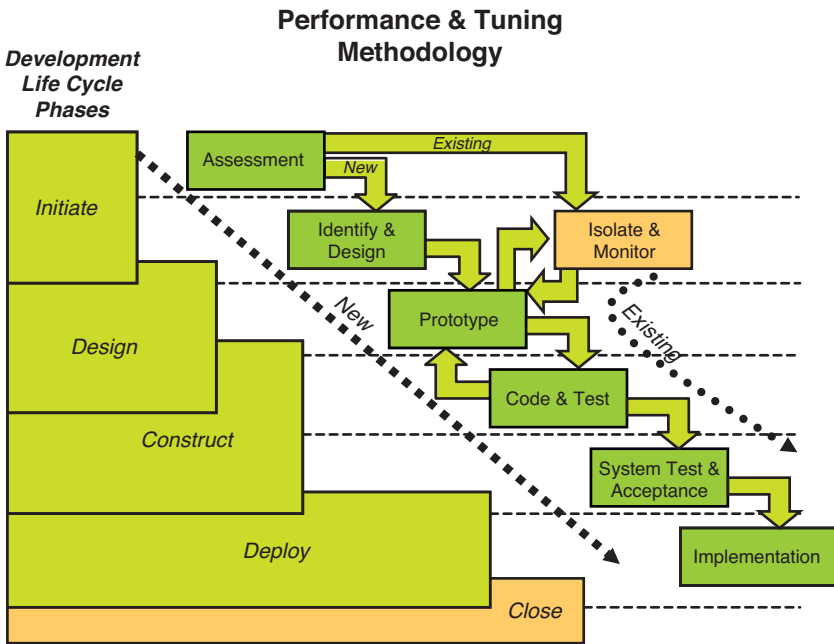

FIGURE 41.4 Generalized performance and tuning methodology for SQL Server.

Notice the two distinct paths labeled “New” and “Existing” indicated by the dashed arrowed lines. As mentioned earlier, one path is for new implementations, and the other is for existing implementations. The following sections describe each of these distinct paths through the methodology.

Designing In Performance and Tuning from the Start

If you are just starting to design and develop a new SQL Server–based implementation, it would be great to factor in all possible performance and tuning considerations from the beginning. In real life, this is rarely done primarily because much is unknown from a data access, number of users, and table design point of view. However, you are not precluded from designing in certain common performance and tuning considerations, nor are you precluded from incorporating a performance and tuning “prototyping” step in your methodology so that you have known and predictable results of what you are building “as you go” and not “at the end.” As you have no doubt experienced (or heard many times), changing something after it is built is more expensive than if you had considered it much

earlier in the development process. In fact, such changes are likely at least 10 or more times more expensive from both a monetary point of view and from a time point of view.

As you can see in Figure 41.4, each path begins with an assessment step. For new development, this step covers the traditional “initiation” type of activities, such as project sizing, scheduling, scope refinement, and resourcing. As you identify project sizing, scheduling, and resourcing, you should add in 5% to each subsequent phase of your traditional development life cycle for performance and tuning activities. We outline these activities shortly. In general, they include capturing performance goals, having performance and tuning design reviews, building prototypes optimized to meet these performance goals, and setting final checkpoints that demonstrate full compliance of performance achievement under full loads. Our performance and tuning methodology for new implementations focuses on six major steps along the way to deployments. We don’t list all the tasks or activities around your programming or user interface activities. Instead, we just focus on the SQL Server–oriented items that pertain to optimal performance and tuning.

The six development methodology steps are

- ▶ Assessment
- ▶ Identify and Design
- ▶ Prototype
- ▶ Code and Test
- ▶ System Test and Acceptance
- ▶ Implementation

Assessment

During this project initiation phase, a complete picture of the effort is usually identified and assessed at a high level. This includes

- ▶ **Project sizing**—Determines if this is a small, medium, or larger project.
- ▶ **Project scope clarifications**—Describe the intent and application scope to be created.
- ▶ **Deliverables identified**—Identifies deliverables for all subsequent phases of the project. This should also include new tasks for performance and tuning activities.
- ▶ **Schedules/milestones**—Reflect what is needed to build this application, when it must be delivered, and everything along the way.
- ▶ **Resources identified and committed to project**—Includes some specialized resources that enable your performance and tuning tasks and reviews.

All organizations have their own version of this step/phase, but you should note that you need to plan in time for performance and tuning from the beginning. We suggest at least adding 5% to the number of hours to performance and tuning tasks for each subsequent step in the development life cycle. That 5% will save you enormous heartache and grief later and will ensure the success of your implementation.

Identify and Design

The identification and design step is centered around the clear identification of what must be built, what service-level agreements are needed, and what performance goals must be met. The performance and tuning-oriented tasks are as follows:

- ▶ **Identify the primary service-level agreements (SLAs)/performance goals**—This task is critical and must be stated clearly and realistically. Sub-second response rates are likely not realistic for every element of an application. You will be measured against these goals.
- ▶ **Estimate work load/use profiles**—These profiles are the general volumes of major activity this application must support, such as 68% online activity, 32% reporting activity, and availability such as 24×7×365. These profiles should also include any known growth estimates for different increments of time such as 6-month growth numbers, 12-month growth numbers, so on.
- ▶ **Generalize to major access patterns**—This task quantifies the major data access patterns that must be supported by the application. Knowing these patterns is essential in order to design in performance from the start. Examples of data access patterns are a shopping cart access pattern and an ATM access pattern. They would be vastly different in their table, indexing, and transactional designs.
- ▶ **Design for all layers of the architecture**—Based on the performance goals, workloads, and major data access patterns, your initial designs should not only cover the SQL Server objects (such as table designs, index designs, and so on), but must also reach out to each other's architectural layer previously identified. Now is the time to design on the correct partitioning scheme, correct transactional model, correct file placement approach, correct disk subsystem to use, correct servers needed, and memory management needs of your application. You should include a task in your project plan for a complete performance and design review.

Prototype

We added a formal prototyping step into this methodology to stress how important it is to fully evaluate and understand the performance expectations of the application you are building. This very iterative process can help greatly in refining the designs being considered. Go ahead and build a prototyping environment where you can thoroughly try out what you have designed in the preceding “Identify and Design” step. Your prototype should illustrate (and implement) the major data access patterns you must support, show how they are achieving planned performance goals, and indicate whose results must be signed off on to pass to the next development phase step. You may have to iterate back through this and the preceding step several times to narrow in on a more optimal design solution. Use this time now to ensure success later.

- ▶ **In a prototype environment, prototype possible solutions**—This is for a generalized design and does not have to include every column of data or functionality of the application. There may be one or more possible solutions that you must prototype. The prototype is at the generic “pattern” level. Often we use tables that have artificial columns as placeholders of known unusual data types along with the

minimal known columns needed to implement a data access pattern and table design.

- ▶ **Dissect trouble areas**—During the prototyping, you will have issues around your design and the performance results you are getting. Now is the right time to solve these types of issues. Not later.
- ▶ **Ramp up for load/stress testing**—Your prototypes should include some level of volume or peak stress testing results so you can have a good understanding of what to expect at peak times. In addition, it is beneficial to prototype and test with data volumes that are representative of your expected production data volumes. This helps to identify ahead of time any performance issues that may arise when querying and processing larger data volumes.

NOTE

Very large volumes of data may require modifications to the database design to provide good performance. The earlier this need is determined in the design/testing process, the less expensive it will be to implement these changes in the system while code is still being developed rather than having to make changes after the system has been put into production.

- ▶ **Iterate back to the “Identify and Design” step (as needed)**—Design and redesign as much as is needed. Prototyping helps you narrow in on an optimized solution quickly. In general, shoot for a 90% solution (one that meets performance within 10% of stated goals).

You should also have the right tools available to you during this prototyping step. This includes monitoring tools, performance and tuning tools, and other instrumentation needed to better understand and resolve any early issues that surface. Later in this chapter, we outline several tools of the trade for performance and tuning in a SQL Server platform and performance and tuning guidelines that you can follow.

Code and Test

In the “Code and Test” stage, you fully code all elements of your application. This includes all table designs, index designs, application coding, and complete testing prior to the system test and user acceptance.

- ▶ **Perform full coding and unit/load testing**—At this point, perform complete coding of your application and database. Each unit test must also include a step to determine how it is meeting performance goals/SLAs. Most programmers are not accustomed to this checkpoint. The code does not go forward unless the goals/SLAs are fully met. No exceptions. Again, whenever possible, testing should be done with data volumes and values that are representative of the expected production data after the system has been running for an extended period of time. Doing so is very important to help avoid future performance issues when the system is in production,

because as data volumes grow, queries may optimize differently. Queries that run quickly with small data volumes may optimize differently and run slowly with larger data volumes. However, if you can optimize the database design and queries to provide good performance when you have large data volumes, performance should be just as good or even better with smaller data volumes as well.

- ▶ **Perform regression testing if desired**—Utilize full regression testing if you desire. This step usually requires complex testing harnesses and dedicated quality assurance resources.
- ▶ **Iterate back to the “Prototype” step (as needed)**—Don’t be afraid to iterate back into the prototyping mode to flesh out a serious issue. You need to solve issues now, not later in production or in acceptance testing.
- ▶ **Assess if service levels have been met**—Create a formal checkpoint that must be passed around the service levels and performance goals being met. You cannot proceed to the next step unless they are met!

System Test and Acceptance

The “System Test and Acceptance” stage is the full-blown integrated system test in a production-like environment. You do final user acceptance and full system-level stress tests here. All your performance goals must be fully met! Again, you need to have a formal checkpoint identified here that requires signoff of the SLAs/performance goals and fully document the results for the system stress tests.

In the full system/stress test/user acceptance, your fully loaded application and database are thoroughly tested by your users, and a full stress test is done to reflect peak system usage. The users should not sign off on this step unless the performance goals are met, and the application’s functional test is successful.

If possible, this stage should reflect what the complete production hardware and software stack will look like. By now, you should also be able to set expectations for both current and future scalability of this application.

Implementation

By design, the implementation should be merely a formality. Certainly, all performance concerns should have been met, documented, and verified even under peak processing scenarios. It is also recommended that any production implementation include a certain amount of performance and tuning instrumentation and monitoring. This should be a standard part of any production implementation environment now.

- ▶ **Production build/implementation**—You should perform a complete buildout of your application in production.
- ▶ **Production performance and monitoring**—You need to have complete performance and tuning instrumentation and monitoring in place and tied to your system monitoring services (SMS) environment. There is usually a proactive monitoring following a new implementation for an extended amount of time. Don’t just implement and walk away. There is likely something that must be adjusted.

- **Final documentation/results**—In this step, you create a set of documents that reflect what you built and also the current performance levels being achieved. These documents will be valuable later as the application changes and workloads increase.

Figure 41.5 shows a holistic picture of the different layers that you have been building on and how these different layers depend on each other and are built on each other. Make sure you have checked off and considered each of them in your pursuit of optimizing your SQL Server–based implementation.

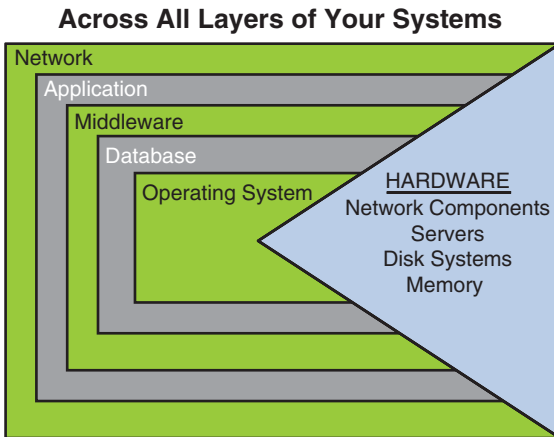

FIGURE 41.5 The many interrelated layers of your system.

Starting at the hardware footprint, to the operating systems that sit on top of the hardware, to the database and middleware implemented on top of the OS, to the application itself (however many application tiers), and the network supporting the communication to the users—all have a part in delivering an optimal implementation.

The next section describes our formal performance and tuning methodology applied to an existing implementation.

Performance and Tuning for an Existing Implementation

Many of you may have just skipped down to this section because you have already built something and are trying to get to some serious performance and tuning for your existing implementation. Regardless of your situation, the essence of this section is describing the methodology for isolation, identification, and migration to get your existing implementation to a well-performing and tuned implementation. We use *isolation* in the sense that you must isolate the major performance issues quickly, *identification* in the sense of locating the exact issues to focus on, and *migration* in the sense of having to get from the current issues to a new issue-free implementation. This last part is often incredibly hard to do—like changing tires on a car while it is still moving. With this in mind, a different path through the performance and tuning methodology is needed—one that starts with an assessment, but an assessment of what issues or shortcomings exist, and then a sepa-

rate branch (path) that includes isolation, monitoring, and identification of the issues rapidly. This is then followed by rapid prototyping and further isolation and monitoring and eventual full system testing and rolling out the changes into your production implementation.

One big advantage of doing performance and tuning on an existing implementation is that you have live transactional information, live data, and other production execution history to work from. From all of these, you should be able to piece together a good execution profile, all the major data access patterns, and other major characteristics critical to tuning what you have. You also are able to include new information or scalability needs as well.

Another initial decision you need to make is whether you want only transparent changes (ones that have no application changes whatsoever, such as index changes, server instance changes, file placement changes, some stored procedure changes, and so on) or if you can tolerate making nontransparent changes (ones that force you to also make schema, structure, and SQL statement changes, and even application changes). Of course, your decision depends on how much trouble you are in.

Now, let's look back at Figure 41.4 and focus on the far right-most path through this methodology. We start by recasting the traditional "initiation" type of activities such as project sizing, scheduling, scope refinement, and resourcing to focus on just the performance and tuning tasks at hand. Again, we don't list all the tasks or activities around your programming or user interface activities; we just focus on the SQL Server-oriented items that pertain to optimal performance and tuning.

Performance and tuning methodology steps for an existing implementation are as follows:

- ▶ Assessment
- ▶ Isolation and Monitor
- ▶ Prototype
- ▶ Code and Test
- ▶ System Test and Acceptance
- ▶ Implementation

Assessment

For this first step, assessment, a complete picture of the performance issues or expectations must be outlined. This includes

- ▶ **Project sizing**—Determines if the performance and tuning effort you are about to engage in will be a small, medium, or large project. Although it is not a full-blown development project, it could certainly be bigger than you realize.
- ▶ **Project scope clarifications**—Identify mostly whether you can tolerate only transparent changes versus nontransparent changes to resolve your performance issues.

- ▶ **Deliverables identified**—Focuses mostly on performance and tuning activities but may be expanded to application activities if the changes needed must extend into the application itself.
- ▶ **Schedules/milestones**—Reflect what is needed to monitor, isolate, identify, and roll out the changes needed.
- ▶ **Resources identified and committed to project**—Identifies resources centered around your best performance and tuning folks. Don't scrimp here. Even if you have to hire some experts to help with this effort, this is money well invested.

Isolate and Monitor

Now comes the specialized path down the performance and tuning methodology for existing implementations. It is time to monitor, isolate, and identify exactly where your problems are. In addition, you must not lose sight of the complete stack and all the layers that will potentially be a part of your performance issues.

You also need to revisit (or define for the first time) what service-level agreements are needed and what performance goals must be met. The performance and tuning-oriented tasks are as follows:

- ▶ **Identify the primary service-level agreements (SLAs)/performance goals**—If you haven't performed this task yet, the time is now. If you did it previously, it is time to revisit what these SLAs should be realistically. Again, subsecond response rates are likely not realistic for every element of an application. You should also add new or emerging scalability and growth needs to your goals now. This may have some very significant impact to new design decisions or performance and tuning approaches that would be different if all you needed to do was tune for an existing, unchanging workload.
- ▶ **Set up your execution capture and monitoring capabilities**—You should perform this task at each of the layers in your architecture if you can. Remember, many performance issues often are spread across multiple areas. Our preference is to get peak production monitoring. This includes basic monitoring using Perfmon counters, SQL Server Profiler tracing, and even third-party monitoring tools that can help you see major issues graphically as they are happening. We talk about tools of the trade later in the chapter.
- ▶ **Isolate hottest issues**—We like to use the 90/10 rule such that 10% of your execution transactions or implementation configurations are likely causing 90% of your problems. If you solve that 10%, you have a well-performing platform. These issues must be isolated layer by layer (network, hardware, OS, application server/application, SQL Server instance, database, SQL statements, and so on).
- ▶ **Create workloads/use profiles**—Utilizing the tracing/capture tools, you need to capture and organize where the problem issues are located at each layer. For SQL statements, this means capturing and ordering the worst-performing SQL into the top 100 worst by I/O and CPU consumption usually. You also need to identify concurrency issues (locking/deadlocks), disk/file utilization queues, cache utilization,

and many other handles. It is from these issues that you must create repeatable execution patterns so that you can tune to support them. You must also execute all activities such as batch processes and so on that might not normally come into play until scheduled events have occurred. For new growth or scalability increases, add the appropriate workloads, use profiles, and SQL statements into the mix.

- ▶ **Identify issues and possible solutions for all layers of the architecture**—Based on the performance goals, workloads, and major data access patterns, you need to come up with a series of performance changes prioritized by the biggest impact. These changes may include SQL Server objects changes (such as table changes, new or different indexes, and so on) but could also reach out to other architectural layers previously identified. These changes can also affect adding or changing a partitioning scheme, fixing a transactional model, correcting the file placements, changing the disk subsystem or server configurations, and adjusting the memory requirements of your application. Before you make any changes, you should have a comprehensive performance review that outlines all issues identified and proposes solutions to each.

Prototype

You now enter an iterative cycle between isolate, monitor, prototype, isolate, monitor, and prototype. This cycle may repeat for any number of iterations as you deem necessary. You should set your overall goals to achieve at least 95% of your performance goals. It isn't too hard to get to that point. However, it is hard to squeeze out that last 5%, though. Often, getting those last few yards isn't really going to buy you that much more relief.

When you want to get good performance and tuning results, it's always best to utilize a prototyping environment that is very much like your production environment (or at least as close to the same as possible in all aspects—memory, CPU, disk subsystems, data volumes, and so on). Optimizer decisions and I/O times, for example, vary greatly from one configuration to another. If your prototyping system is completely different from your production system or configuration, you will likely be able to achieve only 80% of your performance goals and SLAs. Often, we are able to use a company's QA/User Acceptance Testing environment, which is a mirror image of the production system, including a very current and complete production database backup image being used for the system testing. You need to negotiate time with this type of environment. Some prototyping can be accomplished on smaller environments (such as testing new partitioning schemes, new SQL query statements, and so on). But you need to run this all on a full-blown production-like environment before it is all said and done.

Again, your prototype should illustrate (and implement) the major data access patterns you must support, show how they are achieving planned performance goals, and indicate whose results must be signed off on to pass to the next development phase step. You may have to iterate back through this and the preceding step several times to narrow in on a more optimal design solution. You need to have full execution monitoring and tracing set up in this prototyping environment.

- ▶ **Create a complete prototype environment**—Remember that you have to test existing and new solutions, not just one or the other. A change in something new

may adversely affect something that was fine before, but becomes slow performing with the new solution. There may be one or more possible solutions that you must prototype to get the best results. You will be using “live” patterns based on production queries for the most part now. Any new functionality or solutions will be added to this mix.

- ▶ **Ramp up for load/stress testing**—Your prototypes should include some full level of volume or peak stress testing results so you can have a good understanding of what to expect at peak times and the potential impact of performance changes to one aspect of the system on another, such as increased locking contention.
- ▶ **Iterate back to the “Isolate and Monitor” step (as needed)**—Change, enhance, and try out new solutions in this iterative circle. Using a prototyping approach allows you to narrow down to what works best rather quickly.

Remember that you should have the right tools available to you during this prototyping step. They include monitoring tools, performance and tuning tools, and other instrumentation needed to better understand and resolve any early issues that surface. Again, later in this chapter we outline several tools of the trade for performance and tuning in a SQL Server platform and performance and tuning guidelines that you can follow.

Code and Test

The “Code and Test” step takes on a more formal process after the prototyping of all possible performance and tuning enhancements has been completed. In this step, you fully code all elements of your application with any changes that have resulted from the prototyping effort. This includes all table designs, index designs, and application coding prior to the final system test and user acceptance. Remember, if you are doing only the transparent changes, this part should be fairly easy; but if your changes are nontransparent, this will be a full-blown code and test phase of your entire application.

- ▶ **Perform full coding and unit/load testing**—Perform complete coding of the application and database. Each unit test must also include a step determining how they are meeting performance goals/SLAs. Most programmers are not accustomed to this checkpoint. The code does not go forward unless the goals/SLAs are fully met. No exceptions.
- ▶ **Perform regression testing if desired**—Utilize full regression testing if you desire. This step usually requires complex testing harnesses and dedicated quality assurance resources.
- ▶ **Iterate back to the “Prototype” step (as needed)**—Don’t be afraid to iterate back into the prototyping mode to flesh out a serious issue. You need to solve issues now, not later in production or in acceptance testing.
- ▶ **Assess if service levels have been met**—Create a formal checkpoint that must be passed around the service levels and performance goals being met. You cannot proceed to the next step unless these goals are met!

System Test and Acceptance

The next step is the full-blown integrated system test in a production-like environment. You do final user acceptance and full system-level stress tests here. All your performance goals must be fully met! Again, you need to have a formal checkpoint identified here that requires signoff of the SLAs/performance goals and fully document the results for the system stress tests.

In the full system/stress test/user acceptance, your fully loaded application is thoroughly tested by your users, and a full stress test is done to reflect peak system usage. The users should not sign off on this step unless the performance goals are met, and the application's functional test is successful.

If possible, this stage should reflect what the complete production hardware and software stack will look like. By now, you should also be able to set expectations for both current and future scalability of this application.

Implementation

The biggest issues now are migrating your new changes into the existing production implementation. This may include complex data structure changes and data migrations from old structures to new structures, or may simply involve dropping and re-creating indexes. You should plan all steps of your changes to the n^{th} degree and test the upgrades on your QA platform a few times. You may have to schedule downtime for extensive nontransparent changes. You should make full backups at all layers prior to your live upgrade in production. Be sure to have a set of performance benchmark operations ready to run in production to verify the results you intended.

- ▶ **Production build/implementation**—You should perform a complete buildout of your application in production and full migration upgrade scripts/data conversions.
- ▶ **Production performance and monitoring**—You need to have complete performance and tuning instrumentation and monitoring in place and running. Run a series of performance testing scripts/queries as a part of your production upgrade process. Don't just implement and walk away. There is likely something that must be adjusted even at this late stage.
- ▶ **Final documentation/results**—In this step, you create a set of documents that reflect what you built and also the current performance levels being achieved.

In theory, you should now be in an optimized execution implementation. You should be prepared to monitor, monitor, and monitor some more. We traditionally keep a close monitoring eye for about five days of execution and then switch back to a normal amount of proactive monitoring after that.

The following sections highlight some common design techniques, approaches, and guidelines you should consider or utilize as you tune your SQL Server implementation.

Performance and Tuning Design Guidelines

We outline some of the major performance and tuning design guidelines here. There are, of course, many more, but if you at least consider and apply the ones outlined here, you should end up with a decently performing SQL Server implementation. As we have described previously, performance and tuning should first be “designed in” to your SQL Server implementation. Many of the guidelines discussed here can be adopted easily in this way. However, when you put off the performance and tuning until later, you have fewer options to apply and less performance improvement when you do make changes. Remember, addressing performance and tuning is like peeling an onion. And, for this reason, we present our guidelines in that way—layer by layer. This approach helps provide you with a great reference point for each layer and a list you can check off as you develop your SQL Server–based implementation. Just ask yourself whether you have considered the specific layer guidelines when you are dealing with that layer. Also, several chapters take you through the full breadth and depth of options and techniques introduced in many of these guidelines. We point you to those chapters as we outline the guidelines.

Hardware and Operating System Guidelines

Let’s start with the salient hardware and operation system guidelines that you should be considering:

Hardware/Physical Server:

- ▶ **Server sizing/CPU**s—Physical (or virtual) servers that will host a SQL Server instance should be roughly sized to handle the maximum processing load plus 35% more CPUs (and you should always round up). As an example, for a workload that you anticipate may be fully handled by a four-CPU server configuration, we recommend automatically increasing the number of CPUs to six. We also *always* leave at least one CPU for the operating system. So, if six CPUs are on the server, you should allocate only five to SQL Server to use. You can find details on configuring CPUs in Chapter 55, “Configuring, Tuning, and Optimizing SQL Server Options,” and details on monitoring CPU utilization in Chapter 39, “Monitoring SQL Server Performance.”
- ▶ **Memory**—The amount of memory you might need is often directly related to the amount of data you need to be in the cache to achieve 100% or near 100% cache hit ratios. This, of course, yields higher overall performance. We don’t believe there is too much memory for SQL Server, but we do recognize that some memory must be left to the operating system to handle OS-level processing, connections, and so on. So, in general, you should make 90% of memory available to SQL Server and 10% to the OS. You can find details on configuring memory in Chapter 49 and details on monitoring memory utilization in Chapter 39.
- ▶ **Disk/SAN/NAS/RAID**—Your disk subsystem can be a major contributor to performance degradation if not handled properly. We recognize that there are many different options available here. We generally try to have some separate devices on

different I/O channels so that disk I/O isolation techniques can be used. This means that you isolate heavy I/O away from other heavy I/O activity; otherwise, disk head contention causes massive slowdowns in physical I/O. When you use SAN/NAS storage, much of the storage is just logical drives that are heavily cached. This type of situation limits the opportunity to spread out heavy I/O, but the caching layers often alleviate that problem. In general, RAID 10 is great for high update activity, and RAID 5 is great for mostly read-only activity. You can find more information on RAID and storage options in Chapter 38, “Database Design and Performance.”

Operating System:

- ▶ **Page file location**—When physical memory is exceeded, paging occurs to the page file. You need to make sure that the page file is not located on one of your database disk locations; otherwise, performance of the whole server degrades rapidly.
- ▶ **Processes’ priority**—You should never lower the SQL Server processes in priority or to the background. You should always have them set as high as possible.
- ▶ **Memory**—As mentioned earlier, you should make sure that at least 10% of memory is available to the OS for all its housekeeping, connection handling, process threads, and so on.
- ▶ **OS version**—You should make sure you are using the most recent version of the operating systems as you can and have updated with the latest patches or service packs. Also, often you must remove other software on your server, such as specialized virus protection. We have lost track of the number of SQL Server implementations we have found that had some third-party virus software installed (and enabled) on it, and all files and communication to the server were interrupted by the virus scans. Rely on Microsoft Windows and your firewalls for this protection rather than a third-party virus solution that gets in the way of SQL Server. If your organization requires some type of virus protection on the server, at least disable scanning of the database device files.

Network:

- ▶ **Packet sizes/traffic**—With broader bands and faster network adapters (typically at least 1GB now), we recommend you utilize the larger packet sizes to accommodate your heavier-traffic SQL Server instances. Packets of 8KB and larger are easily handled now. Information on configuring the SQL Server packet size is available in Chapter 49.
- ▶ **Routers/switches/balancers**—Depending on if you are using SQL clustering or have multitiered application servers, you likely should utilize some type of load balancing at the network level to spread out connections from the network and avoid bottlenecks.

SQL Server Instance Guidelines

Next comes the SQL Server instance itself and the critical items that must be considered:

- ▶ **SQL Server configuration**—We do not list many of the SQL Server instance options here, but many of the default options are more than sufficient to deal with most SQL Server implementations. See Chapter 49 for information on all the available options.
- ▶ **SQL Server device allocations**—Devices should be treated with care and not over-allocated. SQL databases utilize files and devices as their underlying allocation from the operating system. You do not want dozens and dozens of smaller files or devices for each database. Having all these files or devices becomes harder to administer, move, and manipulate. We often come into a SQL Server implementation and simplify the device allocations before we do any other work on the database. At a minimum, you should create data devices and log devices so that you can easily isolate (separate) them.
- ▶ **tempdb** database—Perhaps the most misunderstood SQL Server shared resource is tempdb. General guidelines for tempdb is to minimize explicit usage (overusage) of it by limiting temp table creation, sorts, queries using DISTINCT clause, so on. You are creating a hot spot in your SQL Server instance that is mostly *not* in your control. You might find it hard to believe, but indexing, table design, and even not executing certain SQL statements can have a huge impact on what gets done in tempdb and have a huge effect on performance. And, of course, you need to isolate tempdb away from all other databases. For additional information on placing and monitoring tempdb, see Chapters 38 and 39.
- ▶ **master** database—There is one simple guideline here: *protect the master database at all costs*. This means frequent backups and isolation of *master* away from all other databases.
- ▶ **model** database—It seems harmless enough, but all databases in SQL Server utilize the model database as their base allocation template. We recommend you tailor this for your particular environment.
- ▶ **Memory**—The best way to utilize and allocate memory to SQL Server depends on a number of factors. One is how many other SQL Server instances are running on the same physical server. Another is what type of SQL Server-based application it is: heavy update versus heavy reads. And yet another is how much of your application has been written with stored procedures, triggers, and so on. In general, you want to give as much of the OS memory to SQL Server as you can. But this amount should never exceed 90% of the available memory at the OS level. You don't want SQL Server or the OS to start thrashing via the page file or competing against each other for memory. Also, when more than one SQL Server instance is on the same physical server, you need to divide the memory correctly for each. Don't pit them against

each other. More information on configuring and monitoring SQL Server memory is available in Chapters 39 and 49.

Database-Level Guidelines

- ▶ **Database allocations**—We like to use an approach of putting database files for heavily used databases on the same drives as lightly used databases when more than one database is being managed by a single SQL Server instance. In other words, pair big with small, not big with big. This approach is termed *reciprocal database pairing*.

You should also not have too many databases on a single SQL Server instance. If the server fails, so do all the applications that were using the databases managed by this one SQL Server instance. It's all about risk mitigation. Remember the adage “never put all your eggs in one basket.”

Databases have two primary file allocations: one for their data portion and the other for their transaction log portion. You should always isolate these file allocations from each other onto separate disk subsystems with separate I/O channels if possible. The transaction log is a hot spot for highly volatile applications (that have frequent update activity). Isolate, isolate, and isolate some more. There is also a notion of something called *reciprocal database device location*. More information is available on this issue in Chapters 38 and 39.

You need to size your database files appropriately large enough to avoid database file fragmentation. Heavily fragmented database files can lead to excessive file I/O within the operating system and poor I/O performance. For example, if you know your database is going to grow to 500GB, size your database files at 500GB from the start so that the operating system can allocate a contiguous 500GB file. In addition, be sure to disable the Auto-Shrink database option. Allowing your database files to continuously grow and shrink also leads to excessive file fragmentation as file space is allocated and deallocated in small chunks.

- ▶ **Database backup/recovery/administration**—You should create a database backup and recovery schedule that matches the database update volatility and recovery point objective. All too often a set schedule is used when, in fact, it is not the schedule that drives how often you do backups or how fast you must recover from failure.

Table Design Guidelines

- ▶ **Table designs**—Given the massively increased CPU, memory, and disk I/O speeds that now exist, you should use a general guideline to create as “normalized” a table design as is humanly possible. No longer is it necessary to massively denormalize for performance. Most normalized table designs are easily supported by SQL Server. Normalized table designs ensure that data has high integrity and low overall redundant data maintenance. See Dr. E. F. Codd's original work on relational database design (*The Relational Model for Database Management: Version 2*, Addison Wesley,

1990). Denormalize for performance as a last resort! For more information on normalization and denormalization techniques, see Chapter 38.

NOTE

Too often, we have seen attempts by developers and database designers to guess at the performance problems they expect to encounter denormalizing the database design before any real performance testing has even been done. This, more often than not, results in an unnecessarily, and sometimes excessively, denormalized database design. Overly denormalized databases require creating additional code to maintain the denormalized data, and this often ends up creating more performance problems than it attempts to solve, not to mention the greater potential for data integrity issues when data is heavily denormalized. It is always best to start with as normalized a database as possible, and begin testing early in the development process with real data volumes to identify potential areas where denormalization may be necessary for performance reasons. Then, and only when absolutely necessary, you can begin to look at areas in your table design where denormalization may provide a performance benefit.

- ▶ **Data types**—You must be consistent! In other words, you need to take the time to make sure you have the same data type definitions for columns that will be joined and/or come from the same data domain—Int to Int, and so on. Often the use of user-defined data types goes a long way to standardize the underlying data types across tables and databases. This is a very strong method of ensuring consistency.
- ▶ **Defaults**—Defaults can help greatly in providing valid data values in columns that are common or that have been specified as mandatory (not NULL). Defaults are tied to the column and are consistently applied, regardless of the application that touches the table.
- ▶ **Check constraints**—Check constraints can also be useful if you need to have checks of data values as part of your table definition. Again, it is a consistency capability at the column level that guarantees that only correct data ends up in the column. Let us add a word of warning, though: you have to be aware of the insert and update errors that can occur in your application from invalid data values that don't meet the check constraints.
- ▶ **Triggers**—Often triggers are used to maintain denormalized data, custom audit logs, and referential integrity. Triggers are often used when you want certain behavior to occur when updates, inserts, and deletes occur, regardless of where they are initiated from. Triggers can result in cascading changes to related (dependent) tables or failures to perform modifications because of restrictions. Keep in mind that triggers add overhead to even the simplest of data modification operations in your database and are a classic item to look at for performance issues. You should implement triggers sparingly and implement only triggers that are “appropriate” for the level of integrity or activity required by your applications, and no more than is necessary. Also, you need to be careful to keep the code within your triggers as efficient as

possible so the impact on your data modifications is kept to a minimum. For more information on coding and using triggers, see Chapter 30, “Creating and Managing Triggers.”

- ▶ **Primary keys/foreign keys**—For OLTP and normalized table designs, you need to utilize explicit primary key and foreign key constraints where possible. For many read-only tables, you may not even have to specify a primary key or foreign key at all. In fact, you will often be penalized with poorer load times or bulk updates to tables that are used mostly as lookup tables. SQL Server must invoke and enforce integrity constraints if they are defined. If you don’t absolutely need them (such as with read-only tables), don’t specify them.
- ▶ **Table allocations**—When creating tables, you should consider using the fill factor (free space) options (when you have a clustered index) to correspond to the volatility of the updates, inserts, and deletes that will be occurring in the table. Fill factor leaves free space in the index and data pages, allowing room for subsequent inserts without incurring a page split. You should avoid page splits as much as possible because they increase the I/O cost of insert and update operations. For more information on fill factor and page splits, see Chapter 34, “Data Structures, Indexes, and Performance.”
- ▶ **Table partitioning**—It can be extremely powerful to segregate a table’s data into physical partitions that are naturally accessed via some natural subsetting such as date or key range. Queries that can take advantage of partitions can help reduce I/O by searching only the appropriate partitions rather than the entire table. For more information on table partitioning, see Chapters 24, “Creating and Managing Tables,” and 34.
- ▶ **Purge/archive strategy**—You should anticipate the growth of your tables and determine whether a purge/archive strategy will be needed. If you need to archive or purge data from large tables that are expected to continue to grow, it is best to plan for archiving and purging from the beginning. Many times, your archive/purge method may require modifications to your table design to support an efficient archive/purge method. In addition, if you are archiving data to improve performance of your OLTP applications, but the historical data needs to be maintained for reporting purposes, this also often requires incorporating the historical data into your database and application design. It is much easier to build in an archive/purge method to your database and application from the start than have to retrofit something back into an existing system. Performance of the archive/purge process often is better when it’s planned from the beginning as well.

Indexing Guidelines

In general, you need to be sure not to overindex your tables, especially for tables that require good performance for data modifications! Common mistakes include creating redundant indexes on primary keys that already have primary key constraints defined or creating multiple indexes with the same set of leading columns. You should understand when an index is required based on need, not just the desire to have an index. Also, you

should make sure that the indexes you define have sufficient cardinality to be useful for your queries. In most performance and tuning engagements that we do, we spend a good portion of our time removing indexes or redefining them correctly to better support the queries being executed against the tables. For more information on defining useful indexes and how queries are optimized, see Chapters 34, and 35, “Understanding Query Optimization.”

Following are some indexing guidelines:

- ▶ Have an indexing strategy that matches the database/table usages; this is paramount. Do not index OLTP tables with a DSS indexing strategy and vice versa.
- ▶ For composite indexes, try to keep the more selective columns leftmost in the index.
- ▶ Be sure to index columns used in joins. Joins are processed inefficiently if no index on the column(s) is specified in a join.
- ▶ Tailor your indexes for your most critical queries and transactions. You cannot index for every possible query that might be run against your tables. However, your applications will perform better if you can identify your critical and most frequently executed queries and design indexes to support them.
- ▶ Avoid indexes on columns that have poor selectivity. The Query Optimizer is not likely to use the indexes, so they would simply take up space and add unnecessary overhead during inserts, updates, and deletes.
- ▶ Use clustered indexes when you need to keep your data rows physically sorted in a specific column order. If your data is growing sequentially or is primarily accessed in a particular order (such as range retrievals by date), the clustered index allows you to achieve this more efficiently.
- ▶ Use nonclustered indexes to provide quicker direct access to data rows than a table scan when searching for data values not defined in your clustered index. Create nonclustered indexes wisely. You can often add a few other data columns in the nonclustered index (to the end of the index definition) to help satisfy SQL queries completely in the index (and not have to read the data page and incur some extra I/O). This is termed “covering your query.” All query columns can be satisfied from the index structure.
- ▶ Consider specifying a clustered index fill factor (free space) value to minimize page splits for volatile tables. Keep in mind, however, that the fill factor is lost over time as rows are added to the table and pages fill up. You might need to implement a database maintenance job that runs periodically to rebuild your indexes and reapply the fill factor to the data and index pages.
- ▶ Be extremely aware of the table/index statistics that the optimizer has available to it. When your table has changed by more than 20% from updates, inserts, or deletes, the data distribution can be affected quite a bit, and the optimizer decisions can change greatly. You’ll often want to ensure that the Auto-Update Statistics option is enabled for your databases to help ensure that index statistics are kept up-to-date as your data changes.

View Design Guidelines

In general, you can have as many views as you want. Views are *not* tables and do not take up any storage space (unless you create an index on the view). They are merely an abstraction for convenience. Except for indexed views, views do not store any data; the results of a view are materialized at the time the query is run against the view and the data is retrieved from the underlying tables. Views can be used to hide complex queries, can be used to control data access, and can be used in the same place as a table in the FROM statement of any SQL statement.

Following are some view design guidelines:

- ▶ Use views to hide tables that change their structure often. By using views to provide a stable data access view to your application, you can greatly reduce programming changes.
- ▶ Utilize views to control security and control access to table data at the data value level.
- ▶ Be careful of overusing views containing complex multitable queries, especially code that joins such views together. When the query is materialized, what may appear as a simple join between two or three views can result in an expensive join between numerous tables, sometimes including joins to a single table multiple times.
- ▶ Use indexed views to dramatically improve performance for data accesses done via views. Essentially, SQL Server creates an indexed lookup via the view to the underlying table's data. There is storage and overhead associated with these views, so be careful when you utilize this performance feature. Although indexed views can help improve the performance of SELECT statements, they add overhead to INSERT, UPDATE, and DELETE statements because the rows in the indexed view need to be maintained as data rows are modified, similar to the maintenance overhead of indexes.

For more information on creating and using views, see Chapter 27, "Creating and Managing Views."

Transact-SQL Guidelines

Overall, how you write your Transact-SQL (T-SQL) code can have one of the greatest impacts on your SQL Server performance. Regardless of how well you've optimized your server configuration and database design, poorly written and inefficient SQL code still results in poor performance. The following sections list some general guidelines to help you write efficient, faster-performing code.

General T-SQL Coding Guidelines

- ▶ Use IF EXISTS instead of SELECT COUNT(*) when checking only for the existence of any matching data values. IF EXISTS stops the processing of the SELECT query as soon as the first matching row is found, whereas SELECT COUNT(*) continues searching until all matches are found, wasting I/O and CPU cycles.

- ▶ Using EXISTS/Not Exists in a sub-query is preferable to IN/ NOT IN for sets that are queried. As the potential target size of the set used in the IN gets larger, the performance benefit increases.
- ▶ Avoid unnecessary ORDER BY or DISTINCT clauses. Unless the Query Optimizer determines that the rows will be returned in sorted order or all rows are unique, these operations require a worktable for processing the results, which incurs extra overhead and I/O. Avoid these operations if it is not imperative for the rows to be returned in a specific order or if it's not necessary to eliminate duplicate rows.
- ▶ Use UNION ALL instead of UNION if you do not need to eliminate duplicate result rows from the result sets being combined with the UNION operator. The UNION statement has to combine the result sets into a worktable to remove any duplicate rows from the result set. UNION ALL simply concatenates the result sets together, without the overhead of putting them into a worktable to remove duplicate rows.
- ▶ Use table variables instead of temporary tables whenever possible or feasible. Table variables are memory resident and do not incur the I/O overhead and system table and I/O contention that can occur in tempdb with normal temporary tables.
- ▶ If you need to use temporary tables, keep them as small as possible so they are created and populated more quickly and use less memory and incur less I/O. Select only the required columns rather than using SELECT *, and retrieve only the rows from the base table that you actually need to reference. The smaller the temporary table, the faster it is to create and access the table.
- ▶ If a temporary table is of sufficient size and will be accessed multiple times, it is often cost effective to create an index on it on the column(s) that will be referenced in the search arguments (SARGs) of queries against the temporary table. Do this only if the time it takes to create the index plus the time the queries take to run using the index is less than the sum total of the time it takes the queries against the temporary table to run without the index.
- ▶ Avoid unnecessary function executions. If you call a SQL Server function (for example, getdate()) repeatedly within T-SQL code, consider using a local variable to hold the value returned by the function and use the local variable repeatedly throughout your SQL statements rather than repeatedly executing the SQL Server function. This saves CPU cycles within your T-SQL code.
- ▶ Try to use set-oriented operations instead of cursor operations whenever possible and feasible. SQL Server is optimized for set-oriented operations, so they are almost always faster than cursor operations performing the same task. However, one potential exception to this rule is if performing a large set-oriented operation lead to locking concurrency issues. Even though a single update runs faster than a cursor, while it is running, the single update might end up locking the entire table, or large portions of the table, for an extended period of time. This would prevent other users from accessing the table during the update. If concurrent access to the table is more important than the time it takes for the update itself to complete, you might want to consider using a cursor.

- ▶ Consider using the `MERGE` statement introduced in SQL Server 2008 when you need to perform multiple updates against a table (`UPDATE`, `INSERT`, or `DELETE`) because it enables you to perform these operations in a single pass of the table rather than perform a separate pass for each operation.
- ▶ Consider using the `OUTPUT` clause to return results from `INSERT`, `UPDATE`, or `DELETE` statements rather than having to perform a separate lookup against the table.
- ▶ Use search arguments that can be effectively optimized by the Query Optimizer. Try to avoid using any negative logic in your SARGs (for example, `!=`, `<>`, `not in`) or performing operations on, or applying functions to, the columns in the SARG. Avoid using expressions in your SARGs where the search value cannot be evaluated until runtime (such as local variables, functions, and aggregations in subqueries) because the optimizer cannot accurately determine the number of matching rows because it doesn't have a value to compare against the histogram values during query optimization. Consider putting the queries into stored procedures and passing in the value of the expression as a parameter. The Query Optimizer evaluates the value of a parameter prior to optimization. SQL Server evaluates the expression prior to optimizing the stored procedure.
- ▶ Avoid data type mismatches on join columns.
- ▶ Avoid writing large complex queries whenever possible. Complex queries with a large number of tables and join conditions can take a long time to optimize. It may not be possible for the Query Optimizer to analyze the entire set of plan alternatives, and it is possible that a suboptimal query plans could be chosen. Typically, if a query involves more than 12 tables, it is likely that the Query Optimizer will have to rely on heuristics and shortcuts to generate a query plan and may miss some optimal strategies.

For more tips and information on coding effective and efficient queries, see Chapters 43, “Transact-SQL Programming Guidelines, Tips, and Tricks,” and 35.

Stored Procedure Guidelines

- ▶ Use stored procedures for SQL execution from your applications. Stored procedure execution can be more efficient than ad hoc SQL due to reduced network traffic and query plan caching for stored procedures.
- ▶ Use stored procedures to make your database sort of a “black box” as far as the application code is concerned. If all database access is managed through stored procedures, the applications are shielded from possible changes to the underlying database structures. You can simply modify the existing stored procedures to reflect the changes to the database structures without requiring any changes to the front-end application code.
- ▶ Ensure that your parameter data types match the column data types they are being compared against to avoid data type mismatches and poor query optimization.

- ▶ Avoid transaction nesting issues in your stored procedures by developing a consistent error-handling strategy for failed transactions or other errors that occur in transactions within your stored procedures. Implement that strategy consistently across all procedures and applications. Within stored procedures that might be nested, you need to check whether the procedure is already being called from within a transaction before issuing another `BEGIN TRAN` statement. If a transaction is already active, you can issue a `SAVE TRAN` statement so that the procedure can roll back only the work that it has performed and allow the calling procedure that initiated the transaction to determine whether to continue or abort the overall transaction.
- ▶ Break up large, complex stored procedures into smaller, more manageable stored procedures. Try to create very modular pieces of code that are easily reused and/or nested.

For more information on using and optimizing stored procedures, see Chapter 28, “Creating and Managing Stored Procedures.”

Coding Efficient Transactions and Minimizing Locking Contention

Poorly written or inefficient transactions can have a detrimental effect on concurrency of access to data and overall application performance. To reduce locking contention for resources, you should keep transactions as short and efficient as possible. During development, you might not even notice that a problem exists; the problem might become noticeable only after the system load is increased and multiple users are executing transactions simultaneously.

Following are some guidelines to consider when coding transactions to minimize locking contention and improve application performance:

- ▶ Do not return result sets within a transaction. Doing so prolongs the transaction unnecessarily. Perform all data retrieval and analysis outside the transaction.
- ▶ *Never* prompt for user input during a transaction. If you do, you lose all control over the duration of the transaction. (Even the best programmers miss this one on occasion.) On the failure of a transaction, be sure to issue the rollback before putting up a message box telling the user that a problem occurred.
- ▶ Use optimistic locking or snapshot isolation. If user input is unavoidable between data retrieval and modification and you need to handle the possibility of another user modifying the data values read, leverage the necessary locking strategy (or isolation) to guarantee that no other user corrupts this data. Simple things like re-read and compare, as opposed to holding the resource.
- ▶ Keep statements that comprise a transaction in a single batch to eliminate unnecessary delays caused by network input/output between the initial `BEGIN TRAN` statement and the subsequent `COMMIT TRAN` commands. Additionally, keeping the `BEGIN TRAN` and `COMMIT/ROLLBACK` statements within the same batch helps avoid the possibility of leaving transactions open should the `COMMIT/ROLLBACK` statement not be issued in a subsequent batch.

- ▶ Consider coding transactions entirely within stored procedures. Stored procedures typically run faster than commands executed from a batch. In addition, because they are server resident, stored procedures reduce the amount of network I/O that occurs during execution of the transaction, resulting in faster completion of the transaction.
- ▶ Keep transactions as short and concise as possible. The shorter the period of time locks are held, the less chance for lock contention. Keep commands that are not essential to the unit of work being managed by the transaction (for example, assignment selects, retrieval of updated or inserted rows) outside the transaction.
- ▶ Use the lowest level of locking isolation required by each process. For example, if dirty reads are acceptable and accurate results are not imperative, consider using transaction Isolation Level 0. Use the Repeatable Read or Serializable Read isolation levels only if absolutely necessary.

For more information on managing transactions and minimizing locking contention, see Chapters 37, “Locking and Performance,” and 31, “Transaction Management and the Transaction Log.”

Application Design Guidelines

- ▶ **Locking/deadlock considerations**—These considerations are often the most misunderstood part of SQL Server implementations. Start by standardizing on update, insert, and delete order for all applications that modify data. You do not want to design in locking or deadlocking issues because of inconsistent resource locking orders that result in a “deadly embrace.” For a more in-depth discussion on locking and deadlocking and recommendations for avoiding locking performance issues, see Chapter 37.
- ▶ **Stateless application design**—To scale out, your application needs to take advantage of load-balancing tiers, application server clustering, and other scaleout options. If you don’t force the application or database to carry state, you will have much more success in your scaleout plans.
- ▶ **Remote Procedure Calls/linked servers**—Often data can be accessed via linked server connections rather than by redundantly copying or replicating data into a database. You can take advantage of this capability with SQL Server to reduce the redundant storage of data and eliminate synchronization issues between redundant data stores. Because Remote Procedure Calls are being deprecated in SQL Server, you should stay away from them.
- ▶ **Transactional integrity**—There is no excuse for sacrificing transactional integrity for performance. The extra overhead (and possible performance impact) comes with holding resources (and locks) until the transaction commit point to ensure data integrity. However, if you keep the logical unit of work (the business transaction) as small as possible, you can usually minimize the impact. In other words, you should keep your transaction sizes small and tight.

Distributed Data Guidelines

- ▶ **Distribute for disaster recovery**—Those organizations that have a disaster recovery requirement that they would like to fulfill with distributed data can use several options. One is traditional bit-level stretch clustering (using third-party products such as from Symantec) to your disaster recovery site. Another is simple log shipping to a secondary data center at some interval. Keep in mind, though, that log shipping will be deprecated at some point. Other options include database mirroring (asynchronous mode), periodic full database backups that are sent to another site and restored to a standby server, and a few variations of data replication.
- ▶ **Distribute to satisfy partitioned data accesses**—If you have very discrete and separate data access by some natural key such as geography or product types, it is often easy to have a huge performance increase by distributing or partitioning your tables to serve these accesses. Data replication options such as peer-to-peer and multiple publishers fit this well when you also need to isolate the data to separate servers and even on separate continents. Chapter 19, “Replication,” describes all replication variations.
- ▶ **Distribute for performance**—Taking the isolation approach a bit further, you can devise a variety of SQL Server configurations that greatly isolate entire classes of data access, such as reporting access isolated away from online transactional processing, and so on. Classic SQL Server-based methods for this now include the use of database mirroring and snapshots on the mirror, a few of the data replication options, and others. Check in both Chapters 20, “Database Mirroring,” and 32, “Database Snapshots,” for details.

High-Availability Guidelines

- ▶ **Understand your high-availability (HA) needs first**—More important than applying a single technical solution to achieve high availability is to actually decide what you really need. You should evaluate exactly what your HA requirements might be with a formal assessment and a cost to the company if you do not have HA for your application. See Chapter 18, “SQL Server High Availability,” for a complete depiction of your needs and options.
- ▶ **Know your options for different levels of HA achievement**—With SQL Server, there are several ways to achieve nearly the same level of high availability, including SQL clustering, data replication, database mirroring, log shipping, so on. But deciding on the right one often depends on many other variables. Again, refer to Chapter 18 for details or pick up *Microsoft SQL Server High Availability* by Sams Publishing as soon as you can to see how to do a complete HA assessment and technology deployment. This book covers it all!
- ▶ **Be aware of sacrifices for HA at the expense of performance**—High availability often comes at the expense of performance. As an example, if you use database mir-

roring in its high availability/automatic failover configuration, you actually end up with slower transaction processing. This can hurt if your SLAs are for subsecond transactions. Be extremely careful here. Apply the HA solution that matches your entire application's service-level agreements.

We have listed many guidelines for you to consider. Our hope is that you run through them for every SQL Server–based system you build. Use them as a checklist so that you catch the big design issues early and that you are designing in performance from the start.

Tools of the Performance and Tuning Trade

If you are going off to war (Performance and Tuning war), you should not come empty handed. Bring all your heaviest artillery. In other words, make sure you have plenty of performance and tuning tools to help you diagnose and resolve your issues (to fight your war). One tool we are providing you is this formal performance and tuning methodology outlined in this chapter. But methodologies are only part of the process. There are tools you can use out of the box from Microsoft as well as plenty of third-party tools that will help you shed much light on any issues you may be having. In the following sections, we outline a few of both so you can see various methods of getting to the heart of your performance and tuning problems. Some tools are highly graphic and easy to use; others are more text-based and require much more effort and organizing. But you need to come prepared to fight the war. Do not wait until you have a performance problem in your production environment to learn how to use one of these tools or to have bought a performance and tuning tool. Get what you need upfront.

Microsoft Out-of-the-Box

Microsoft continues to offer some built-in capabilities around performance and tuning with tools such as SQL Server Profiler, Data Collection Services, Performance Monitor counters that monitor many of the execution aspects of SQL Server, and plenty of SQL options at the server level to ensure optimal execution. We mention a few here, but other chapters in this book describe these offerings in greater detail:

- ▶ **SQL Server Profiler**—This rock-solid Microsoft-bundled offering is slowly getting better and better. As you can see in Figure 41.6, the SQL statements across a SQL Server instance are captured along with the execution statistics and other performance handles. You can save your traces and even import them into SQL Server tables for analysis by sorting the raw SQL code into the Top 10 (or 100) worst-performing queries. We include SQL statements on the CD of this book to help you manipulate the raw queries and organize them into a usable order (such as the top 100 worst queries).

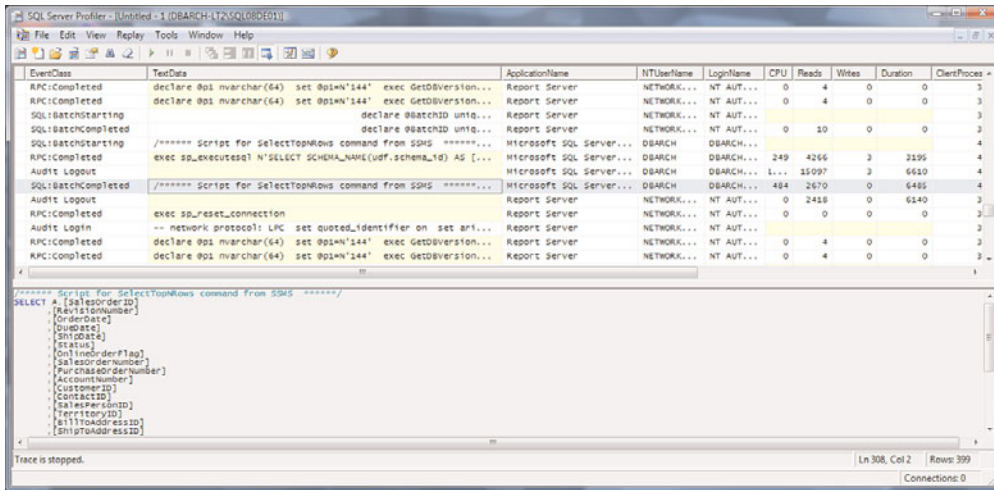

FIGURE 41.6 SQL Server Profiler tracing SQL statements.

- ▶ **Other Microsoft tools**—As mentioned previously, you can also use other tools such as Perfmon counters to isolate locking, deadlocking, memory utilization, CPU utilization, cache hit ratios, physical and logical disk I/Os, disk queue lengths, and a host of others. This includes counters for database mirroring execution, data replication execution, and many others. Even DBCC is still a viable tool for helping track down pesky things like excessive page splits that play havoc on performance. Chapters 39 and 49 take you deep into these out-of-the-box capabilities for SQL Server.

Third-Party Performance and Tuning Tools

There are a number of performance monitoring and tuning tools available for third-party vendors. Here, we list a few that we have some personal experience with:

- ▶ **Precise 8.5**—For database and other tier monitoring in one package, Precise TPM (formerly Precise i3 from Symantec but spun out a few years ago) is one of the best out there. It's a bit pricey, but for larger organizations that have vast implementations, investing in this type of holistic toolset can pay dividends. See www.precise.com for a current release of database and J2EE monitoring capabilities.
- ▶ **SQL Shot**—This tool uses a different approach from Microsoft. In particular, SQL Shot bubbles up all SQL Server–based execution information into a cockpit of visuals (or graphics). Figure 41.7 shows how easy it is to see trouble spots in your SQL Server–based system by using SQL Shot's main GUI. See www.dbarchitects.com for a current release of the SQL Server 2008 R2 version.

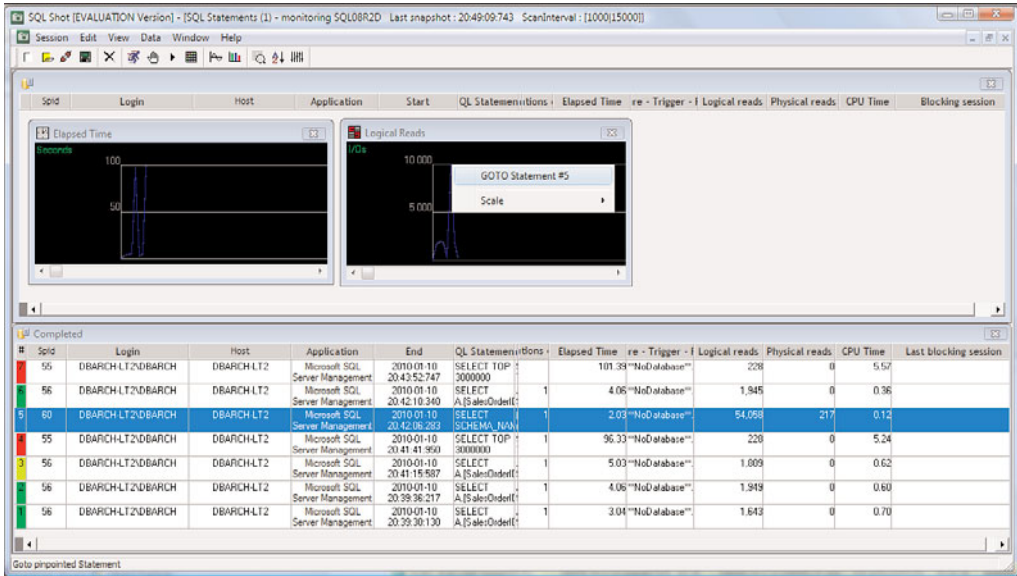

FIGURE 41.7 Graphic depiction of SQL Server performance issues using SQL Shot.

- ▶ **Proactive DBA SQL Capture**—This tool provides no-impact database monitoring of end-user response times and SQL activity. SQL Capture works by “sniffing” network SQL conversations between clients and SQL Server, gathering a wide variety of metrics on the SQL executed by clients. Capturing can occur right on the target server for convenient, low-impact monitoring or on a separate machine for true, no-impact capturing of database activity. You can log all or only selected SQL details to a repository database of your choice and/or to operating system flat files for later viewing and analysis. See www.proactivedba.com for more detailed information on the current release.
- ▶ **Idera SQL Diagnostic Monitor SQL**—This performance monitoring and diagnostics solution can proactively alert administrators to health, performance, or availability problems within their SQL Server environment, all from a central console. In addition to real-time monitoring and analysis, current versions also provide the History Browser, which allows you to diagnose historical SQL Server performance problems by selecting a historical point-in-time to view. See www.idera.com for information on the current release.

Again, come to the war with all your weapons. This is critical work, and you need to make great performance and tuning decisions, be able to isolate issues quickly, and uncover even the most complex problems.

Summary

In this chapter, you saw the difference a formal performance and tuning methodology can make when applied to completely new SQL Server–based implementations. We also showed you a modified version for attacking performance issues you might have with your existing SQL Server deployment. You should use the one that fits your needs best and guarantees you a great-running SQL Server implementation. But you need to use something that you can follow to the letter so that nothing falls between the cracks. We also outlined a series of performance and tuning guidelines for you that correspond with all the major layers of your SQL Server environment. You should take these along with you to every design review, code walkthrough, or solution architecture checkpoint. Make sure you consider these guidelines and factor them into all you do. Designing in performance takes deliberate actions and attention to the bigger picture. You have to know what questions to ask and what guidelines to follow. The guidelines presented in this chapter should serve you well. And lastly, we highlighted some of the tools by Microsoft and others to help you with the daunting task of tuning your SQL Server–based implementation. If you always come to the war with heavy artillery, you'll get great results!

Chapter 42, “What’s New for Transact-SQL in SQL Server 2008,” highlights new features and changes to some existing ones to help you stay current with the ever-expanding Transact-SQL offering.

CHAPTER 42

What's New for Transact-SQL in SQL Server 2008

Although SQL Server 2008 introduces some new features and changes to the Transact-SQL (T-SQL) language that provide additional capabilities, there is not a significant number of new features over what was available in 2005. T-SQL does offer the following new features:

- ▶ MERGE statement
- ▶ Insert over DML
- ▶ GROUP BY clause enhancements
- ▶ Variable assignment in DECLARE statement
- ▶ Compound assignment operators
- ▶ Row Constructors
- ▶ date and time data types
- ▶ Table-valued parameters
- ▶ Hierarchyid data type
- ▶ FILESTREAM Storage
- ▶ Sparse Columns
- ▶ Spatial Data Types
- ▶ Change Data Capture
- ▶ Change Tracking

IN THIS CHAPTER

- ▶ **MERGE** Statement
- ▶ Insert over DML
- ▶ **GROUP BY** Clause Enhancements
- ▶ Variable Assignment in **DECLARE** Statement
- ▶ Compound Assignment Operators
- ▶ Row Constructors
- ▶ New **date** and **time** Data Types and Functions
- ▶ Table-Valued Parameters
- ▶ **Hierarchyid** Data Type
- ▶ Using FILESTREAM Storage
- ▶ Sparse Columns
- ▶ Spatial Data Types
- ▶ Change Data Capture
- ▶ Change Tracking

NOTE

If you are making the leap from SQL Server 2000 (or earlier) to SQL Server 2008 or SQL Server 2008 R2, you may not be familiar with a number of T-SQL enhancements introduced in SQL Server 2005. Some of these enhancements are used in the examples in this chapter. If you are looking for an introduction to the new T-SQL features introduced in SQL Server 2005, check out the “In Case you Missed It...” section in Chapter 43, “Transact-SQL Programming Guidelines, Tips, and Tricks,” which is provided on the CD included with this book.

NOTE

Unless stated otherwise, all examples in this chapter use tables in the `bigpubs2008` database.

MERGE Statement

In versions of SQL Server prior to SQL Server 2008, if you had a set of data rows in a source table that you wanted to synchronize with a target table, you had to perform at least three operations: one scan of the source table to find matching rows to update in the target table, another scan of the source table to find nonmatching rows to insert into the target table, and a third scan to find rows in the target table not contained in the source table that needed to be deleted. SQL Server 2008, however, introduces the `MERGE` statement. With the `MERGE` statement, you can synchronize two tables by inserting, updating, or deleting rows in one table based on differences found in the other table, all in just a single statement, minimizing the number of times that rows in the source and target tables need to be processed. The `MERGE` statement can also be used for performing conditional inserts or updates of rows in a target table from a source table.

The `MERGE` syntax consists of the following primary clauses:

- ▶ The `MERGE` clause specifies the table or view that is the target of the insert, update, or delete operations.
- ▶ The `USING` clause specifies the data source being joined with the target.
- ▶ The `ON` clause specifies the join conditions that determine how the target and source match.
- ▶ The `WHEN MATCHED` clause specifies either the update or delete operation to perform when rows of target table match rows in the source table and any additional search conditions.
- ▶ `WHEN NOT MATCHED BY TARGET` specifies the insert operation when a row in the source table does not have a match in the target table.

- ▶ **WHEN NOT MATCHED BY SOURCE** specifies the update or delete operation to perform when rows of the target table do not have matches in the source table.
- ▶ The **OUTPUT** clause returns a row for each row in the target that is inserted, updated, or deleted.

The basic syntax of the MERGE statement is as follows:

```
[ WITH common_table_expression [,...n] ]
MERGE
  [ TOP ( N ) [ PERCENT ] ]
  [ INTO ] target_table [ [ AS ] table_alias ]
  USING table_or_view_name [ [ AS ] table_alias ]
  ON merge_search_condition
  [ WHEN MATCHED [ AND search_condition ]
    THEN { UPDATE SET set_clause | DELETE } ] [ ...n ]
  [ WHEN NOT MATCHED [ BY TARGET ] [ AND search_condition ]
    THEN { INSERT [ ( column_list ) ] { VALUES ( values_list ) | DEFAULT VALUES
}} ] ]
  [ WHEN NOT MATCHED BY SOURCE [ AND search_condition ]
    THEN { UPDATE SET set_clause | DELETE } ] [ ...n ]
  [ OUTPUT column_name | scalar_expression
INTO { @table_variable | output_table } [ ( column_list ) ] ]
  [ OUTPUT column_name | scalar_expression [ [AS] column_alias_identifier ] [
, ...n ] ] ;
```

The **WHEN** clauses specify the actions to take on the rows identified by the conditions specified in the **ON** clause. The conditions specified in the **ON** clause determine the full result set that will be operated on. Additional filtering to restrict the affected rows can be specified in the **WHEN** clauses. Multiple **WHEN** clauses with different search conditions can be specified. However, if there is a **MATCH** clause that includes a search condition, it must be specified before all other **WHEN MATCH** clauses.

Note that the **MERGE** command must be terminated with a semicolon (;). Otherwise, you receive a syntax error.

When you run a **MERGE** statement, rows in the source are matched with rows in the target based on the join predicate that you specify in the **ON** clause. The rows are processed in a single pass, and one insert, update, or delete operation is performed per input row depending on the **WHEN** clauses specified. The **WHEN** clauses determine which of the following matches exist in the result set:

- ▶ A matched pair consisting of one row from the target and one from the source as a result of matching condition in the **WHEN MATCHED** clause
- ▶ A row from the source that has no matching row in the target as a result of the condition specified the **WHEN NOT MATCHED BY TARGET** clause
- ▶ A row from the target that has no corresponding row in the source as a result of the condition specified in the **WHEN NOT MATCHED BY SOURCE** clause

The combination of **WHEN** clauses specified in the **MERGE** statement determines the join method that SQL Server will use to process the query (see Table 42.1).

TABLE 42.1 Join Methods Used for **WHEN** Clauses

Specified WHEN Clauses	Join Method
WHEN MATCHED clause only	INNER JOIN
WHEN NOT MATCHED BY TARGET clause, but <i>not</i> the WHEN NOT MATCHED BY SOURCE clause	LEFT OUTER JOIN from source to target
WHEN MATCHED clause and the WHEN NOT MATCHED BY SOURCE clause, but <i>not</i> the WHEN NOT MATCHED BY TARGET clause	RIGHT OUTER JOIN from source to target
WHEN NOT MATCHED BY TARGET clause and the WHEN NOT MATCHED BY SOURCE clause	FULL OUTER JOIN
WHEN NOT MATCHED BY SOURCE clause only	ANTI SEMI JOIN

To improve the performance of the **MERGE** statement, you should make sure you have appropriate indexes to support the join columns between the source table and target table. Any additional columns in the source table index that will help to cover the query may help improve performance even more (for information on index covering, see Chapter 34, “Data Structures, Indexes, and Performance”). The indexes should ensure that the join keys are unique and, if possible, sort the data in the tables in the order it will be processed so additional sort operations are not necessary. Unique indexes supporting the join conditions for the **MERGE** statement will improve query performance because the query optimizer does not need to perform extra validation processing to locate and update duplicate rows.

To better understand how the **MERGE** statement works, let's look at an example. First, you need to set up some data in a source table. In the `bigpubs2008` database, there is a table called `stores`. For this example, let's assume you want to set up a new table that keeps track of each store's inventory to support an application that can monitor each store's inventory and send notifications when certain items run low, as well as to support the ability of each store to search other store inventories to locate rare and out-of-print books that other stores may have available. On a daily basis, each store uploads a full refresh of its current inventory to a staging table (`inventory_load`), which is the source table for the **MERGE**. You then use the `inventory_load` table to modify the store's inventory in the `store_inventory` table (which is the target table for the **MERGE** operation).

First, let's create the new `store_inventory` table (see Listing 42.1). Just for sake of the example, you can create and populate it with the existing data from the `sales` table for `stor_id 'A011'` and create a primary key constraint on the `stor_id` and `title_id` columns. The next step is to load the `inventory_load` table. Normally, in a real-world scenario, this table would likely be populated via a `BULK INSERT` statement or SQL Server Integration Services. However, for the sake of this example, you simply are going to create

some test data by creating and populating the `inventory_load` table using `SELECT INTO` with data merged from the sales data for both `stor_id` 'A011' and 'A017'.

When the `inventory_load` table is created and populated, you can create a primary key on the `stor_id` and `title_id` columns as well to support the join with the `store_inventory` table.

The next step is to build out the `MERGE` statement. Following are the rules to be applied:

- ▶ If there is a matching row between the source and target tables and the `qty` value is different, update the `qty` value in the target table to the value in the source table.
- ▶ If a row in the source table doesn't have a match in the target table, this is a new inventory item, so insert the new row to the target table.
- ▶ If a row in the target table doesn't have a matching row in the source table, that inventory item no longer exists, so delete it from the target table.

Also for the sake of the example so that you can see just what the `MERGE` statement ends up doing, the `OUTPUT` clause has been added with the `$action` column included. The `$action` column displays what operation (`INSERT`, `UPDATE`, `DELETE`) was performed on each row, and displays the `title_id` and `qty` values for both the source and target tables for each row processed (note that if the `title_id` and `qty` columns are `NULL`, that was a nonmatching row).

LISTING 42.1 A **MERGE** Example

```
use bigpubs2008
go
if OBJECT_ID('store_inventory') is not null
    drop table store_inventory
go
-- Create and populate the store_inventory table
select stor_id, title_id, qty = SUM(qty), update_dt = GETDATE()
into store_inventory
from sales s
where stor_id = 'A011'
group by stor_id, title_id
go
-- add primary key on store_inventory to support the join to source table
alter table store_inventory add constraint PK_store_inventory primary key
(stor_id, title_id)
Go
if OBJECT_ID('inventory_load') is not null
    drop table inventory_load
go

-- Now, create and populate the inventory_load table
select stor_id = 'A011',
```

```

        title_id,
        qty = SUM(qty)
into inventory_load
from sales s
where stor_id like 'A01[17]'
and title_id not like '%8'
group by title_id
go
-- add primary key on store_inventory to support the join to target table
alter table inventory_load add constraint PK_inventory_load primary key
    (stor_id, title_id)
go
select * from store_inventory
go

-- perform the merge, updating any matching rows with different quantities
-- adding any rows in source not in the target, and deleting any rows from the
-- target that are not in the source.
-- Output clause is specified to display the results of the MERGE
MERGE
    INTO store_inventory as s
    USING inventory_load as i
    ON s.stor_id = i.stor_id
    and s.title_id = i.title_id
    WHEN MATCHED and s.qty <> i.qty
        THEN UPDATE
            SET s.qty = i.qty,
                update_dt = getdate()
    WHEN NOT MATCHED
        THEN INSERT (stor_id, title_id, qty, update_dt)
        VALUES (i.stor_id, i.title_id, i.qty, getdate())
    WHEN NOT MATCHED BY SOURCE
        THEN DELETE
    OUTPUT $action,
        isnull(inserted.title_id, '') as src_titleid, isnull(str(inserted.qty, 5),
        '') as src_qty,
        isnull(deleted.title_id, '') as tgt_titleid, isnull(str(deleted.qty, 5),
        '') as tgt_qty
;
go
select * from store_inventory
go

```

If you run the script in Listing 42.1, you should see output like the following.

stor_id	title_id	qty	update_dt

(21 row(s) affected)

If you examine the results and compare the before and after contents of the `store_inventory`, you see that eight new rows were inserted to `store_inventory`, two rows were deleted, and one row was updated.

MERGE Statement Best Practices and Guidelines

The MERGE statement is a great addition to the T-SQL language. It provides a concise and efficient mechanism to perform multiple operations on a table based on contents in a source table without having to resort to using a cursor or running multiple set-oriented operations against the table. However, there are some guidelines and best practices you should keep in mind to help ensure you get the best performance from your MERGE statements.

First, you should try to reduce the number of rows accessed by the MERGE statement early in the process by specifying any additional search condition to the `ON` clause that filters out rows that do not need to be processed. You should avoid using the conditions in the `WHEN` clauses as row filters. However, you need to be careful if you are using any of the `WHEN NOT MATCHED` clauses because the elimination of rows via the `ON` clause may cause unexpected and incorrect results. Because the additional search conditions specified in the `ON` clause are not used for matching the source and target data, they can be misapplied.

To ensure correct results are obtained, you should specify only search conditions in the `ON` clause that determine the criteria for matching data in the source and target tables. That is, specify only columns from the target table that are compared to the corresponding columns of the source table. Do not include comparisons to other values such as a constant.

To filter out rows from the source or target tables, you should consider using one of the following methods.

- Specify the search condition for row filtering in the appropriate `WHEN` clause. For example, `WHEN NOT MATCHED AND qty > 0 THEN INSERT...`

- ▶ Define a view on the source or target that returns the filtered rows and reference the view as the source or target table. If the view is used as the target, make sure the view is updateable (for more information about updating data by using a view, see Chapter 27, “Creating and Managing Views”).
- ▶ Use the WITH *<common table expression>* clause to filter out rows from the source or target tables. However, if you are not careful, this method is similar to specifying additional search criteria in the ON clause and may produce incorrect results. You should test this approach thoroughly before implementing it (for information on using common table expressions, see Chapter 43, “Transact-SQL Programming Guidelines, Tips, and Tricks”).

Insert over DML

Another T-SQL enhancement in SQL Server 2008 applies to the use of the OUTPUT clause. The OUTPUT clause allows you to return data from a modification statement (INSERT, UPDATE, MERGE, or DELETE) as a result set or into a table variable or an output table. In SQL Server 2008, you can include one of these Data Manipulation Language (DML) statements with an OUTPUT clause within the context of an INSERT...SELECT statement.

In the MERGE statement in Listing 42.1, the OUTPUT clause was used to display the rows affected by the statement. Suppose that you want the output of this to be put into a separate audit or processing table. In SQL Server 2008, you can do so by allowing the MERGE statement with the OUTPUT clause to be incorporated as a derived table in the SELECT clause of an INSERT statement.

To demonstrate this approach, you first need to create a table for storing that data:

```
if OBJECT_ID('inventory_audit') is not null
    drop table inventory_audit
go
CREATE TABLE inventory_audit
(
    Action      varchar(10) not null,
    Src_title_id  varchar(6) null,
    Src_qty      int null,
    Tgt_title_id  varchar(6) null,
    Tgt_qty      int null,
    Loginname    varchar(30) null default suser_name(),
    Action_DT    datetime2 null default sysdatetime()
)
```

Now it is possible to be put a SELECT statement atop the MERGE command as the values clause for an INSERT into the inventory_audit table (see Listing 42.2).

LISTING 42.2 Insert over DML Example

```
-- NOTE: to see the results for this example
--      you first need to clear out and repopulate
--      the store_inventory table
Truncate table store_inventory
Insert store_inventory (stor_id, title_id, qty, update_dt)
select stor_id, title_id, qty = SUM(qty), update_dt = GETDATE()
from sales s
where stor_id = 'A011'
group by stor_id, title_id
go
insert inventory_audit
    (action,
     Src_title_id,
     Src_qty    ,
     Tgt_title_id,
     Tgt_qty    ,
     Loginname,
     Action_DT
    )
select *, SUSER_NAME(), SYSDATETIME()
from (
    MERGE
        INTO store_inventory as s
        USING inventory_load as i
        ON s.stor_id = i.stor_id
        and s.title_id = i.title_id
        WHEN MATCHED and s.qty <> i.qty
            THEN UPDATE
    SET s.qty = i.qty,
        update_dt = getdate()
        WHEN NOT MATCHED
            THEN INSERT (stor_id, title_id, qty, update_dt)
            VALUES (i.stor_id, i.title_id, i.qty, getdate())
        WHEN NOT MATCHED BY SOURCE
            THEN DELETE
    OUTPUT $action,
           isnull(inserted.title_id, '') as src_titleid,
           isnull(str(inserted.qty, 5), '') as src_qty,
           isnull(deleted.title_id, '') as tgt_titleid,
           isnull(str(deleted.qty, 5), '') as tgt_qty
    ) changes ( action,
               Src_title_id,
               Src_qty    ,
               Tgt_title_id,
```

```

        Tgt_qty );
go
select * from inventory_audit
go

```

Action	Src_title_id	Src_qty	Tgt_title_id	Tgt_qty	Loginname	Action_DT

GROUP BY Clause Enhancements

SQL Server 2008 introduces a number of enhancements and changes to the grouping aggregate relational result set. These changes include the following:

- ▶ ROLLUP and CUBE operator syntax changes
- ▶ New GROUPING SETS operator
- ▶ New GROUPING_ID() function

ROLLUP and CUBE Operator Syntax Changes

The ROLLUP and CUBE operators produce additional aggregate groupings and are appended to the GROUP BY clause. Prior to SQL Server 2008, to include ROLLUP or CUBE groupings, you had to specify the WITH ROLLUP or WITH CUBE options in the GROUP BY clause after the list of grouping columns. In SQL Server 2008, the syntax now follows the ANSI standard for ROLLUP and CUBE; you first designate the ROLLUP or CUBE option and then provide the grouping columns to these operators as a comma-separated list enclosed in parentheses. The new syntax is

```
GROUP BY [ROLLUP | CUBE ( non-aggregate_column_list ) ]
```

Following are examples using the pre-2008 syntax:

```
SELECT type, pub_id, AVG(price) AS average
FROM titles
```

```
GROUP BY type, pub_id
WITH CUBE
```

```
SELECT pub_id, type, SUM(ytd_sales) as ytd_sales
FROM dbo.titles
where type like '%cook%' or type = 'business'
GROUP BY type, pub_id
WITH ROLLUP
```

An example of the new ANSI standard syntax supported in SQL Server 2008 is as follows:

```
SELECT type, pub_id, AVG(price) AS average
FROM titles
GROUP BY CUBE ( type, pub_id)
```

```
SELECT pub_id, type, SUM(ytd_sales) as ytd_sales
FROM dbo.titles
where type like '%cook%' or type = 'business'
GROUP BY ROLLUP (type, pub_id)
```

NOTE

The old-style CUBE and ROLLUP syntax is still supported for backward-compatibility purposes but is being deprecated. You should convert any existing queries using the pre-2008 WITH CUBE or WITH ROLLUP syntax to the new syntax to ensure future compatibility.

GROUPING SETS

The CUBE and ROLLUP operators allow you to run a single query and generate multiple sets of groupings. However, the sets of groupings are fixed. For example, if you use GROUP BY ROLLUP (A, B, C), you get aggregates generated for the following groupings of nonaggregate columns:

- ▶ GROUP BY A, B, C
- ▶ GROUP BY A, B
- ▶ GROUP BY A
- ▶ A super-aggregate for all rows

If you use GROUP BY CUBE (A, B, C), you get aggregates generated for the following groupings of nonaggregate columns:

- ▶ GROUP BY A, B, C
- ▶ GROUP BY A, B
- ▶ GROUP BY A, C

- ▶ GROUP BY B, C
- ▶ GROUP BY A
- ▶ GROUP BY B
- ▶ GROUP BY C
- ▶ A super-aggregate for all rows

SQL Server 2008 introduces the `GROUPING SETS` operator in addition to the `CUBE` and `ROLLUP` operators for performing several groupings in a single query. With `GROUPING SETS`, only the specified groups are aggregated instead of the full set of aggregations generated by `CUBE` or `ROLLUP`. `GROUPING SETS` enables you to generate results with multiple groupings in a single query, without having to resort to writing multiple `GROUP BY` queries and combining the results using a `UNION ALL` statement.

The `GROUPING SETS` operator supports concatenating column groupings and an optional super aggregate row. The syntax for defining grouping sets is as follows:

```
GROUP BY [ GROUPING SETS ( ( ) | grouping_set_item | grouping_set_item_list
  [, ...n ] ) ]
```

The `GROUPING SETS` items can be single columns or a list of columns. The null field list " () " can also be used to generate a super-aggregate (that is, a grand total for the entire result set). A non-nested list of columns works as separate simple `GROUP BY` statements, which are then combined in an implied `UNION ALL`. A nested list of columns in parentheses within the `GROUPING SETS` item list works as a `GROUP BY` on that set of columns. Table 42.2 demonstrates examples of `GROUPING SETS` clauses and the corresponding groupings that the query generates.

TABLE 42.2 Grouping Sets Examples

GROUPING SETS Clause	Equivalent Statement
GROUP BY GROUPING SETS (A,B,C)	GROUP BY A UNION ALL GROUP BY B UNION ALL GROUP BY C
GROUP BY GROUPING SETS ((A,B,C))	GROUP BY A,B,C
GROUP BY GROUPING SETS (A,(B,C))	GROUP BY A UNION ALL GROUP BY B,C
GROUP BY GROUPING SETS ((A,C),(B,C))	GROUP BY A,C UNION ALL GROUP BY B,C

Listing 42.3 demonstrates how to use the `GROUPING SETS` operator to perform three groupings on three individual columns in a single query.

LISTING 42.3 GROUPING SETS Example

```

/****
** Perform a grouping by type, grouping by pub_id, and grouping by price
***/
SELECT type, pub_id, price, sum(isnull(ytd_sales, 0)) AS ytd_sales
FROM titles
where pub_id < '9'
GROUP BY GROUPING SETS ( type, pub_id, price)
go

```

type	pub_id	price	ytd_sales
NULL	NULL	NULL	0
NULL	NULL	0.0006	111
NULL	NULL	0.0017	750
NULL	NULL	14.3279	4095
NULL	NULL	14.595	18972
NULL	NULL	14.9532	14294
NULL	NULL	14.9611	4095
NULL	NULL	15.894	40968
NULL	NULL	15.9329	3336
NULL	NULL	17.0884	2045
NULL	NULL	17.1675	8780
NULL	0736	NULL	28286
NULL	0877	NULL	44219
NULL	1389	NULL	24941
business	NULL	NULL	30788
mod_cook	NULL	NULL	24278
popular_comp	NULL	NULL	12875
psychology	NULL	NULL	9939
trad_cook	NULL	NULL	19566

In the output in Listing 42.3, the first 11 rows are the results grouped by price, the next 3 rows are grouped by `pub_id`, and the bottom 5 rows are grouped by type. Now, you can modify this query to include a super-aggregate for all rows by adding a null field list, as shown in Listing 42.4.

LISTING 42.4 **GROUPING SETS** Example with Null Field List to Generate Super-Aggregate

```

SELECT type, pub_id, price, sum(isnull(ytd_sales, 0)) AS ytd_sales
FROM titles
where pub_id < '9'
GROUP BY GROUPING SETS ( type, pub_id, price, ( ) )
go

```

type	pub_id	price	ytd_sales
NULL	NULL	NULL	0
NULL	NULL	0.0006	111
NULL	NULL	0.0017	750
NULL	NULL	14.3279	4095
NULL	NULL	14.595	18972
NULL	NULL	14.9532	14294
NULL	NULL	14.9611	4095
NULL	NULL	15.894	40968
NULL	NULL	15.9329	3336
NULL	NULL	17.0884	2045
NULL	NULL	17.1675	8780
NULL	NULL	NULL	97446
NULL	0736	NULL	28286
NULL	0877	NULL	44219
NULL	1389	NULL	24941
business	NULL	NULL	30788
mod_cook	NULL	NULL	24278
popular_comp	NULL	NULL	12875
psychology	NULL	NULL	9939
trad_cook	NULL	NULL	19566

If you look closely at the results in Listing 42.4, you see there are two rows with NULL values for all three columns for type, pub_id, and price. How can you determine definitively which row is the super-aggregate of all three rows, and which is a row grouped by price where the value of price is NULL? This is where the new `grouping_id()` function comes in.

The `grouping_id()` Function

The `grouping_id()` function, new in SQL Server 2008, can be used to determine the level of grouping in a query using `GROUPING SETS` or the `CUBE` and `ROLLUP` operators. Unlike the `GROUPING()` function, which takes only a single column expression as an argument and returns a 1 or 0 to indicate whether that individual column is being aggregated, the `grouping_id()` function accepts multiple column expressions and returns a bitmap to indicate which columns are being aggregated for that row.

For example, you can add the `grouping_id()` and `grouping()` functions to the query in Listing 42.4 and examine the results (see Listing 42.5).

LISTING 42.5 Using the **grouping_id()** Function

```
SELECT type, pub_id, price, sum(isnull(ytd_sales, 0)) AS ytd_sales,
grouping_id(type, pub_id, price) as grp_id,
grouping(type) type_rlp,
grouping(pub_id) pub_id_rlp,
grouping(price) price_rlp
FROM titles
where pub_id < '9'
GROUP BY GROUPING SETS ( type, pub_id, price, () )
go
```

type	pub_id	price	ytd_sales	grp_id	type_rlp	pub_id_rlp	price_rlp
NULL	NULL	NULL	0	6	1	1	0
NULL	NULL	0.0006	111	6	1	1	0
NULL	NULL	0.0017	750	6	1	1	0
NULL	NULL	14.3279	4095	6	1	1	0
NULL	NULL	14.595	18972	6	1	1	0
NULL	NULL	14.9532	14294	6	1	1	0
NULL	NULL	14.9611	4095	6	1	1	0
NULL	NULL	15.894	40968	6	1	1	0
NULL	NULL	15.9329	3336	6	1	1	0
NULL	NULL	17.0884	2045	6	1	1	0
NULL	NULL	17.1675	8780	6	1	1	0
NULL	NULL	NULL	97446	7	1	1	1
NULL	0736	NULL	28286	5	1	0	1
NULL	0877	NULL	44219	5	1	0	1
NULL	1389	NULL	24941	5	1	0	1
business	NULL	NULL	30788	3	0	1	1
mod_cook	NULL	NULL	24278	3	0	1	1
popular_comp	NULL	NULL	12875	3	0	1	1
psychology	NULL	NULL	9939	3	0	1	1
trad_cook	NULL	NULL	19566	3	0	1	1

Unlike the `grouping()` function, which takes only a single column name as an argument, the `grouping_id()` function accepts all columns that participate in any grouping set. The `grouping_id()` function produces an integer result that is a bitmap, where each bit represents a different column, producing a unique integer for each grouping set. The bits in the bitmap indicate whether the columns are being aggregated in the grouping set (bit value is 1) or if the column is used to determine the grouping set (bit value is 0) used to calculate the aggregate value.

The bit values are assigned to columns from right to left in the order the columns are listed in the `grouping_id()` function. For example, in the query in Listing 42.5, `price` is the rightmost bit value, bit 1; `pub_id` is assigned the next bit value, bit 2, and `type` is assigned the leftmost bit value, bit 3. When the `grouping_id()` value equals 6, that means the bits 2 and 3 are turned on ($4 + 2 + 0 = 6$). This indicates that the `type` and `pub_id` columns are being aggregated in the grouping set, and the `price` column defines the grouping set.

The `grouping_id()` column can thus be used to determine which of the two rows where `type`, `pub_id`, and `price` are all NULL is the row with the super-aggregate of all three columns (`grouping_id = 7`), and which row is an aggregate rolled up where the value of `price` is NULL (`grouping_id = 6`).

The values returned by the `grouping_id()` function can also be used for further filtering your grouping set results or for sorting your grouping set results, as shown in Listing 42.6.

LISTING 42.6 Using the **grouping_id()** Function to Sort Results

```
SELECT type, pub_id, price, sum(isnull(ytd_sales, 0)) AS ytd_sales,
grouping_id(type, pub_id, price) as grping_id
FROM titles
where pub_id < '9'
GROUP BY GROUPING SETS ( type, pub_id, price, ( ) )
order by grping_id
go
```

type	pub_id	price	ytd_sales	grping_id
business	NULL	NULL	30788	3
mod_cook	NULL	NULL	24278	3
popular_comp	NULL	NULL	12875	3
psychology	NULL	NULL	9939	3
trad_cook	NULL	NULL	19566	3
NULL	0736	NULL	28286	5
NULL	0877	NULL	44219	5
NULL	1389	NULL	24941	5
NULL	NULL	NULL	0	6
NULL	NULL	0.0006	111	6
NULL	NULL	0.0017	750	6
NULL	NULL	14.3279	4095	6
NULL	NULL	14.595	18972	6
NULL	NULL	14.9532	14294	6
NULL	NULL	14.9611	4095	6
NULL	NULL	15.894	40968	6
NULL	NULL	15.9329	3336	6

NULL	NULL	17.0884	2045	6
NULL	NULL	17.1675	8780	6
NULL	NULL	NULL	97446	7

Variable Assignment in DECLARE Statement

In SQL Server 2008, you can now set a variable's initial value at the same time you declare it. For example, the following line of code declares a variable named @ctr of type int and set its value to 100:

```
DECLARE @ctr int = 100
```

Previously, this functionality was only possible with stored procedure parameters. Assigning an initial value to a variable required a separate SET or SELECT statement. This new syntax simply streamlines the process of assigning an initial value to a variable. The value specified can be a constant or a constant expression, as in the following:

```
DECLARE @start_time datetime = getdate()
```

You can even assign the initial value via a subquery, as long as the subquery returns only a single value, as in the following example:

```
declare @max_price money = (select MAX(price) from titles)
```

The value being assigned to the variable must be of the same type as the variable or be implicitly convertible to that type.

Compound Assignment Operators

Another new feature that streamlines and improves the efficiency of your T-SQL code is *compound operators*. This is a concept that has been around in many other programming languages for a long time, but has now finally found its way into T-SQL. Compound operators are used when you want to apply an arithmetic operation on a variable and assign the value back into the variable.

For example, the += operator adds the specified value to the variable and then assigns the new value back into the variable. For example,

```
SET @ctr += 1
```

is functionally the same as

```
SET @ctr = @ctr + 1
```

The compound operators are a quicker to type, and they offer a cleaner piece of finished code. Following is the complete list of compound operators provided in SQL Server 2008:

- `+=` Add and assign
- `-=` Subtract and assign
- `*=` Multiply and assign
- `/=` Divide and assign
- `%=` Modulo and assign
- `&=` Bitwise AND and assign
- `^=` Bitwise XOR and assign
- `|=` Bitwise OR and assign

Row Constructors

SQL Server 2008 provides a new method to insert data to SQL Server tables, referred to as row constructors. *Row constructors* are a feature that can be used to simplify data insertion, allowing multiple rows of data to be specified in a single DML statement. Row constructors are used to specify a set of row value expressions to be constructed into a data row.

Row constructors can be specified in the `VALUES` clause of the `INSERT` statement, in the `USING` clause of the `MERGE` statement, and in the definition of a derived table in the `FROM` clause. The general syntax of the row constructor is as follows:

```
VALUES ( { expression | DEFAULT | NULL } [ ,...n ] ) [ ,...n ]
```

Each column of data defined in the `VALUES` clause is separated from the next using a comma. Multiple rows (which may also contain multiple columns) are separated from each other using parentheses and a comma. When multiple rows are specified, the corresponding column values must be of the same data type or implicitly convertible data type. The following example shows the row constructor `VALUES` clause being used within a `SELECT` statement to define a set of rows and columns with explicit values:

```
SELECT a, b FROM (VALUES (1, 2), (3, 4), (5, 6), (7, 8), (9, 10) )
AS MyTable(a, b);
GO
a          b
-----
1          2
3          4
```

5 6
7 8
9 10

The VALUES clause is commonly used in this manner to populate temporary tables but can also be used in a view, as shown in Listing 42.7.

LISTING 42.7 Using the **VALUES** Clause in a View

```
create view book_types
as
SELECT type, description
FROM (VALUES ('mod_cook', 'Modern Cooking'),
            ('trad_cook', 'Traditional Cooking'),
            ('popular_comp', 'Popular Computing'),
            ('biography', 'Biography'),
            ('business', 'Business Development'),
            ('children', 'Children's Literature'),
            ('fiction', 'Fiction'),
            ('nonfiction', 'NonFiction'),
            ('psychology', 'Psychology and Self Help'),
            ('drama', 'Drama and Theater'),
            ('lit_crit', 'Literary Criticism'))
) AS type_lookup(type, description)
go
```

Defining a view in this manner can be useful as a code lookup table:

```
select top 10
    convert(varchar(50), title) as title, description
from titles t
    inner join
book_types bt
    on t.type = bt.type
order by title_id desc
go
```

The advantage of this approach is that unlike a permanent code table, the view with the VALUES clause doesn't really take up any space; it's materialized only when it's referenced. Maintaining it involves simply dropping and re-creating the view rather than having to perform inserts, updates, and deletes as you would for a permanent table.

The primary use of row constructors is to insert multiple rows of data in a single INSERT statement. Essentially, if you have multiple rows to insert, you can specify multiple rows in the VALUES clause. The maximum number of rows that can be specified in the VALUES clause is 1000. The following example shows how to use the row constructor VALUES clause in a single INSERT statement to insert five rows:

```
insert sales (stor_id, ord_num, ord_date, qty, payterms, title_id)
VALUES ('6380', '1234', '3/26/2010', 50, 'Net 30', 'BU1032'),
       ('6380', '1234', '3/26/2010', 150, 'Net 30', 'PS2091'),
       ('6380', '1234', '3/26/2010', 25, 'Net 30', 'CH2480'),
       ('6380', '1234', '3/26/2010', 30, 'Net 30', 'FI2046'),
       ('6380', '1234', '3/26/2010', 10, 'Net 30', 'FI6318')
```

As you can see, this new syntax is much more concise and simple than having to issue five individual INSERT statements as you would have had to do in versions of SQL Server prior to SQL Server 2008.

The VALUES clause can also be used in the MERGE statement as the source table. Listing 42.8 uses the VALUES clause to define five rows as the source data to perform INSERT/UPDATE operations on the store_inventory table defined in Listing 42.1.

LISTING 42.8 Using the **VALUES** Clause in a **MERGE** Statement

```
MERGE
  INTO store_inventory as s
  USING
    (VALUES
      ('A011', 'CH3348', 41, getdate()),
      ('A011', 'CH2480', 125, getdate()),
      ('A011', 'FI0392', 1100, getdate()),
      ('A011', 'FI2046', 1476, getdate()),
      ('A011', 'FI1872', 520, getdate())

New date and time Data Types and Functions

SQL Server 2008 introduces four new date and time data types:

- ▶ `date`
- ▶ `time (precision)`
- ▶ `datetime2 (precision)`
- ▶ `datetimeoffset (precision)`

Two of the most welcome of these new types are the new date and time data types. These new data types allow you to store date-only and time-only values. In previous versions of SQL Server, the `datetime` and `smalldatetime` data types were the only available types for storing date or time values, and they always store both the date and time. This made date-only or time-only comparisons tricky at times because you always had to account for the other component (for more detailed examples on working with `datetime` values in SQL Server, see Chapter 43). In addition, the `datetime` stored date values range only from 1/1/1753 to 12/31/9999, with accuracy only to 3.33 milliseconds. The `smalldatetime` stored date values range only from 1/1/1900 to 6/6/2079, with accuracy of only 1 minute.

The new `date` data type stores only the date component without the time component, and stores date values ranging from 1/1/0001 to 12/31/9999.

The new `time` data type stores only the time component with accuracy that can be specified down to seven decimal places (100 nanoseconds). The default is seven decimal places.

The `datetime2` data type stores both date and time components, similar to `datetime`, increases the range of allowed values to 1/1/0001 to 12/31/9999, also with accuracy down to seven decimal places (100 ns). The default precision is seven decimal places.

The `datetimeoffset` data type also stores both date and time components just like `datetime2`, but includes the time zone offset from Universal Time Coordinates (UTC). The time zone offset ranges from -14:00 to +14:00.

Along with the new date and time data types, SQL Server 2008 also introduces some new date and time functions for returning the current system date and time in different formats:

- ▶ **SYSDATETIME()**—Returns the current system datetime as a **DATETIME2(7)** value
- ▶ **SYSDATETIMEOFFSET()**—Returns the current system datetime as a **DATETIMEOFFSET(7)** value
- ▶ **SYSUTCDATETIME**—Returns the current system datetime as a **DATETIME2(7)** value representing the current UTC time
- ▶ **SWITCHOFFSET (DATETIMEOFFSET, time_zone)**—Changes the **DATETIMEOFFSET** value from the stored time zone offset to the specified time zone
- ▶ **TODATETIMEOFFSET (datetime, time_zone)**—Applies the specified time zone to the datetime value that does not reflect time zone difference from UTC

Listing 42.9 demonstrates the use of some of the new data types and functions. Notice the difference in the specified decimal precision returned for the time values.

LISTING 42.9 Using the new **date** and **time** Data Types and Functions

```
declare @date date,
        @time time,
        @time3 time(3),
        @datetime2 datetime2(7),
        @datetimeoffset datetimeoffset,
        @datetime datetime,
        @utcdatetime datetime2(7)

select @datetime = getdate(),
       @date = getdate(),
       @time = sysdatetime(),
       @time3 = sysdatetime(),
       @datetime2 = SYSDATETIME(),
       @datetimeoffset = SYSDATETIMEOFFSET(),
       @utcdatetime = SYSUTCDATETIME()

select @datetime as 'datetime',
       @date as 'date',
       @time as 'time',
```

```

        @time3      as 'time3'
select
    @datetime2     as 'datetime2',
    @datetimeoffset as 'datetimeoffset',
    @utcdatetime   as 'utcdatetime'

select SYSDATETIMEOFFSET() as sysdatetimeoffset,
       SYSDATETIME() as sysdatetime
go

datetime          date          time          time3
-----
2010-03-28 23:18:30.490 2010-03-28 23:18:30.4904294 23:18:30.492

datetime2          datetimeoffset          utcdatetime
-----
2010-03-28 23:18:30.49 2010-03-28 23:18:30.4924295 -04:00 2010-03-29 03:18:30.49

sysdatetimeoffset          sysdatetime
-----
2010-03-28 23:24:10.7485902 -04:00 2010-03-28 23:24:10.74

```

Be aware that retrieving the value from `getdate()` or `sysdatetime()` into a `datetimeoffset` variable or column does not capture the offset from UTC, even if you store the returned value in a column or variable defined with the `datetimeoffset` data type. To do so, you need to use the `SYSDATETIMEOFFSET()` function:

```

declare @datetimeoffset1 datetimeoffset,
        @datetimeoffset2 datetimeoffset
select
    @datetimeoffset1 = SYSDATETIME(),
    @datetimeoffset2 = SYSDATETIMEOFFSET()
select @datetimeoffset1, @datetimeoffset2
go

-----
2010-03-28 23:36:39.7271831 +00:00 2010-03-28 23:36:39.7271831 -04:00

```

Note that in the output, SQL Server Management Studio (SSMS) trims the time values down to two decimal places when it displays the results in the Text Results tab. However, this is just for display purposes (and applies only with text results; grid results display the full decimal precision). The actual value does store the precision down to the specified number of decimal places, which can be seen if you convert the `datetime2` value to a string format that displays all the decimal places:

```
select SYSDATETIME() as datetime2_trim,
       convert(varchar(30), SYSDATETIME(), 121) as datetime2_full
go
```

```
datetime2_trim          datetime2_full
-----
2010-03-30 23:52:30.68 2010-03-30 23:52:30.6851262
```

The SWITCHOFFSET() function can be used to convert a datetimeoffset value into a different time zone offset value:

```
select SYSDATETIMEOFFSET(), SWITCHOFFSET ( SYSDATETIMEOFFSET(), '-07:00' )
go
```

```
-----
2010-03-29 00:07:21.1335738 -04:00 2010-03-28 21:07:21.1335738 -07:00
```

When you are specifying a time zone value for the SWITCHOFFSET or TODATETIMEOFFSET offset functions, the value can be specified as an integer value representing the number of minutes of offset or as a time value in *hh:mm* format. The range of allowed values is +14 hours to -13 hours.

```
select TODATETIMEOFFSET ( SYSDATETIME(), -300 )
select TODATETIMEOFFSET ( SYSDATETIME(), '-05:00' )
go
```

```
-----
2010-03-29 00:23:05.5773288 -05:00
```

```
-----
2010-03-29 00:23:05.5773288 -05:00
```

Date and Time Conversions

If an existing CONVERT style includes the time part, and the conversion is from datetimeoffset to a string, the time zone offset (except for style 127) is included. If you do not want the time zone offset, you need to use cast or convert the datetimeoffset value to datetime2 first and then to a string:

```
select convert(varchar(35), SYSDATETIMEOFFSET(), 121) as datetime_offset,
       CONVERT(varchar(30), cast(SYSDATETIMEOFFSET() as datetime2),121) as datetime2
go
```

```
datetime_offset          datetime2
-----
2010-03-30 23:57:36.1015950 -04:00 2010-03-30 23:57:36.1015950
```

When you convert from `datetime2` or `datetimeoffset` to `date`, there is no rounding and the date part is extracted explicitly. For any implicit conversion from `datetimeoffset` to `date`, `time`, `datetime2`, `datetime`, or `smalldatetime`, conversion is based on the local date and time value (to the persistent time zone offset). For example, when the `datetimeoffset(3)` value, `2006-10-21 12:20:20.999 -8:00`, is converted to `time(3)`, the result is `12:20:20.999`, not `20:20:20.999(UTC)`.

If you convert from a higher-precision time value to a lower-precision value, the conversion is permitted, and the higher-precision values are truncated to fit the lower precision type.

If you are converting a `time(n)`, `datetime2(n)`, or `datetimeoffset(n)` value to a string, the number of digits depends on the type specification. If you want a specific precision in the resulting string, convert to a data type with the appropriate precision first and then to a string, as follows:

```
select
    convert(varchar(35), sysdatetime(), 121) as datetime_offset,
    CONVERT(varchar(30), cast(sysdatetime() as datetime2(3)), 121) as datetime2
go
```

datetime_offset	datetime2
-----	-----
2010-03-31 00:04:37.3306880	2010-03-31 00:04:37.331

If you attempt to cast a string literal with a fractional seconds precision that is more than that allowed for `smalldatetime` or `datetime`, Error 241 is raised:

```
declare @datetime datetime
select @datetime = '2010-03-31 00:04:37.3306880'
go
```

Msg 241, Level 16, State 1, Line 2

Conversion failed when converting date and/or time from character string.

Table-Valued Parameters

In previous versions of SQL Server, it was not possible to share the contents of table variables between stored procedures. SQL Server 2008 changes that with the introduction of table-valued parameters, which allow you to pass table variables to stored procedures as input parameters. Table-valued parameters provide more flexibility and, in many cases, better performance than temporary tables as a means to pass result sets between stored procedures.

To create and use table-valued parameters, you must first create a user-defined table type as a TABLE data type and define the table structure. This is done using the CREATE TYPE command, as shown in Listing 42.10.

LISTING 42.10 Defining a User-Defined Table Type

```
if exists (select * from sys.systypes t where t.name = 'ytdsales_tabletype'
          and t.uid = USER_ID('dbo'))
    drop type ytdsales_tabletype
go
CREATE TYPE ytdsales_tabletype AS TABLE
(title_id char(6),
 title varchar(50),
 pubdate date,
 ytd_sales int)
go
```

After creating the user-defined table data type, you can use it for declaring local table variables and for stored procedure parameters. To use the table-valued parameter in a procedure, you create a procedure to receive and access data through a table-valued parameter, as shown in Listing 42.11.

LISTING 42.11 Defining a Stored Procedure with a Table-Valued Parameter

```
/* Create a procedure to receive data for the table-valued parameter. */
if OBJECT_ID('tab_parm_test') is not null
    drop proc tab_parm_test
go
create proc tab_parm_test
    @pubdate datetime = null,
    @sales_minimum int = 0,
    @ytd_sales_tab ytdsales_tabletype READONLY
as
set nocount on

if @pubdate is null
    -- if no date is specified, set date to last year
    set @pubdate = dateadd(month, -12, getdate())

select * from @ytd_sales_tab
where pubdate > @pubdate
and ytd_sales >= @sales_minimum
return
go
```

Then, when calling that stored procedure, you declare a local table variable using the table data type defined previously, populate the table variable with data, and then pass the table variable to the stored procedure (see Listing 42.12).

LISTING 42.12 Executing a Stored Procedure with a Table-Valued Parameter

```

/* Declare a variable that references the table type. */
declare @ytd_sales_tab ytdsales_tabletype

/* Add data to the table variable. */
insert @ytd_sales_tab
    select title_id, convert(varchar(50), title), pubdate, ytd_sales
    from titles

/* Pass the table variable populated with data to a stored procedure. */
exec tab_parm_test '6/1/2001', 10000, @ytd_sales_tab
go

```

title_id	title	ytd_sales
BU2075	You Can Combat Computer Stress!	18722
MC3021	The Gourmet Microwave	22246
TC4203	Fifty Years in Buckingham Palace Kitchens	15096

The scope of a table-valued parameter is limited to only the stored procedure to which it is passed. To access the contents of a table-valued parameter in a procedure called by another procedure that contains a table-valued parameter, you need to pass the table-valued parameter to the subprocedure. Listing 42.13 provides an example of a subprocedure and alters the procedure created in Listing 42.6 to call the subprocedure.

LISTING 42.13 Passing a Table-Valued Parameter to a Subprocedure

```

/* Create the sub-procedure */
create proc tab_parm_subproc
    @pubdate datetime = null,
    @sales_minimum int = 0,
    @ytd_sales_tab ytdsales_tabletype READONLY
as
select * from @ytd_sales_tab
where ytd_sales <= @sales_minimum
and ytd_sales <> 0

```

```

go

/* modify the tab_part_test proc to call the sub-procedure */
alter proc tab_parm_test
    @pubdate datetime = null,
    @sales_minimum int = 0,
    @ytd_sales_tab ytdsales_tabletype READONLY
as
set nocount on

if @pubdate is null
    -- if no date is specified, set date to last year
    set @pubdate = dateadd(month, -12, getdate())

select * from @ytd_sales_tab
where pubdate > @pubdate
and ytd_sales >= @sales_minimum

exec tab_parm_subproc @pubdate,
    @sales_minimum,
    @ytd_sales_tab

return
go

/* Declare a variable that references the type. */
declare @ytd_sales_tab ytdsales_tabletype

/* Add data to the table variable. */
insert @ytd_sales_tab
    select title_id, convert(varchar(50), title), pubdate, ytd_sales
    from titles
    where type = 'business'

/* Pass the table variable populated with data to a stored procedure. */
exec tab_parm_test '6/1/2001', 10000, @ytd_sales_tab
go

```

Table-Valued Parameters Versus Temporary Tables

Table-valued parameters offer more flexibility and in some cases better performance than temporary tables or other ways to pass a list of values to a stored procedure. One benefit is table-valued parameters do not acquire locks for the initial population of data from a client. Also, table-valued parameters are memory resident and do not incur physical I/O unless they grow too large to remain in cache memory.

However, table-valued parameters do have some restrictions:

- ▶ SQL Server does not create or maintain statistics on columns of table-valued parameters.
- ▶ Table-valued parameters can be passed only as READONLY input parameters to T-SQL routines. You cannot perform UPDATE, DELETE, or INSERT operations on a table-valued parameter within the body of the stored procedure to which it is passed.
- ▶ Like table variables, a table-valued parameter cannot be specified as the target of a SELECT INTO or INSERT EXEC statement. They can only be populated using an INSERT statement.

Hierarchyid Data Type

The Hierarchyid data type introduced in SQL Server 2008 is actually a system-supplied common language runtime (CLR) user-defined type (UDT) that can be used for storing and manipulating hierarchical structures (for example, parent-child relationships) in a relational database. The Hierarchyid type is stored as a varbinary value that represents the position of the current node in the hierarchy (both in terms of parent-child position and position among siblings). You can perform manipulations on the type in Transact-SQL by invoking methods exposed by the type.

Creating a Hierarchy

First, let's define a hierarchy in a table using the Hierarchyid data type. For example, this section uses the Parts table example used in Chapter 28, "Creating and Managing Stored Procedures," to demonstrate how a stored procedure could be used to traverse a hierarchy stored in a table. There is also an example in Chapter 52 using a recursive common table expression (CTE) to perform a similar action. Let's see how to implement an alternative solution by adding a Hierarchyid column to the Parts table. First, you create a version of the Parts table using the Hierarchyid data type (see Listing 42.14).

LISTING 42.14 Creating the **Parts** Table with a **Hierarchyid** Data Type

```

Use bigpubs2008
Go
CREATE TABLE PARTS_hierarchy(
    partid int NOT NULL,
    hid hierarchyid not null,
    lvl as hid.GetLevel() persisted,
    partname varchar(30) NOT NULL,
PRIMARY KEY NONCLUSTERED (partid),
UNIQUE NONCLUSTERED (partname)
)

```

Note the `hid` column defined with the `Hierarchyid` data type. Notice also how the `lvl` column is defined as a compute column using the `GetLevel` method of the `hid` column to define the persisted computed column level. The `GetLevel` method returns the level of the current node in the hierarchy.

The `Hierarchyid` data type provides topological sorting, meaning that a child's sort value is guaranteed to be greater than the parent's sort value. This guarantees that a node's sort value will be higher than all its ancestors. You can take advantage of this feature by creating an index on the `Hierarchyid` column because the index will sort the data in a depth-first manner. This ensures that all members of the same subtree are close to each other in the leaf level of the index, which makes the index useful as an efficient mechanism for returning all descendants of a node. To take advantage of this, you can create a clustered index on the `hid` column:

```
CREATE UNIQUE CLUSTERED INDEX idx_hid_first ON Parts_hierarchy (hid);
```

You can also use another indexing strategy called *breadth-first*, in which you organize all nodes from the same level close to each other in the leaf level of the index. This is done by building the index such that the leading column is level in the hierarchy. Queries that need to get all nodes from the same level in the hierarchy can benefit from this type of index:

```
CREATE UNIQUE INDEX idx_lvl_first ON Parts_hierarchy(lvl, hid);
```

Populating the Hierarchy

Now that you've created the hierarchy table, the next step is to populate it. To insert a new node into the hierarchy, you must first produce a new `Hierarchyid` value that represents the correct position in the hierarchy. There are two methods available with the `Hierarchyid` data type to do this: the `HIERARCHYID::GetRoot()` method and `GetDescendant` method. You use the `HIERARCHYID::GetRoot()` method to produce the value for the root node of the hierarchy. This method simply produces a `Hierarchyid` value that is internally an empty binary string representing the root of the tree.

You can use the `GetDescendant` method to produce a value below a given parent. The `GetDescendant` method accepts two optional `Hierarchyid` input values that represent the two nodes between which you want to position the new node. If both values are not `NULL`, the method produces a new value positioned between the two nodes. If the first parameter

is not NULL and the second parameter is NULL, the method produces a value greater than the first parameter. Finally, if the first parameter is NULL and the second parameter is not NULL, the method produces a value smaller than the second parameter. If both parameters are NULL, the method produces a value simply below the given parent.

NOTE

The `GetDescendant` method does not guarantee that `Hierarchyid` values are unique. To enforce uniqueness, you must define either a primary key, unique constraint, or unique index on the `Hierarchyid` column.

The code in Listing 42.15 uses a cursor to loop through the rows currently in the `Parts` table and populates the `Parts_hierarchy` table. If the part is the first node in the hierarchy, the procedure uses the `HIERARCHYID::GetRoot()` method to assign the `hid` value for the root node of the hierarchy. Otherwise, the code in the cursor looks for the last child `hid` value of the new part's parent part and uses the `GetDescendant` method to produce a value that positions the new node after the last child of that parent part.

NOTE

Listing 42.15 also makes use of a recursive common table expression to traverse the existing `Parts` table in hierarchical order to add in the rows at the proper level, starting with the top-most parent part. If you are unfamiliar with CTEs (which were introduced in SQL Server 2005), you may want to review the "In Case you Missed it..." section in Chapter 43.

LISTING 42.15 Populating the **Parts_hierarchy** Table

```

DECLARE
    @hid          AS HIERARCHYID,
    @parent_hid  AS HIERARCHYID,
    @last_child_hid AS HIERARCHYID,
    @partid     int,
    @partname   varchar(30),
    @parentpartid int

declare parts_cur cursor for
WITH PartsCTE(partid, partname, parentpartid, lvl)
AS
(
    SELECT partid, partname, parentpartid, 0
    FROM PARTS
    WHERE parentpartid is null

```

```

UNION ALL
SELECT P.partid, P.partname, P.parentpartid, PP.lvl+1
FROM Parts as P
     JOIN PartsCTE as PP
       ON P.parentpartid = PP.Partid
)
SELECT PartID, Partname, ParentPartid
FROM PartsCTE
order by lvl

open parts_cur

fetch parts_cur into @partid, @partname, @parentpartid

while @@FETCH_STATUS = 0
begin
    if @parentpartid is null
        set @hid = HIERARCHYID::GetRoot()
    else
        begin
            select @parent_hid = hid from PARTS_hierarchy
                where partid = @parentpartid
            select @last_child_hid = MAX(hid) from PARTS_hierarchy
                where hid.GetAncestor(1) = @parent_hid
            select @hid = @parent_hid.GetDescendant(@last_child_hid, NULL)
        end

    insert PARTS_hierarchy (partid, hid, partname)
        values (@partid, @hid, @partname)

    fetch parts_cur into @partid, @partname, @parentpartid
end

close parts_cur
deallocate parts_cur
go

```

Querying the Hierarchy

Now that you've populated the hierarchy, you should query it to view the data and verify the hierarchy was populated correctly. However, if you query the `hid` value directly, you see only its binary representation, which is not very meaningful. To view the `Hierarchyid` value in a more useful manner, you can use the `ToString` method, which returns a logical string representation of the `Hierarchyid`. This string representation is shown as a path

with a slash sign used as a separator between the levels. For example, you can run the following query to get both the binary and logical representations of the hid value:

```
select cast(hid as varbinary(6)) as hid,
       substring(hid.ToString(), 1, 12) as path,
       lvl,
       partid,
       partname
From parts_hierarchy
go
```

hid	path	lvl	partid	partname
0x	/	0	22	Car
0x58	/1/	1	1	DriveTrain
0x68	/2/	1	23	Body
0x78	/3/	1	24	Frame
0x5AC0	/1/1/	2	2	Engine
0x5B40	/1/2/	2	3	Transmission
0x5BC0	/1/3/	2	4	Axle
0x5C20	/1/4/	2	12	Drive Shaft
0x5B56	/1/2/1/	3	9	Flywheel
0x5B5A	/1/2/2/	3	10	Clutch
0x5B5E	/1/2/3/	3	16	Gear Box
0x5AD6	/1/1/1/	3	5	Radiator
0x5ADA	/1/1/2/	3	6	Intake Manifold
0x5ADE	/1/1/3/	3	7	Exhaust Manifold
0x5AE1	/1/1/4/	3	8	Carburetor
0x5AE3	/1/1/5/	3	13	Piston
0x5AE5	/1/1/6/	3	14	Crankshaft
0x5AE358	/1/1/5/1/	4	21	Piston Rings
0x5AE158	/1/1/4/1/	4	11	Float Valve
0x5B5EB0	/1/2/3/1/	4	15	Reverse Gear
0x5B5ED0	/1/2/3/2/	4	17	First Gear
0x5B5EF0	/1/2/3/3/	4	18	Second Gear
0x5B5F08	/1/2/3/4/	4	19	Third Gear
0x5B5F18	/1/2/3/5/	4	20	Fourth Gear

As stated previously, the values stored in a Hierarchyid column provide topological sorting of the nodes in the hierarchy. The `GetLevel` method can be used to produce the level in the hierarchy (as it was to store the level in the computed `lvl` column in the `Parts_hierarchy` table). Using the `lvl` column or the `GetLevel` method, you can easily produce a graphical depiction of the hierarchy by simply sorting the rows by `hid` and generating indentation for each row based on the `lvl` column, as shown in the following example:

```

SELECT
  REPLICATE('--', lvl)
  + right('>', lvl)
  + partname AS partname
FROM Parts_hierarchy
order by hid
go

```

```

partname
-----
Car
-->DriveTrain
---->Engine
----->Radiator
----->Intake Manifold
----->Exhaust Manifold
----->Carburetor
----->Float Valve
----->Piston
----->Piston Rings
----->Crankshaft
---->Transmission
----->Flywheel
----->Clutch
----->Gear Box
----->Reverse Gear
----->First Gear
----->Second Gear
----->Third Gear
----->Fourth Gear
---->Axle
---->Drive Shaft
-->Body
-->Frame

```

To return only the subparts of a specific part, you can use the `IsDescendantOf` method. The parameter passed to this method is a node's `Hierarchyid` value. The method returns 1 if the queried node is a descendant of the input node. For example, the following query returns all subparts of the engine:

```

select child.partid, child.partname, child.lvl
from
  parts_hierarchy as parent
  inner join
  parts_hierarchy as child
  on parent.partname = 'Engine'
  and child.hid.IsDescendantOf(parent.hid) = 1

```

```
go
```

partid	partname	lvl
2	Engine	2
5	Radiator	3
6	Intake Manifold	3
7	Exhaust Manifold	3
8	Carburetor	3
13	Piston	3
14	Crankshaft	3
21	Piston Rings	4
11	Float Valve	4

You can also use the `IsDescendantOf` method to return all parent parts of a given part:

```
select parent.partid, parent.partname, parent.lvl
from
    parts_hierarchy as parent
    inner join
    parts_hierarchy as child
    on child.partname = 'Piston'
    and child.hid.IsDescendantOf(parent.hid) = 1
go
```

partid	partname	lvl
22	Car	0
1	DriveTrain	1
2	Engine	2
13	Piston	3

To return a specific level of subparts for a given part, you can use the `GetAncestor` method. You pass this method an integer value indicating the level below the parent you want to display. The function returns the `Hierarchyid` value of the ancestor n levels above the queried node. For example, the following query returns all the subparts two levels down from the drivetrain:

```
select child.partid, child.partname
from
    parts_hierarchy as parent
    inner join
    parts_hierarchy as child
    on parent.partname = 'Drivetrain'
    and child.hid.GetAncestor(2) = parent.hid
go
```

partid	partname	lvl
9	Flywheel	3
10	Clutch	3
16	Gear Box	3
5	Radiator	3
6	Intake Manifold	3
7	Exhaust Manifold	3
8	Carburetor	3
13	Piston	3
14	Crankshaft	3

Modifying the Hierarchy

The script in Listing 42.15 performs the initial population of the `Parts_hierarchy` table. What if you need to add additional records into the table? Let's look at how to use the `GetDescendant` method to add new records at different levels of the hierarchy.

For example, to add a child part to the `Body` node (node `/2/`), you can use the `GetDescendant` method without any arguments to add the new row below `Body` node at node `/2/1/`:

```
INSERT Parts_hierarchy (hid, partid, partname)
  select hid.GetDescendant(null, null), 25, 'left front fender'
  from Parts_hierarchy
  where partname = 'Body'
```

To add a new row as a higher descendant node at the same level as the left front fender inserted in the previous example, you use the `GetDescendant` method again, but this time passing the `Hierarchyid` of the existing child node as the first parameter. This specifies that the new node will follow the existing node, becoming `/2/2/`. There are a couple of ways to specify the `Hierarchyid` of the existing child node. You can retrieve it from the table as a `Hierarchyid` data type, or if you know the string representation of the node, you can use the `Parse` method. The `Parse` method converts a canonical string representation of a hierarchical value to `Hierarchyid`. `Parse` is also called implicitly when a conversion from a string type to `Hierarchyid` occurs, as in `CAST(input AS hierarchyid)`. `Parse` is essentially the opposite of the `ToString` method.

```
INSERT Parts_hierarchy (hid, partid, partname)
  select hid.GetDescendant(hierarchyid::Parse('/2/1/'), null), 26, 'right
  front fender'
  from Parts_hierarchy
  where partname = 'Body'
```

Now, what if you need to add a new node between the two existing nodes you just added? Again, you use the `GetDescendant` methods, but this time, you pass it the hierarchy IDs of both existing nodes between which you want to insert the new node:

```
declare @child1 hierarchyid,
        @child2 hierarchyid
select @child1 = hid from Parts_hierarchy where partname = 'left front fender'
select @child2 = hid from Parts_hierarchy where partname = 'right front fender'
```

```
INSERT Parts_hierarchy (hid, partid, partname)
select hid.GetDescendant(@child1, @child2), 27, 'front bumper'
from Parts_hierarchy
where partname = 'Body'
```

Now, let's run a query of the `Body` subtree to examine the newly inserted child nodes:

```
select child.partid, child.partname, child.lvl,
       substring(child.hid.ToString(), 1, 12) as path
from
  parts_hierarchy as parent
  inner join
  parts_hierarchy as child
  on parent.partname = 'Body'
  and child.hid.IsDescendantOf(parent.hid) = 1
order by child.hid
go
```

partid	partname	lvl	path
23	Body	1	/2/
25	left front fender	2	/2/1/
27	front bumper	2	/2/1.1/
26	right front fender	2	/2/2/

Notice that the first child added (left front fender) has a node path of `/2/1/`, and the second row added (right front fender) has a node path of `/2/2/`. The new child node inserted between these two nodes (front bumper) was given a node path of `/2/1.1/` so that it maintains the designated topological ordering of the nodes.

What if you need to make other types of changes within hierarchies? For example, you might need to move a whole subtree of parts from one part to another (that is, move a part and all its subordinates). To move nodes or subtrees in a hierarchy, you can use the `GetReparentedValue` method of the `Hierarchyid` data type. You invoke this method on the `Hierarchyid` value of the node you want to reparent and provide as inputs the value of the old parent and the value of the new parent.

Note that this method doesn't change the `Hierarchyid` value for the existing node that you want to move. Instead, it returns a new `Hierarchyid` value that you can use to update

the target node's Hierarchyid value. Logically, the `GetReparentedValue` method simply substitutes the part of the existing node's path that represents the old parent's path with the new parent's path. For example, if the path of the existing node is `/1/2/1/`, the path of the old parent is `/1/2/`, and the path of the new parent is `/2/1/3/`, the `GetReparentedValue` method would return `/2/1/3/1/`.

You have to be careful, though. If the target parent node already has child nodes, the `GetReparentedValue` method may not produce a unique hierarchy path. If you reparent node `/1/2/1/` from old parent `/1/2/` to new parent `/2/1/3/`, and `/2/1/3/` already has a child `/2/1/3/1/`, you generate a duplicate value. To avoid this situation when moving a single node from one parent to another, you should not use the `GetReparentedValue` method but instead use the `GetDescendant` method to produce a completely new value for the single node. For example, let's assume you want to move the `Flywheel` part from the `Transmission` node to the `Engine` node. A sample approach is shown in Listing 42.16. This example uses the `GetDescendant` method to generate a new Hierarchyid under the `Engine` node following the last child node and updates the `hid` column for the `Flywheel` record to the new Hierarchyid generated.

LISTING 42.16 Moving a Single Node in a Hierarchy

```

declare @newhid hierarchyid,
        @maxchild hierarchyid
-- first, find the max child node under the Engine node
-- this is the node we will move the Flywheel node after
select @maxchild = max(child.hid)
from
    parts_hierarchy as parent
    inner join
    parts_hierarchy as child
        on parent.partname = 'Engine'
        and child.hid.GetAncestor(1) = parent.hid
select 'Child to insert after' = @maxchild.ToString()
-- Now, generate a new descendant hid for the Engine node
-- after the max child node
select @newhid = hid.GetDescendant(@maxchild, null)
    from Parts_hierarchy
    where partname = 'Engine'
-- Update the hid for the Flywheel node to the new hid
update Parts_hierarchy
    set hid = @newhid
    where partname = 'Flywheel'
go

Child to insert after
.....
/1/1/6/

```

If you need to move an entire subtree within a hierarchy, you can use the `GetReparentedValue` method in conjunction with the `GetDescendant` method. For example, suppose you want to move the whole Engine subtree from its current parent node of `Drivetrain` to the new parent node of `Car`. The `Car` node obviously already has children. If you want to avoid conflicts, the best approach is to generate a new `Hierarchyid` value for the root node of the subtree. You can achieve this with the following steps:

1. Use the `GetDescendant` method to produce a completely new `Hierarchyid` value for the root node of the subtree.
2. Update the `Hierarchyid` value of all nodes in the subtree to the value returned by the `GetReparentedValue` method.

Because you are generating a completely new `Hierarchyid` value under the target parent, this new child node has no existing children, which avoids any duplicate `Hierarchyid` values. Listing 42.17 provides an example for changing the parent node of the Engine subtree from `Drivetrain` to `Car`.

LISTING 42.17 Reparenting a Subtree in a Hierarchy

```

DECLARE
    @old_root AS HIERARCHYID,
    @new_root AS HIERARCHYID,
    @new_parent_hid AS HIERARCHYID,
    @max_child as hierarchyid

-- Get the hid of the new parent
select @new_parent_hid = hid
    FROM dbo.parts_hierarchy
    WHERE partname = 'Car'

-- Get the hid of the current root of the subnode
Select @old_root = hid
    FROM dbo.parts_hierarchy
    WHERE partname = 'Engine'

-- Get the max hid of child nodes of the new parent
select @max_child = MAX(hid)
    FROM parts_hierarchy
    WHERE hid.GetAncestor(1) = @new_parent_hid

-- get a new hid for the moving child node
-- that is after the current max child node of the new parent
SET @new_root = @new_parent_hid.GetDescendant (@max_child, null)

-- Next, reparent the moving child node and all descendants
UPDATE dbo.parts_hierarchy

```

```

SET hid = hid.GetReparentedValue(@old_root, @new_root)
WHERE hid.IsDescendantOf(@old_root) = 1

```

Now, let's reexamine the hierarchy after the updates made in Listings 42.16. and 42.17:

```

SELECT
  left(REPLICATE('-', lvl)
    + right('>', lvl)
    + partname, 30) AS partname,
  hid.ToString() AS path
FROM Parts_hierarchy
order by hid
go

```

partname	path
-----	-----
Car	/
-->DriveTrain	/1/
---->Transmission	/1/2/
----->Clutch	/1/2/2/
----->Gear Box	/1/2/3/
----->Reverse Gear	/1/2/3/1/
----->First Gear	/1/2/3/2/
----->Second Gear	/1/2/3/3/
----->Third Gear	/1/2/3/4/
----->Fourth Gear	/1/2/3/5/
---->Axle	/1/3/
---->Drive Shaft	/1/4/
-->Body	/2/
---->left front fender	/2/1/
---->front bumper	/2/1.1/
---->right front fender	/2/2/
-->Frame	/3/
-->Engine	/4/
---->Radiator	/4/1/
---->Intake Manifold	/4/2/
---->Exhaust Manifold	/4/3/
---->Carburetor	/4/4/
----->Float Valve	/4/4/1/
---->Piston	/4/5/
----->Piston Rings	/4/5/1/
---->Crankshaft	/4/6/
---->Flywheel	/4/7/

As you can see from the results, the Flywheel node is now under the Engine node, and the entire Engine subtree is now under the Car node.

Using FILESTREAM Storage

In versions of SQL Server prior to SQL Server 2008, there were two ways of storing unstructured data: as a binary large object (BLOB) in an image or varbinary(max) column, or in files outside the database, separate from the structured relational data, storing a reference or pathname to the file in a varchar column. Neither of these methods is ideal for handling unstructured data. Storing the data outside the database makes managing the unstructured data and keeping it associated with structured data more complex. This approach lacks transactional consistency, coordinating backups and restores with the structured data in the database is difficult, and implementing proper data security can be quite cumbersome.

Storing the unstructured data in the database solves the transactional consistency, backup/restore, and security issues, but BLOBs have different usage patterns than relational data. SQL Server's storage engine is primarily concerned with doing I/O on relational data stored in pages and extents, not streaming large BLOBs. I/O performance typically degrades dramatically if the size of the BLOB data increases beyond 1MB. Accessing BLOB data stored inside a SQL Server database is generally slower than storing it externally in a location such as the NTFS file system. In addition, BLOB storage is not as efficient as the file system for storing large data values, so more storage space is required.

FILESTREAM storage, introduced in SQL Server 2008, helps to solve the issues with using unstructured data by integrating the SQL Server Database Engine with the NTFS file system for storing unstructured data such as documents and images on the file system with a pointer to the data in the database. The file pointer is implemented in SQL Server as a varbinary(max) column, and the actual data is stored in files in the file system.

In addition to enabling client applications to leverage the rich NTFS streaming APIs and the performance of the file system for storing and retrieving unstructured data, other advantages of FILESTREAM storage include the following:

- ▶ You are able to use T-SQL statements to insert, update, query, and back up FILESTREAM data even though the actual data resides outside the database in the NTFS file system.
- ▶ You are able to maintain transactional consistency between the unstructured data and corresponding structured data.
- ▶ You are able to enforce the same level of security on the unstructured data as with your relational data using built-in SQL Server security mechanisms.

- ▶ FILESTREAM uses the NT system cache for caching file data rather than caching the data in the SQL Server buffer pool, leaving more memory available for query processing.
- ▶ FILESTREAM storage also eliminates the size limitation of BLOBS stored in the database. Whereas standard `image` and `varbinary(max)` columns have a size limitation of 2GB, the sizes of the FILESTREAM BLOBS are limited only by the available space of the file system.

Columns with the FILESTREAM attribute set can be managed just like any other BLOB column in SQL Server. Administrators can use the manageability and security capabilities of SQL Server to integrate FILESTREAM data management with the rest of the data in the relational database—without needing to manage the file system data separately. This includes maintenance operations such as backup and restore, complete integration with the SQL Server security model, and full-transaction support to ensure data-level consistency between the relational data in the database and the unstructured data physically stored on the file system. The database administrator does not need to manage the file system data separately.

Whether you should use database storage or file system storage for your BLOB data is determined by the size and use of the unstructured data. If the following conditions are true, you should consider using FILESTREAM:

- ▶ The objects being stored as BLOBS are, on average, larger than 1MB.
- ▶ Fast read access is important.
- ▶ You are developing applications that use a middle tier for application logic.

Enabling FILESTREAM Storage

If you decide to use FILESTREAM storage, it first needs to be enabled at both the Windows level as well as at the SQL Server Instance level. FILESTREAM storage can be enabled automatically during SQL Server installation or manually after installation.

If you are enabling FILESTREAM during SQL Server installation, you need to provide the Windows share location where the FILESTREAM data will be stored. You can also choose whether to allow remote clients to access the FILESTREAM data. For more information on how to enable FILESTREAM storage during installation, see Chapter 8, “Installing SQL Server 2008.”

If you did not enable the FILESTREAM option during installation, you can enable it for a running instance of SQL Server 2008 at any time using SQL Server Configuration Manager (SSCM). In SSCM, right-click on the SQL Server Service and select Properties. Then select the FILESTREAM tab, which provides similar options as those displayed during SQL Server installation (see Figure 42.1). This enables SQL Server to work directly with the Windows

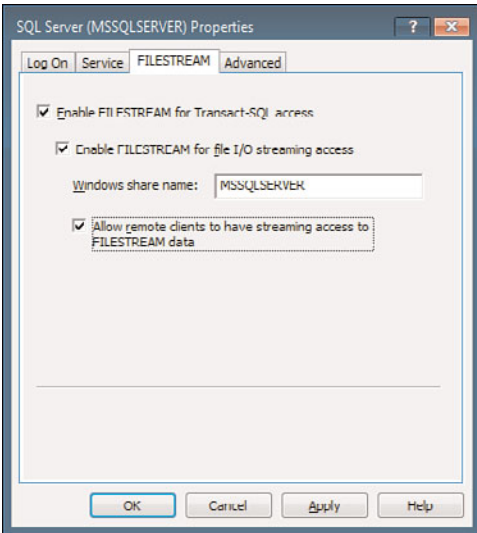

FIGURE 42.1 Setting FILESTREAM options in SQL Server Configuration Manager.

file system for storing FILESTREAM data. You have three options for how FILESTREAM functionality will be enabled:

- ▶ Allowing only T-SQL access (by checking only the Enable FILESTREAM for Transact-SQL Access option).
- ▶ Allowing both T-SQL and Win32 access to FILESTREAM data (by checking the Enable FILESTREAM for File I/O Streaming Access option and providing a Windows share name to be used to access the FILESTREAM data). This allows Win32 file system interfaces to provide streaming access to the data.
- ▶ Allowing remote clients to have access to the FILESTREAM data that is stored on this share (by selecting the Allow Remote Clients to Have Streaming Access to FILESTREAM Data option).

NOTE

You need to be Windows Administrator on a local system and have `sysadmin` rights to enable FILESTREAM for SQL Server.

After you enable FILESTREAM in SQL Server Configuration Manager, a new share is created on the host system with the name specified. This share is intended only to allow very low-level streaming interaction between SQL Server and authorized clients. It is recommended that only the service account used by the SQL Server instance should have access to this share. Also, because this change takes place at the OS level and not from within SQL Server, you need to stop and restart the SQL Server instance for the change to take effect.

After restarting the SQL Server instance to enable FILESTREAM at the Windows OS level, you next need to enable FILESTREAM for the SQL Server Instance. You can do this either through SQL Server Management Studio or via T-SQL. To enable FILESTREAM for the SQL Server instance using SQL Server Management Studio, right-click on the SQL Server instance in the Object Explorer, select Properties, select the Advanced page, and set the Filestream Access Level property as shown in Figure 42.2. The available options are

- ▶ **Disabled (0)**—FILESTREAM access is not permitted.
- ▶ **Transact SQL Access Enabled (1)**—FILESTREAM data can be accessed only by T-SQL commands.
- ▶ **Full Access Enabled (2)**—Both T-SQL and Win32 access to FILESTREAM data are permitted.

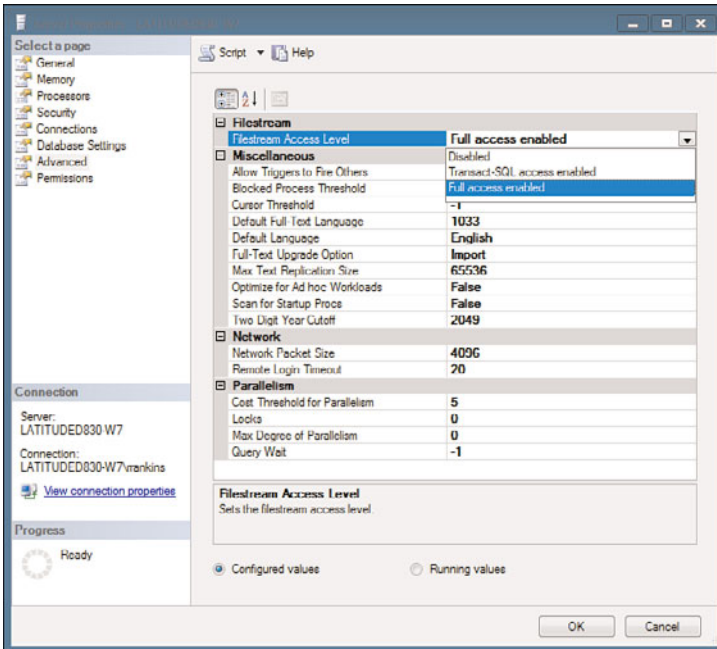

FIGURE 42.2 Enabling FILESTREAM for a SQL Server Instance in SSMS.

You can also optionally enable FILESTREAM for the SQL Server instance using the `sp_configure` system procedure, specifying the 'filestream access level' as the setting and passing the option of 0 (disabled), 1 (T-SQL access), or 2 (Full access). The following example shows full access being enabled for the current SQL Server instance:

```
EXEC sp_configure 'filestream access level', 2
GO
RECONFIGURE
GO
```

After you configure the SQL Server instance for FILESTREAM access, the next step is to set up a database to store FILESTREAM data.

Setting Up a Database for FILESTREAM Storage

After you enable FILESTREAM for the SQL Server instance, you can store FILESTREAM data in a database by creating a FILESTREAM filegroup. You can do this when creating the database or by adding a new filegroup to an existing database. The filegroup designated for FILESTREAM storage must include the `CONTAINS FILESTREAM` clause and be defined. The code in Listing 42.18 creates the Customer database and then adds a FILESTREAM filegroup.

LISTING 42.18 Setting Up a Database for FILESTREAM Storage

```
CREATE DATABASE Customer
ON ( NAME='Customer_Data',
     FILENAME='C:\SQLData\Customer_Data1.mdf',
     SIZE=50,
     MAXSIZE=100,
     FILEGROWTH=10)
LOG ON ( NAME='Customer_Log',
        FILENAME='C:\SQLData\Customer_Log.1df',
        SIZE=50,
        FILEGROWTH=20%)
GO

ALTER DATABASE Customer
ADD FILEGROUP Cust_FSGroup CONTAINS FILESTREAM
GO

ALTER DATABASE Customer
ADD FILE ( NAME=custinfo_FS,
          FILENAME = 'G:\SQLData\custinfo_FS')
TO FILEGROUP Cust_FSGroup
GO
```

Notice in Listing 42.18 the FILESTREAM filegroup points to a file system folder rather than an actual file. This folder must not exist already (although the path up to the folder must exist); SQL Server creates the FILESTREAM folder (for example, in Listing 42.18, the `custinfo_FS` folder is created automatically by SQL Server in the `G:\SQLData` folder). The FILESTREAM files and file data actually end up being stored in the created folder. A FILESTREAM filegroup is restricted to referencing only a single file folder.

Using FILESTREAM Storage for Data Columns

Once FILESTREAM storage is enabled for a database, you can specify the FILESTREAM attribute on a `varbinary(max)` column to indicate that a column should store data in the FILESTREAM filegroup on the file system. When columns are defined with the FILESTREAM attribute, the Database Engine stores all data for that column on the file system instead of in the database file. In addition to a `varbinary(max)` column with the FILESTREAM attribute, tables used to store FILESTREAM data also require the existence of a UNIQUE ROWGUIDCOL, as shown in Listing 42.19, which creates a `custinfo` table on the FILESTREAM filegroup. `CUSTDATA` is defined as the FILESTREAM column, and `ID` is defined as the unique ROWGUID column.

LISTING 42.19 Creating a FILESTREAM-Enabled Table

```
CREATE TABLE CUSTINFO
(ID UNIQUEIDENTIFIER ROWGUIDCOL NOT NULL UNIQUE,
CUSTDATA VARBINARY (MAX) FILESTREAM NULL )
FILESTREAM_ON Cust_FSGroup
```

Each table created with a FILESTREAM column(s) creates a new subfolder in the FILESTREAM filegroup folder, and each FILESTREAM column in the table creates a separate subfolder under the `table` folder. These column folders are where the actual FILESTREAM files are stored. Initially, these folders are empty until you start adding rows into the table. A file is created in the `column` subfolder for each row inserted into the table with a non-NULL value for the FILESTREAM column.

NOTE

For more detailed information on how FILESTREAM data is stored and managed, see Chapter 34.

To ensure that SQL Server creates a new, blank file within the FILESTREAM storage folder for each row inserted in the table, you can specify a default value of `0x` for the FILESTREAM column:

```
alter table CUSTINFO add constraint custdata_def default 0x for CUSTDATA
```

Creating a default is not required if all access to the FILESTREAM data is going to be done through T-SQL. However, if you will be using Win32 streaming clients to upload file contents into the FILESTREAM column, the file needs to exist already. Without the default to ensure creation of a “blank” file for each row, new files would have to be created first by inserting contents directly through T-SQL before they could be accessed via Win32 client streaming applications.

To insert data into a FILESTREAM column, you use a normal INSERT statement and provide a varbinary(max) value to store into the FILESTREAM column:

```
INSERT CUSTINFO (ID, CUSTDATA)
VALUES (NEWID(), CONVERT(VARBINARY(MAX), REPLICATE ('CUST DATA', 10000)))
```

To retrieve FILESTREAM data, you can use a simple T-SQL SELECT statement, although you may need to convert the varbinary(max) to varchar to be able to display text data:

```
select ID, CONVERT(varchar(40), CUSTDATA) as CUSTDATA
from CUSTINFO
go
```

```
ID                                CUSTDATA
-----
FA67BF05-51B5-4BA7-A383-7F88DAAE9C49 CUST DATA CUST DATA CUST DATA CUST DATA
```

The preceding examples work fine if the FILESTREAM data is essentially text data; however, neither SQL Server Management Studio nor SQL Server itself really has any user interface, or native way, to let you stream the contents of an actual file into a table that's been marked with the FILESTREAM attribute on one of your varbinary(max) columns. In other words, if you have a .jpg or .mp3 file that you want to store within SQL Server, there's no native functionality to convert that image's byte stream into something that you could put, for example, into a simple INSERT statement. To read or store this type of data, you need to use Win32 to read and write data to a FILESTREAM BLOB. Following are the steps you need to perform in your client applications:

1. Read the FILESTREAM file path.
2. Read the current transaction context.
3. Obtain a Win32 handle and use the handle to read and write data to the FILESTREAM BLOB.

Each cell in a FILESTREAM table has a file path associated with it. You can use the PATHNAME property to retrieve the file path of a varbinary(max) column in a T-SQL statement:

```
DECLARE @filePath varchar(max)

SELECT @filePath = CUSTDATA.PathName()
FROM CUSTINFO
WHERE ID = 'FA67BF05-51B5-4BA7-A383-7F88DAAE9C49'
```

```
PRINT @filepath
go
```

```
\\LATTITUDE830-W7\FILESTREAM\v1\Customer\dbo\CUSTINFO\CUSTDATA
\FA67BF05-51B5-4BA7-A383-7F88DAAE9C49
```

Next, to obtain the current transaction context and return it to the client application, use the `GET_FILESTREAM_TRANSACTION_CONTEXT()` T-SQL function:

```
BEGIN TRAN
SELECT GET_FILESTREAM_TRANSACTION_CONTEXT()
```

After you obtain the transaction context, the next step in your application code is to obtain a Win32 file handle to read or write the data to the FILESTREAM column. To obtain a Win32 file handle, you call the `OpenSqlFilestream` API. The returned handle can then be passed to any of the following Win32 APIs to read and write data to a FILESTREAM BLOB:

- ▶ `ReadFile`
- ▶ `WriteFile`
- ▶ `TransmitFile`
- ▶ `SetFilePointer`
- ▶ `SetEndOfFile`
- ▶ `FlushFileBuffers`

To summarize, the steps you perform to upload a file to a FILESTREAM column are as follows:

1. Start a new transaction and obtain the transaction context ID that can be used to initiate the Win32 file-streaming process.
2. Execute a `SqlDataReader` connection to pull back the full path (in SQL Server) of the FILESTREAM file to which you will be uploading data.
3. Initiate a straight file-streaming operation using the `System.Data.SqlTypes.SqlFileStream` class.
4. Create a new `System.IO.FileStream` object to read the file locally and buffer bytes along to the `SqlFileStream` object until there are no more bytes to transfer.
5. Close the transaction.

NOTE

Because you're streaming file contents via a Win32 process, you need to use integrated security to connect to SQL Server because native SQL logins can't generate the needed security tokens to access the underlying file system where the FILESTREAM data is stored.

To retrieve data from a FILESTREAM column to a file on the client, you primarily follow the same steps as you do for inserting data; however, instead you pull data from a `SqlFileStream` object into a buffer and push it into a local FILESTREAM object until there are no more bytes left to retrieve.

TIP

Refer to the “Managing FILESTREAM Data by Using Win32” topic in SQL Server 2008 R2 Books Online for specific C#, Visual Basic, and Visual C++ application code examples showing how to obtain a Win32 file handle and use it to read and write data to a FILESTREAM column.

Sparse Columns

SQL Server 2008 provides a new space-saving storage option referred to as *sparse columns*. Sparse columns can provide optimized and efficient storage for columns that contain predominately NULL values. The NULL values require no storage space, but these space savings come at a cost of increased space for storing non-NULL values (an additional 2–4 bytes of space is needed for non-NULL values). For this reason, Microsoft recommends using sparse columns only when the space saved is at least 20% to 40%. However, the consensus rule of thumb that is emerging from experience with sparse columns is that it is best to use them only when more than 90% of the values are NULL.

There are a number of restrictions and limitations regarding the use of sparse columns, including the following:

- ▶ Sparse columns cannot be defined with the ROWGUIDCOL or IDENTITY properties.
- ▶ Sparse columns cannot be defined with a default value.
- ▶ Sparse columns cannot be used in a user-defined table type.
- ▶ Although sparse columns allow up to 30,000 columns per table, the total row size is reduced to 8,018 bytes due to the additional overhead for sparse columns.
- ▶ If a table has sparse columns, you can't compress it at either the row or page level.
- ▶ Columns defined with the geography, geometry, text, ntext, timestamp, image, or user-defined data types cannot be defined as sparse columns.
- ▶ You can't define varbinary(max) fields that use FILESTREAM storage as sparse columns.
- ▶ You can't define a computed column as sparse, but you can use a sparse column in the calculation of a computed column.
- ▶ A table cannot have more than 1,024 non-sparse columns.

Column Sets

Column sets provide an alternative way to view and work with all the sparse columns in a table. The sparse columns are aggregated into a single untyped XML column, which simplifies working with many sparse columns in a table. The XML column used for a column set is similar to a calculated column in that it is not physically stored, but unlike calculated columns, it is updateable.

There are some restrictions on column sets:

- ▶ You cannot add a column set to a table that already has sparse columns.
- ▶ You can define only one column set per table.
- ▶ Constraints or default values cannot be defined on a column set.
- ▶ Computed columns cannot contain column set columns.
- ▶ A column set cannot be changed; you must delete and re-create the column set. However, sparse columns can be added to the table after a column set has been defined and is automatically included in the column set.
- ▶ Distributed queries, replication, and Change Data Capture do not support column sets.
- ▶ A column set cannot be part of any kind of index, including XML indexes, full-text indexes, and indexed views.

NOTE

Sparse columns and column sets are defined by using the `CREATE TABLE` or `ALTER TABLE` statements. This chapter focuses on using and working with sparse columns. For more information on defining sparse columns and column sets, see Chapter 24, “Creating and Managing Tables.”

Working with Sparse Columns

Querying and manipulation of sparse columns is the same as for regular columns, with one exception described later in this chapter. There’s nothing functionally different about a table that includes sparse columns, except the way the sparse columns are stored. You can still use all the standard `INSERT`, `UPDATE`, and `DELETE` statements on tables with sparse columns just like a table that doesn’t have sparse columns. You can also wrap operations on a table with sparse columns in transactions as usual.

To work with sparse columns, let’s first create a table with sparse columns. Listing 42.20 creates a version of the `Product` table in the `AdventureWorks2008R2` database and then populates the table with data from the `Production.Product` table. The `Color`, `Weight`, and `SellEndDate` columns are defined as sparse columns (the source data contains a significant number of `NULL` values for these columns). These columns are also defined as part of the column set, `ProductInfo`.

LISTING 42.20 Creating a Table with Sparse Columns

```
USE AdventureWorks2008R2
GO
CREATE TABLE Product_sparse
(
    ProductID INT NOT NULL PRIMARY KEY,
    ProductName NVARCHAR(50) NOT NULL,
```

```

Color NVARCHAR(15) SPARSE NULL,
Weight DECIMAL(8,2) SPARSE NULL,
SellEndDate DATETIME SPARSE NULL,
ProductInfo XML COLUMN_SET FOR ALL_SPARSE_COLUMNS
)
GO
INSERT INTO Product_sparse
(ProductID, ProductName, Color, Weight, SellEndDate)
SELECT ProductID, Name, Color, Weight, SellEndDate
FROM Production.Product
GO

```

You can reference the sparse columns in your queries just as you would any type of column:

```

SELECT productID, productName, Color, Weight, SellEndDate
FROM Product_sparse
where ProductID < 320
go

```

productID	productName	Color	Weight	SellEndDate
1	Adjustable Race	NULL	NULL	NULL
2	Bearing Ball	NULL	NULL	NULL
3	BB Ball Bearing	NULL	NULL	NULL
4	Headset Ball Bearings	NULL	NULL	NULL
316	Blade	NULL	NULL	NULL
317	LL Crankarm	Black	NULL	NULL
318	ML Crankarm	Black	NULL	NULL
319	HL Crankarm	Black	NULL	NULL

Note, however, that if you use `SELECT *` in a query and the table has a column set defined for the sparse columns, the column set is returned as a single XML column instead of the individual columns:

```

SELECT *
FROM Product_sparse
where ProductID < 320
go

```

ProductID	ProductName	ProductInfo
1	Adjustable Race	NULL
2	Bearing Ball	NULL
3	BB Ball Bearing	NULL
4	Headset Ball Bearings	NULL

```

316         Blade                NULL
317         LL Crankarm           <Color>Black</Color>
318         ML Crankarm           <Color>Black</Color>
319         HL Crankarm           <Color>Black</Color>

```

You need to explicitly list the columns in the SELECT clause to have the result columns returned as relational columns.

When the column set is defined, you can also operate on the column set by using XML operations instead of relational operations. For example, the following code inserts a row into the table by using the column set and specifying a value for Weight as XML:

```

INSERT Product_sparse(ProductID, ProductName, ProductInfo)
VALUES(5, 'ValveStem', '<Weight>.12</Weight>')
go

```

```

SELECT productID, productName, Color, Weight, SellEndDate
FROM Product_sparse
where productID = 5
go

```

```

productID  productName  Color  Weight  SellEndDate
-----
5          ValveStem   NULL   0.12   NULL

```

Notice that NULL is assumed for any column omitted from the XML value, such as Color and SellEndDate in this example.

When updating a column set using an XML value, you must include values for all the columns in the column set you want to set, including any existing values. Any values not specified in the XML string are set to NULL. For example, the following query sets both Color and Weight where ProductID = 5:

```

Update Product_sparse
set ProductInfo = '<Color>black</Color><Weight>.20</Weight>'
where productID = 5

```

```

SELECT productID, productName, Color, Weight, SellEndDate
FROM Product_sparse
where productID = 5
go

```

```

productID  productName  Color  Weight  SellEndDate
-----
5          ValveStem   black  0.20   NULL

```

Now, if you run another update but only specify a value for `Weight` in the XML string, the `Color` column is set to `NULL`:

```
Update Product_sparse
set ProductInfo = '<Weight>.10</Weight>'
where productID = 5
```

```
SELECT productID, productName, Color, Weight, SellEndDate
FROM Product_sparse
where productID = 5
go
```

```
productID  productName Color Weight SellEndDate
-----
5          ValveStem  NULL  0.10  NULL
```

However, if you reference the sparse columns explicitly in an `UPDATE` statement, the other values remain unchanged:

```
Update Product_sparse
set Color = 'silver'
where ProductID = 5
```

```
SELECT productID, productName, Color, Weight, SellEndDate
FROM Product_sparse
where productID = 5
go
```

```
productID  productName Color Weight SellEndDate
-----
5          ValveStem  silver 0.10  NULL
```

Column sets are most useful when you have many sparse columns in a table (for example, hundreds) and operating on them individually is cumbersome. Your client applications may more easily and efficiently generate the appropriate XML string to populate the column set rather than your having to build an `UPDATE` statement dynamically to determine which of the sparse columns need to be included in the `SET` clause. Applications might actually see some performance improvement when they select, insert, or update data by using column sets on tables that have lots of columns.

Sparse Columns: Good or Bad?

There is some disagreement in the SQL Server community whether or not sparse columns are appropriate. A number of professionals are of the opinion that any table design that requires sparse columns is a bad design that does not follow good relational design guidelines. Sparse columns, by their nature, are heavily denormalized. On the other hand, many times you have to live in the real world and make the best of a bad database design

that you've inherited. Sparse columns can help solve performance and storage issues in databases that may have been poorly designed.

Although sparse columns can solve certain kinds of problems with database design, you should never use them as an alternative to proper database and table design. As cool as sparse columns are, they aren't appropriate for every scenario, particularly when you're tempted to violate normalization rules to be able to cram more fields into a table.

Spatial Data Types

SQL Server's support of SQLCLR allows for very rich user-defined types to be utilized. For example, a developer could create a single object that contains multiple properties and can also perform calculations internally (methods), yet still store it in a single column in a single row in a database table. This allows multiple complex types of data to be stored and queried in the database, instead of just strings and numbers.

SQL Server 2008 makes use of SQLCLR to support two new .NET CLR data types for storing spatial data: `GEOMETRY` and `GEOGRAPHY`. These types support methods and properties that allow for the creation, comparison, analysis, and retrieval of spatial data. Spatial data types provide a comprehensive, high-performance, and extensible data storage solution for spatial data, enabling organizations of any scale to integrate geospatial features into their applications and services.

The `GEOMETRY` data type is a .NET CLR data type that supports the planar model/data, which assumes a flat projection and is therefore sometimes called *flat earth*. Geometry data represents information in a uniform two-dimensional plane as points, lines, and polygons on a flat surface, such as maps and interior floor plans where the curvature of the earth does not need to be taken into account. For example, perhaps your user-defined coordinate space is being used to represent a warehouse facility. Within that coordinate space, you can use the `GEOMETRY` data type to define areas that represent storage bays within the warehouse. You can then store data in your database that tracks which inventory is located in which area. You could then query the data to determine which forklift driver is closest to a certain type of item, for example.

The `GEOGRAPHY` data type provides a storage structure for geodetic data, sometimes referred to as *round-earth data* because it assumes a roughly spherical model of the world. It provides a storage structure for spatial data that is defined by latitude and longitude coordinates using an industry standard ellipsoid such as WGS84, the projection method used by Global Positioning System (GPS) applications. The SQL Server `GEOGRAPHY` data type uses latitude and longitude angles to identify points on the earth. Latitude measures how far north (or south) of the equator a point is, while longitude measures how far east (or west) of a prime meridian a point is. Note that this coordinate system can be used to identify points on any spherical object, be it a baseball, the earth, or even the moon.

The `GEOMETRY` and `GEOGRAPHY` data types support seven instance types that you can create and work with in a database:

- ▶ **POINT**—A **POINT** is an exact location and is defined in terms of an X and Y pair of coordinates, as well as optionally by Z (elevation) and M (measure) coordinates. It

does not have a length or any area associated with it. These instance types are used as the fundamental building blocks of more complex spatial types.

- ▶ **MULTIPOINT**—A **MULTIPOINT** is a collection of zero or more points.
- ▶ **LINestring**—A **LINestring** is the path between a sequence of points (that is, a series of connected line segments). It is considered *simple* if it does not cross over itself and is considered a *ring* if the starting point is the same as the ending point. A **LINestring** is always considered to be a one-dimensional object; it has length but does not have area (even if it is a ring).
- ▶ **MULTILINestring**—A **MULTILINestring** is a collection of zero or more **GEOMETRY** or **GEOGRAPHY** **LINestring** instances.
- ▶ **POLYGON**—A **POLYGON** is a closed two-dimensional shape defined by a ring. It has both length and area and has at least three distinct points. A **POLYGON** may also have *holes* in its interior (a hole is defined by another **POLYGON**). Area within a hole is considered to be exterior to the **POLYGON** itself.
- ▶ **MULTIPOLYGON**—A **MULTIPOLYGON** instance is a collection of zero or more **POLYGON** instances.
- ▶ **GEOMETRYCOLLECTION**—A **GEOMETRYCOLLECTION** is a collection of zero or more **GEOMETRY** or **GEOGRAPHY** instances. A **GEOMETRYCOLLECTION** can be empty. This is similar to a list or an array in most programming languages. The most generic type of collection is the **GEOMCOLLECTION**, whose members can be of any type.

Representing Spatial Data

The Open Geospatial Consortium, Inc. (OGC) is a nonprofit, international, voluntary consensus standards organization that is leading the development of standards for geospatial and location-based services. The OGC defines different ways to represent geospatial information as bytes of data that can then be interpreted by the **GEOMETRY** or **GEOGRAPHY** types as being **POINTS**, **LINestrings**, and so on. SQL Server 2008 supports three such formats:

- ▶ Well-Known Text (WKT)
- ▶ Well-Known Binary (WKB)
- ▶ Geography Markup Language (GML)

For the purposes of this chapter, we stick to WKT examples because they are both concise and somewhat readable. The syntax of WKT is not too difficult to understand, so let's look at some examples:

- ▶ **POINT(10 100)**—Here, 10 and 100 represent X and Y values of the point.
- ▶ **POINT(10 100 10 1)**—This example shows Z and M values in addition to X and Y.
- ▶ **LINestring(0 0, 10 100)**—The first two values represent the starting point, and the last two values represent the end point of the line.

- ▶ **POLYGON((0 0, 0 10, 10 10, 10 0, 0 0))**—Each pair of numbers represents a point on the edge of the polygon. Note that the end point is the same as the starting point.

Working with Geometry Data

As mentioned previously, the geometry data type is implemented as a common language runtime (CLR) data type in SQL Server and is used to represent data in a Euclidean (flat) coordinate system. The `GEOMETRY` type is predefined and available in each database. Any variable, parameter, or table column can be declared with the `GEOMETRY` data type, and you can operate on geometry data in the same manner as you would use other CLR types using the built-in methods to create, validate, and query geometry data.

NOTE

SQL Server provides a number of methods for the `GEOMETRY` and `GEOGRAPHY` data types. Covering all the available methods is beyond the scope of this chapter. The examples provided here touch on some of the more common methods. For more information on other `GEOMETRY` and `GEOGRAPHY` methods, refer to *SQL Server 2008 Books Online*.

To assign a value to a column or variable of type `GEOMETRY`, you must use one of the static methods to parse the representation of the data into the spatial data type. For example, to parse geometry data provided in a valid WKT syntax, you can use the `STGeomFromText` method:

```
Declare @geom GEOMETRY
Declare @geom2 GEOMETRY
SET @geom = geometry::STGeomFromText('LINESTRING (100 100, 20 180, 180 180)', 0)
SET @geom2 = geometry::STGeomFromText
                ('POLYGON ((0 0, 150 0, 150 150, 0 150, 0 0))', 0)
```

NOTE

The last parameter passed to the method is the spatial reference ID (SRID) parameter. The SRID is required. SQL Server 2008 does not perform calculations on pieces of spatial information that belong to separate spatial reference systems (for example, if one system uses centimeters and another uses miles, SQL Server simply does not have the means to automatically convert units). For the `GEOMETRY` type, the default SRID value is 0. The default SRID for `GEOGRAPHY` is 4326, which maps to the WGS 84 spatial reference system.

If you are declaring a `LINESTRING` specifically, you can use the `STLineFromText` static method that accepts only valid `LINESTRING`s as input:

```
Declare @geom GEOMETRY
SET @geom = geometry::STLineFromText('LINESTRING (100 100, 20 180, 180 180)', 0)
```

The GEOMETRY type, like other SQLCLR UDTs, supports implicit conversion to and from a string. The string format supported by the GEOMETRY type for implicit conversion is WKT. Due to this feature, all the following SET statements are functionally equivalent (the last two SET statements use an implicit SRID of 0):

```
DECLARE @geom GEOMETRY
SET @geom = geometry::STLineFromText('LINESTRING (100 100, 20 180, 180 180)', 0)
set @geom = Geometry::Parse('LINESTRING (100 100, 20 180, 180 180)')
set @geom = 'LINESTRING (100 100, 20 180, 180 180)'
```

After defining a GEOMETRY instance, you can use the CLR UDT dot notation to access other properties and methods of the GEOGRAPHY instance. For example, the following code uses the STLength() method to return the length of the LINESTRING:

```
DECLARE @geom GEOMETRY
SET @geom = geometry::STLineFromText('LINESTRING (100 100, 20 180, 180 180)', 0)
```

```
select @geom.STLength() as "Length"
go
```

```
Length
-----
273.137084989848
```

The following example uses the STIntersection() method to return the points where two GEOMETRY instances intersect:

```
DECLARE @geom1 GEOMETRY;
DECLARE @geom2 GEOMETRY;
DECLARE @result GEOMETRY;

SET @geom1 = geometry::STGeomFromText('LINESTRING (100 100, 20 180, 180 180)', 0)
SET @geom2 = geometry::STGeomFromText('POLYGON ((0 0, 150 0, 150 150, 0 150, 0
0))', 0)
SELECT @result = @geom1.STIntersection(@geom2);
SELECT @result.STAsText();
go
```

```
-----
LINESTRING (50 150, 100 100)
```

All the preceding examples use local variables in a batch. You also can declare columns in a table with the GEOMETRY type, and you can use the instance properties and methods against the columns as well:

```

CREATE TABLE #geom_demo
(
    GeomID      INT IDENTITY NOT NULL,
    GeomCol     GEOMETRY
)

INSERT INTO #geom_demo (GeomCol)
VALUES      ('LINESTRING (100 100, 20 180, 180 180)'),
            ('POLYGON ((0 0, 150 0, 150 150, 0 150, 0 0))'),
            ('POINT(10 10)')

SELECT
    GeomID,
    GeomCol.ToString() AS WKT,
    GeomCol.STLength() AS LENGTH,
    GeomCol.STArea() as Area
FROM #geom_demo

drop table #geom_demo
go

```

GeomID	WKT	LENGTH	Area
1	LINESTRING (100 100, 20 180, 180 180)	273.137084989848	0
2	POLYGON ((0 0, 150 0, 150 150, 0 150, 0 0))	600	22500
3	POINT (10 10)	0	0

Working with Geography Data

The GEOGRAPHY data type is also implemented as a .NET common language runtime data type in SQL Server. Unlike the GEOMETRY data type in which locations are defined in terms of X and Y coordinates that can conceivably extend to infinity, the GEOGRAPHY type represents data in a round-earth coordinate system. Whereas flat models do not “wrap around,” the round-earth coordinate system does wrap around such that if you start at a point on the globe and continue in one direction, you eventually return to the starting point.

Because defining points on a ball using X and Y is not very practical, the GEOGRAPHY data type instead defines points using angles. The SQL Server GEOGRAPHY data type stores ellipsoidal (round-earth) data as GPS latitude and longitude coordinates. Longitude represents the horizontal angle and ranges from -180 degrees to 180 degrees, and latitude represents the vertical angle and ranges from -90 degrees to 90 degrees.

The GEOGRAPHY data type provides similar built-in methods as the GEOMETRY data type that you can use to create, validate, and query geography instances.

To assign a value to a geography column or variable, you can use the `STGeomFromText` methods to parse the parse geometry data provided in a valid WKT syntax into a valid geography value:

```
Declare @geog GEOGRAPHY
Declare @geog2 GEOGRAPHY
SET @geog =
geography::STGeomFromText('LINESTRING(-122.360 47.656,
                                -122.343 47.656)', 4326)
SET @geog2 =
geography::STGeomFromText('POLYGON((-122.358 47.653,
                                -122.348 47.649,
                                -122.348 47.658,
                                -122.358 47.658,
                                -122.358 47.653))', 4326)
```

As with the `GEOMETRY` data type, you can also use the `STLineFromText` static method that accepts only valid `LINESTRINGS` as input, or you can take advantage of the support for implicit conversion of WKT strings:

```
DECLARE @geog GEOGRAPHY
SET @geog = Geography::STLineFromText('LINESTRING (-122.360 47.656,
                                -122.343 47.656)', 4326)
set @geog = Geography::Parse('LINESTRING (-122.360 47.656,
                                -122.343 47.656)')

set @geog = 'LINESTRING (-122.360 47.656, -122.343 47.656)'
```

The following code uses the `STLength()` and `STArea()` methods to return the length of the `LINESTRING`:

```
DECLARE @geom GEOMETRY
SET @geom = geometry::STLineFromText('LINESTRING (100 100, 20 180, 180 180)', 0)

select @geom.STLength() as "Length"
go

Length
-----
273.137084989848
```

The preceding examples use local variables in a batch. You also can declare columns in a table using the geography data type, and you can use the instance properties and methods against the columns as well:

```
CREATE TABLE #geog
( id int IDENTITY (1,1),
```

```

    GeogCol1 GEOGRAPHY,
    GeogCol2 AS GeogCol1.STAsText() );
GO

INSERT INTO #geog (GeogCol1)
VALUES (geography::STGeomFromText
        ('LINESTRING(-122.360 47.656, -122.343 47.656)', 4326));

INSERT INTO #geog (GeogCol1)
VALUES (geography::STGeomFromText
        ('POLYGON((-122.358 47.653,
                    -122.348 47.649,
                    -122.348 47.658,
                    -122.358 47.658,
                    -122.358 47.653))', 4326));
GO

DECLARE @geog1 GEOGRAPHY;
DECLARE @geog2 GEOGRAPHY;
DECLARE @result GEOGRAPHY;

SELECT @geog1 = GeogCol1 FROM #geog WHERE id = 1;
SELECT @geog2 = GeogCol1 FROM #geog WHERE id = 2;
SELECT @result = @geog1.STIntersection(@geog2);
SELECT Intersection = @result.STAsText();
go

```

Intersection

```

-----
-----
LINESTRING (-122.3479999999668 47.656000260658459
, -122.35799999998773 47.656000130309728)

```

Spatial Data Support in SSMS

When querying spatial data in SSMS, you'll find that SSMS has a built-in capability to plot and display some basic maps of your spatial data.

To demonstrate this, you can run the following query in the AdventureWorks2008R2 or AdventureWorks2008 database in SSMS:

```

select SpatialLocation
    from person.Address a
        inner join
    person.StateProvince sp
        on a.StateProvinceID = sp.StateProvinceID
        and sp.CountryRegionCode = 'US'

```

After the query runs, you should see a Spatial Results tab next to the Results tab (see Figure 42.3). Click on this tab, and the location points are plotted on a map. Select the Bonne Projection. If you look closely, you can see that the geographical points plotted roughly provide an outline of the United States. If you mouse over one of the points, SSMS displays the associated address information displayed in the `Person.Address` table.

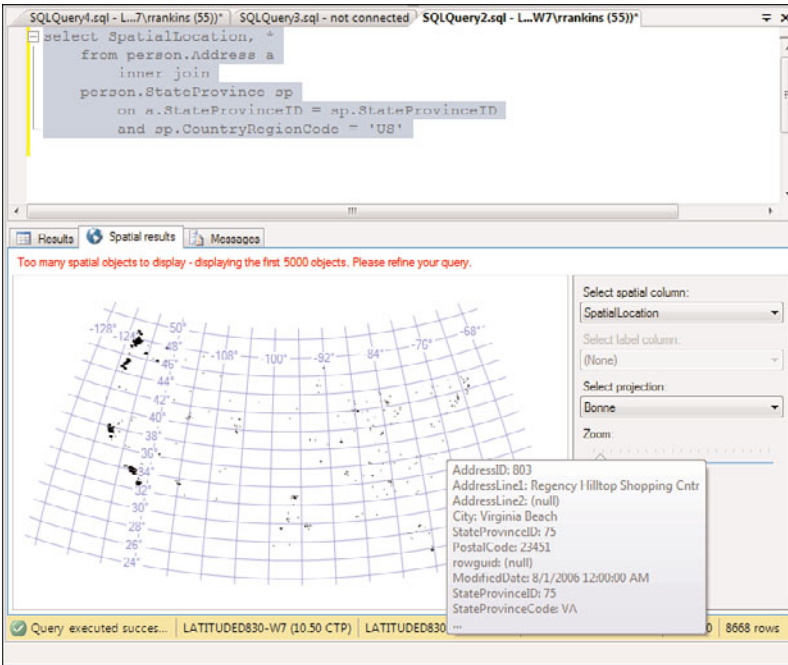

FIGURE 42.3 Displaying a map of **Person.Address** records in SSMS.

In addition to displaying maps of geography data values, SSMS can also display geometry data, showing lines, points, and polygons in an X-Y grid. For example, if you run the following query and click on the Spatial Results tab, it should display a box like the one shown in Figure 42.4:

```
declare @smallBox GEOMETRY = 'polygon((0 0, 0 2, 2 2, 2 0, 0 0))';
select @smallBox
```

If you want to display multiple polygons, points, or lines together at the same time, they have to be returned as multiple rows in a single table. If you return them as multiple columns, SSMS displays only one column at a time in the Spatial Results tab. For example, if you run the following query, SSMS displays two boxes, the polygon defined by the intersection of the two boxes, as well as the overlapping line defined by the `LineString`, as shown in Figure 42.5:

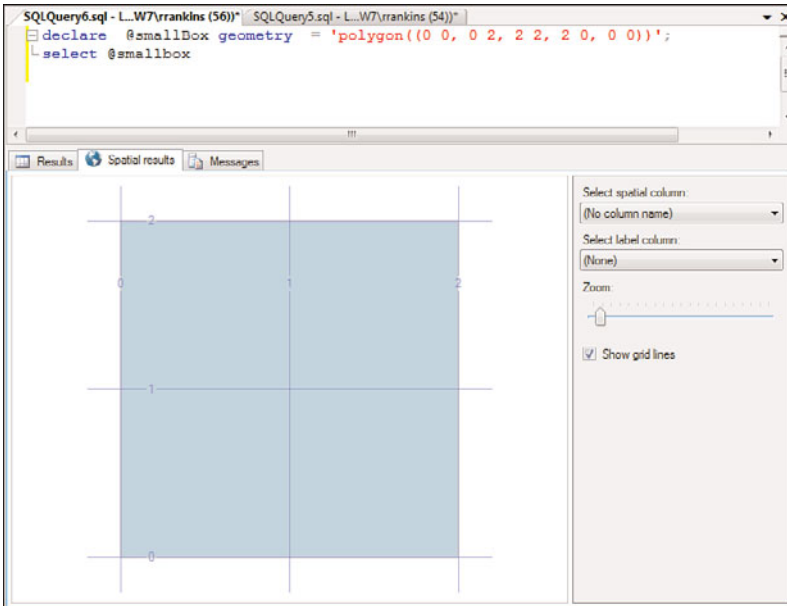

FIGURE 42.4 Displaying a polygon in SSMS.

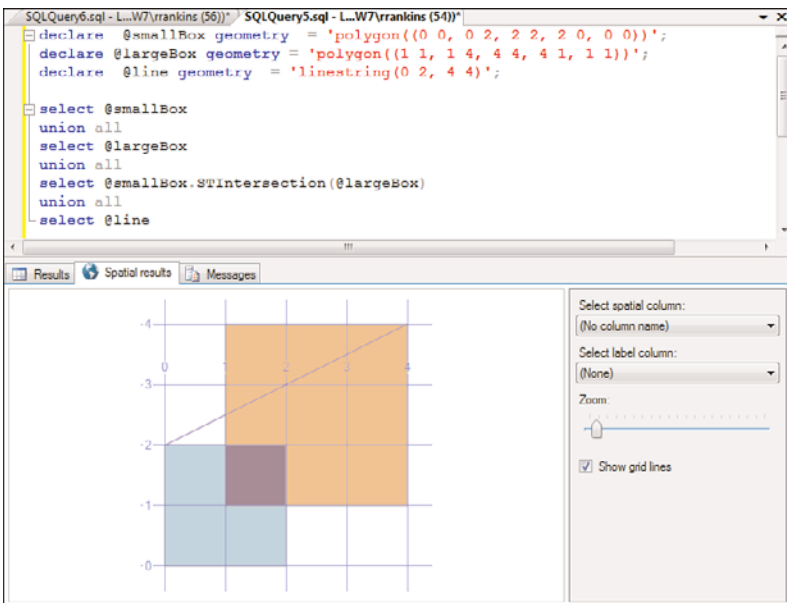

FIGURE 42.5 Displaying intersecting polygons and an overlapping Line in SSMS.

```

declare @smallBox GEOMETRY = 'polygon((0 0, 0 2, 2 2, 2 0, 0 0))';
declare @largeBox GEOMETRY = 'polygon((1 1, 1 4, 4 4, 4 1, 1 1))';
declare @line GEOMETRY = 'linestring(0 2, 4 4)';

select @smallBox
union all
select @largeBox
union all
select @smallBox.STIntersection(@largeBox)
union all
select @line

```

Spatial Data Types: Where to Go from Here?

The preceding sections provide only a brief introduction to spatial data types and how to work with geometry and geography data. For more information on working with spatial data, in addition to Books Online, you might want to visit the Microsoft SQL Server 2008 Spatial Data page at <http://www.microsoft.com/sqlserver/2008/en/us/spatial-data.aspx>. This page provides links to whitepapers and other technical documents related to working with spatial data in SQL Server 2008.

In addition, all examples here deal with spatial data only as data values and coordinates. Spatial data is often most useful when it can be displayed visually, such as on a map. SQL Server 2008 R2 Reporting Services provides new map controls and a map wizard for creating map reports based on spatial data. For more information, see Chapter 53, “SQL Server 2008 Reporting Services.”

Change Data Capture

In SQL Server 2008, Microsoft introduced a new feature called Change Data Capture (CDC), which is designed to make it much easier and less resource intensive to identify and retrieve changed data from tables in an online transaction processing (OLTP) database. In a nutshell, CDC captures and records INSERT, UPDATE, and DELETE activity in an OLTP database and stores it in a form that is easily consumed by an application, such as a SQL Server Integration Services (SSIS) package.

In the past, capturing data changes for your tables for auditing or extract, transform, and load (ETL) purposes required using replication, time stamp columns, triggers, complex queries, or expensive third-party tools. None of these other methods are easy to implement, and many of them use a lot of server resources, negatively affecting the performance of the OLTP server.

Change Data Capture provides for a more efficient mechanism for capturing the data changes in a table.

NOTE

Change Data Capture is available only in the SQL Server 2008 Developer, Enterprise, and Datacenter Editions.

The source of change data for Change Data Capture is the SQL Server transaction log. As inserts, updates, and deletes are applied to tables, entries that describe those changes are added to the transaction log. When Change Data Capture is enabled for a database, a SQL Server Agent capture job is created to invoke the `sp_replcmds` system procedure. This procedure is an internal server function and is the same mechanism used by transactional replication to harvest changes from the transaction log.

NOTE

If replication is already enabled for the database, the transactional log reader used for replication is also used for CDC. This strategy significantly reduces log contention when both replication and Change Data Capture are enabled for the same database.

The principal task of the Change Data Capture process is to scan the log and identify changes to data rows in any tables configured for Change Data Capture. As these changes are identified, the process writes column data and transaction-related information to the Change Data Capture tables. The changes can then be read from these change tables to be applied as needed.

The Change Data Capture Tables

When CDC is enabled for a database and one or more tables, an associated Change Data Capture table is created for each table being monitored. The Change Data Capture tables are used to store the changes made to the data in corresponding source tables, along with some metadata used to track the changes. By default, the name of the CDC change table is `schemaname_tablename_CT` and is based on the name of the source table.

The first five columns of a Change Data Capture change table are metadata columns and contain additional information relevant to the recorded change:

- ▶ **__\$start_lsn**—Identifies the commit log sequence number (LSN) assigned to the change. This value can be used to determine the order of the transactions.
- ▶ **__\$end_lsn**—Is currently not used and in SQL Server 2008 is always **NULL**.
- ▶ **__\$seqval**—Can be used to order changes that occur within the same transaction.

- ▶ **__\$operation**—Records the operation associated with the change: 1 = delete, 2 = insert, 3 = update before image(delete), and 4 = update after image(insert)
- ▶ **__\$update_mask**—Is a variable bit mask with one defined bit for each captured column to identify what columns were changed. For insert and delete entries, the update mask always has all bits set. Update rows have the bits set only for the columns that were modified.

The remaining columns in the Change Data Capture change table are identical to the columns from the source table in name and type and are used to store the column data gathered from the source table when an insert, update, or delete operation is performed on the table.

For every row inserted into the source table, a single row is inserted into the change table, and this row contains the column values inserted into the source table. Every row deleted from the source table is also inserted as a single row into the change table but contains the column values in the row before the delete operation. An update operation is captured as a delete followed by an insert, so two rows are captured for each update: one row entry to capture the column values before the update, and a second row entry to capture the column values after the update.

In addition to the Change Data Capture tables, the following Change Data Capture meta-data tables are also created:

- ▶ **cdc.change_tables**—Contains one row for each change table in the created when Change Data Capture is enabled on a source table.
- ▶ **cdc.index_columns**—Contains one row for each index column used by Change Data Capture to uniquely identify rows in the source table. By default, this is the column of the primary key of the source table, but a different unique index on the source table can be specified when Change Data Capture is enabled on the source table. A primary key or unique index is required on the source table only if Net Change Tracking is enabled.
- ▶ **cdc.captured_columns**—Contains one row for each column tracked in each source table. By default, all columns of the source table are captured, but you can include or exclude columns when enabling Change Data Capture for a table by specifying a column list.
- ▶ **cdc.ddl_history**—Contains a row for each Data Definition Language (DDL) change made to any table enabled for Change Data Capture. You can use this table to determine when a DDL change occurred on a source table and what the change was.
- ▶ **cdc.lsn_time_mapping**—Contains a row for each transaction stored in a change table and is used to map between log sequence number (LSN) commit values and the actual time the transaction was committed.

Although you can query the Change Data Capture tables directly, it is not recommended. Instead, you should use the Change Data Capture functions, which are discussed later.

All these objects associated with a CDC instance are created in the special schema called `cdc` when Change Data Capture is enabled for a database.

Enabling CDC for a Database

Before you can begin capturing data changes for a table, you must first enable the database for Change Data Capture. You do this by running the stored procedure `sys.sp_cdc_enable_db` within the desired database context. When a database is enabled for Change Data Capture, the `cdc` schema, `cdc` user, metadata tables, as well as the system functions, are used to query for change data.

42

NOTE

To determine whether a database is already enabled for CDC, you can check the value in the `is_cdc_enabled` column in the `sys.databases` catalog view. A value of 1 indicates that CDC is enabled for the specified database.

The following SQL code enables CDC for the `AdventureWorks2008R2` database and then checks that CDC is enabled by querying the `sys.databases` catalog view:

```
use AdventureWorks2008R2
go
exec sys.sp_cdc_enable_db
go
select is_cdc_enabled
from sys.databases
where name = 'AdventureWorks2008R2'
go

is_cdc_enabled
-----
1
```

NOTE

Although the examples presented here are run against the `AdventureWorks2008R2` database, they can also be run against the `AdventureWorks2008` database. However, you should be aware that some of the column values displayed may not be exactly the same.

Enabling CDC for a Table

When the database is enabled for Change Data Capture, you can use the `sys.sp_cdc_enable_table` stored procedure to enable a Change Data Capture instance for any tables in that database. The `sp_cdc_enable_Table` stored procedure supports the following parameters:

- ▶ **@source_schema**—Specifies the name of the schema in which the source table resides.
- ▶ **@source_name**—Specifies the name of the source table.
- ▶ **@role_name**—Indicates the name of the database role used to control access to Change Data Capture tables. If this parameter is set to `NULL`, no role is used to limit access to the change data. If the specified role does not exist, SQL Server creates a database role with the specified name.
- ▶ **@capture_instance**—Specifies the name of the capture instance used to name the instance-specific Change Data Capture objects. By default, this is the source schema name plus the source table name in the format *schemaname_sourcename*. A source table can have a maximum of two capture instances.
- ▶ **@supports_net_changes**—Is set to `1` or `0` to indicate whether support for querying for net changes is to be enabled for this capture instance. If this parameter is set to `1`, the source table must have a defined primary key, or an alternate unique index must be specified for the `@index_name` parameter.
- ▶ **@index_name**—Specifies the name of a unique index to use to uniquely identify rows in the source table.
- ▶ **@captured_column_list**—Specifies the source table columns to be included in the change table. By default, all columns are included in the change table.
- ▶ **@filegroup_name**—Specifies the filegroup to be used for the change table created for the capture instance. If this parameter is `NULL` or not specified, the default filegroup is used. If possible, it is recommended you create a separate filegroup from your source tables for the Change Data Capture change tables.
- ▶ **@allow_partition_switch**—Indicates whether the **SWITCH PARTITION** command of `ALTER TABLE` can be executed against a table that is enabled for Change Data Capture. The default is `1` (enabled). If any partition switches occur, Change Data Capture does not track the changes resulting from the switch. This causes data inconsistencies when the change data is consumed.

The `@source_schema`, `@source_name`, and `@role_name` parameters are the only required parameters. All the others are optional and apply default values if not specified.

To implement basic change data tracking for a table, let's first create a copy of the `Customer` table to play around with:

```
select * into MyCustomer from Sales.Customer
alter table MyCustomer add Primary key (CUsomerID)
```

Now, to enable CDC on the `MyCustomer` table, you can execute the following:

```
EXEC sys.sp_cdc_enable_table
@source_schema = N'dbo',
@source_name   = N'MyCustomer',
@role_name     = NULL
```

NOTE

If this is the first time you are enabling CDC for a table in the database, you may see the following messages, which indicate that SQL Server is enabling the SQL Agent jobs to begin capturing the data changes in the database:

```
Job 'cdc.AdventureWorks2008R2_capture' started successfully.
```

```
Job 'cdc.AdventureWorks2008R2_cleanup' started successfully.
```

The Capture job that is created generally runs continuously and is used to move changed data to the CDC tables from the transaction log. The Cleanup job runs on a scheduled basis to remove older data from the CDC tables so that they don't grow too large. By default, it automatically removes data that is more than three days old. The properties of these jobs can be viewed and modified using the `sys.sp_cdc_help_jobs` and `sys.sp_cdc_change_job` procedures, respectively.

42

To determine whether or not a source table has been enabled for Change Data Capture, you can query the `is_tracked_by_cdc` column in the `sys.tables` catalog view for that table:

```
select is_tracked_by_cdc
from sys.tables
where name = 'MyCustomer'
go
```

```
is_tracked_by_cdc
-----
1
```

TIP

To get information on which tables are configured for CDC and what the settings for each are, you can execute the `sys.sp_cdc_help_change_data_capture` stored procedure. It reports the name and ID of the source and Change Tracking tables, the CDC table properties, the columns included in the capture, and the date the CDC was enabled/created for the source table.

Querying the CDC Tables

After you enable change data tracking for a table, SQL Server begins capturing any data changes for the table in the Change Data Capture tables. To identify the data changes, you need to query the Change Data Capture tables. Although you can query the Change Data Capture tables directly, it is recommended that you use the CDC functions instead. The main CDC table-valued functions (TVFs) are

- ▶ `cdc.fn_cdc_get_all_changes_capture_instance`

► `cdc.fn_cdc_get_net_changes_capture_instance`

NOTE

The Change Data Capture change table and associated CDC table-valued functions created along with it constitute what is referred to as a *capture instance*. A capture instance is created for every source table that is enabled for CDC.

Each capture instance is given a unique name based on the schema and table names. For example, if the table named `sales.products` is CDC enabled, the capture instance created is named `sales_products`. The name of the CDC change table within the capture instance is `sales_products_CT`, and the names of the two associated CDC query functions are `cdc.fn_cdc_get_all_changes_sales_products` and `cdc.fn_cdc_get_net_changes_sales_products`.

Both of the CDC table-valued functions require two parameters to define the range of log sequence numbers to use as the upper and lower bounds to determine which records are to be included in the returned result set. A third required parameter, the `row_filter_option`, specifies the content of the metadata columns as well as the rows to be returned in the result set. Two values can be specified for the `row_filter` for the `cdc.fn_cdc_get_all_changes_capture_instance` function: "all" and "all update old".

If "all" is specified, the function returns all changes within the specified log sequence number (LSN) range. For changes due to an update operation, only the row containing the new values after the update are returned. If "all update old" is specified, the function returns all changes within the specified LSN range. For changes due to an update operation, this option returns both the before and after update copies of the row.

For the `cdc.fn_cdc_get_net_changes_capture_instance` function, three values can be specified for the `row_filter` parameter: "all", "all with mask", and "all with merge". If "all" is specified, the function returns the LSN of the final change to the row, and the operation needed to apply the change to the row is returned in the `__$start_lsn` and `__$operation` metadata columns. The `__$update_mask` column is always NULL. If "all with mask" is specified, the function returns the LSN of the final change to the row and the operation needed to apply the change to the row. Plus, if the `__$operation` equals 4 (that is, it contains the after update row values), the columns actually modified in the update are identified by the bit mask returned in the `__$update_mask` column.

If the "all with merge" option is passed, the function returns the LSN of the final change to the row and the operation needed to apply the change to the row. The `__$operation` column will have one of two values: 1 for delete and 5 to indicate that the operation needed to apply the change is either an insert or update. The column `__$update_mask` is always NULL.

So how do you determine what LSNs to specify to return the rows you need? Fortunately, SQL Server provides several functions to help determine the appropriate LSN values for use in querying the TVFs:

- ▶ **sys.fn_cdc_get_min_lsn**—Returns the smallest LSN associated with a capture instance validity interval. The validity interval is the time interval for which change data is currently available for its capture instances.
- ▶ **sys.fn_cdc_get_max_lsn**—Returns the largest LSN in the validity **interval**.
- ▶ **sys.fn_cdc_map_time_to_lsn** and **sys.fn_cdc_map_lsn_to_time**—Are used to correlate LSN values with a standard time value.
- ▶ **sys.fn_cdc_increment_lsn** and **sys.fn_cdc_decrement_lsn**—Can be used to make an incremental adjustment to an LSN value. This adjustment is sometimes necessary to ensure that changes are not duplicated in consecutive query windows.

So, before you can start querying the CDC tables, you need to generate some records in them by running some data modifications against the source tables. First, you need to run the statements in Listing 42.21 against the MyCustomer table to generate some records in the dbo_MyCustomer_CT Change Data Capture change table.

LISTING 42.21 Some Data Modifications to Populate the **MyCustomer** CDC Capture Table

```
delete MyCustomer where CustomerID = 22

Insert MyCustomer (PersonID, StoreID, TerritoryID,
                  AccountNumber, rowguid, ModifiedDate)
Values (20778, null, 9,
       'AW' + RIGHT('00000000'
                   + convert(varchar(8), IDENT_Current('MyCustomer')), 8),
       NEWID(),
       GETDATE())

declare @ident int
select @ident = SCOPE_IDENTITY()

update MyCustomer
set TerritoryID = 3,
    ModifiedDate = GETDATE()
where CustomerID = @ident
```

Now that you have some rows in the CDC capture table, you can start retrieving them. First, you need to identify the min and max LSN values to pass to the

cdc.fn_cdc_get_all_changes_dbo_MyCustomer function. This can be done using the sys.fn_cdc_get_min_lsn and sys.fn_cdc_get_max_lsn functions. Listing 42.22 puts all these pieces together to return the records stored in the CDC capture table.

LISTING 42.22 Querying the **MyCustomer** CDC Capture Table

```
USE AdventureWorks2008R2
GO

--declare variables to represent beginning and ending lsn
DECLARE @from_lsn BINARY(10), @to_lsn BINARY(10)

-- get the first LSN for table changes
SELECT @from_lsn = sys.fn_cdc_get_min_lsn('dbo_MyCustomer')

-- get the last LSN for table changes
SELECT @to_lsn = sys.fn_cdc_get_max_lsn()

-- get all changes in the range using "all update old" parameter
SELECT *
FROM cdc.fn_cdc_get_all_changes_dbo_MyCustomer
      (@from_lsn, @to_lsn, 'all update old');

GO

__ $start_lsn          __ $seqval          __ $operation
__ $update_mask CustomerID PersonID      StoreID      TerritoryID
AccountNumber rowguid
ModifiedDate
-----
-----
-----
0x00000039000014400004 0x00000039000014400002 1
0x7F          22          NULL          494          3
AW00000022    9774AED6-D673-412D-B481-2573E470B478
2008-10-13 11:15:07.263
0x00000039000014410004 0x00000039000014410003 2
0x7F          30119          20778          NULL          9
AW00030119    2385A86E-6FD2-4815-8BFE-B3F4DF4AEA74
2010-04-27 22:38:44.267
0x000000390000144C0004 0x000000390000144C0002 3
0x48          30119          20778          NULL          9
AW00030119    2385A86E-6FD2-4815-8BFE-B3F4DF4AEA74
2010-04-27 22:38:44.267
ccc0x000000390000144C0004 0x000000390000144C0002 4
```

```
ccc0x48          30119          20778          NULL          3
cccAW00030119   2385A86E-6FD2-4815-8BFE-B3F4DF4AEA74
ccc2010-04-27 22:38:48.263
```

Because the option "all update old" is specified in Listing 42.22, all the rows in the `dbo_MyCustomer_CT` capture table are returned, including the deleted row, inserted row, and both the before and after copies of the row updated.

If you want to return only the final version of each row within the LSN range (and the `@supports_net_changes` was set to 1 when CDC was enabled for the table), you can use the `cdc.fn_cdc_get_net_changes_capture_instance` function, as shown in Listing 42.23.

LISTING 42.23 Querying the **MyCustomer** CDC Capture Table for Net Changes

```
USE AdventureWorks2008R2
GO

--declare variables to represent beginning and ending lsn
DECLARE @from_lsn BINARY(10), @to_lsn BINARY(10)

-- get the first LSN for table changes
SELECT @from_lsn = sys.fn_cdc_get_min_lsn('dbo_MyCustomer')

-- get the last LSN for table changes
SELECT @to_lsn = sys.fn_cdc_get_max_lsn()

-- get all changes in the range using "all with_merge" parameter
SELECT *
FROM cdc.fn_cdc_get_net_changes_dbo_MyCustomer
      (@from_lsn, @to_lsn, 'all with merge');

GO

__ $start_lsn          __ $operation __ $update_mask CustomerID
PersonID   StoreID     TerritoryID AccountNumber
rowguid                                         ModifiedDate
-----
-----
-----
0x00000039000014400004 1          NULL          22
NULL        494         3             AW00000022
9774AED6-D673-412D-B481-2573E470B478 2008-10-13 11:15:07.263
ccc0x000000390000144C0004 5          NULL          30119
ccc20778    NULL         3             AW00030119
ccc2385A86E-6FD2-4815-8BFE-B3F4DF4AEA74 2010-04-27 22:38:48.263
```

For typical ETL-type applications, querying for change data is an ongoing process, making periodic requests for all the changes that occurred since the last request which need to be applied to the target. For these types of queries, you can use the `sys.fn_cdc_increment_lsn` function to determine the next lowest LSN boundary that is greater than the max LSN boundary of the previous query. To demonstrate this, let's first execute some additional data modifications against the `MyCustomer` table:

```
Insert MyCustomer (PersonID, StoreID, TerritoryID,
                  AccountNumber, rowguid, ModifiedDate)
Values (20779, null, 12,
       'AW' + RIGHT('00000000'
                   + convert(varchar(8), IDENT_Current('MyCustomer')), 8),
       NEWID(),
       GETDATE())
```

```
delete MyCustomer where CustomerID = 30119
```

The max LSN from the previous examples is `0x000000390000144C0004`. We want to increment from this LSN to find the next set of changes. In Listing 42.24, you pass this value to the `sys.fn_cdc_increment_lsn` to set the min LSN value you'll use with the `cdc.fn_cdc_get_net_changes_dbo_MyCustomer` function as the lower bound.

LISTING 42.24 Using `sys.fn_cdc_increment_lsn` to Return the Net Changes to the `MyCustomer` CDC Capture Table Since the Last Retrieval

```
--declare variables to represent beginning and ending lsn
DECLARE @from_lsn BINARY(10), @to_lsn BINARY(10)

-- get the Next lowest LSN after the previous Max LSN
SELECT @from_lsn = sys.fn_cdc_increment_lsn(0x000000390000144C0004)

-- get the last LSN for table changes
SELECT @to_lsn = sys.fn_cdc_get_max_lsn()

-- get all changes in the range using "all with_merge" parameter
SELECT *
FROM cdc.fn_cdc_get_net_changes_dbo_MyCustomer
     (@from_lsn, @to_lsn, 'all with merge');

GO
```

```
__$start_lsn     __$operation__$update_mask CustomerID
PersonID      StoreID      TerritoryID AccountNumber
rowguid                               ModifiedDate
.....
```

```

-----
-----
0x00000039000017D30004 5          NULL          30120
20779          NULL          12          AW00030120
CE8BBAA1-04C0-4A81-9A7E-85B4EDB5C36D 2010-04-27 23:52:36.477
ccc0x00000039000017E50004 1          NULL          30119

CDC and DDL Changes to Source Tables

One of the common challenges when capturing data changes from your source tables is how to handle DDL changes to the source tables. This can be an issue if the downstream consumer of the changes has not reflected the same DDL changes for its destination tables.

Enabling Change Data Capture on a source table in SQL Server 2008 does not prevent DDL changes from occurring. However, Change Data Capture does help to mitigate the effect on the downstream consumers by allowing the delivered result sets that are returned from the CDC capture tables to remain unchanged even as the column structure of the underlying source table changes. Essentially, the capture process responsible for populating the change table ignores any new columns not present when the source table was enabled for Change Data Capture. If a tracked column is dropped, NULL values are supplied for the column in the subsequent change entries.

However, if the data type of a tracked column is modified, the data type change is also propagated to the change table to ensure that the capture mechanism does not introduce data loss in tracked columns as a result of mismatched data types. When a column is modified, the capture process posts any detected changes to the `cdc.ddl_history` table. Downstream consumers of the change data from the source tables that may need to be alerted of the column changes (and make similar adjustments to the destination tables) can use the stored procedure `sys.sp_cdc_get_ddl_history` to identify any modifications to the source table columns.

So how do you modify the capture instance to recognize any added or dropped columns in the source table? Unfortunately, the only way to do this is to disable CDC on the table and re-enable it. However, in an active source environment where it's not possible to suspend processing while CDC is being disabled and re-enabled, there is the possibility of data loss between when CDC is disabled and re-enabled.

Fortunately, CDC allows two capture instances to be associated with a single source table. This makes it possible to create a second capture instance for the table that reflects the new column structure. The capture process then captures changes to the same source table into two distinct change tables having two different column structures. While the original change table continues to feed current operational programs, the new change table feeds environments that have been modified to incorporate the new column data. Allowing the capture mechanism to populate both change tables in tandem provides a mechanism for smoothly transitioning from one table structure to the other without any loss of change data. When the transition to the new table structure has been fully effected, the obsolete capture instance can be removed.

Change Tracking

In addition to Change Data Capture, SQL Server 2008 also introduces Change Tracking. Change Tracking is a lightweight solution that provides an efficient change tracking mechanism for applications. Although they are similar in name, the purposes of Change Tracking and Change Data Capture are different.

Change Data Capture is an asynchronous mechanism that uses the transaction log to record all the changes to a data row and store them in change tables. All intermediate versions of a row are available in the change tables. The information captured is stored in a relational format that can be queried by client applications such as ETL processes.

Change Tracking, in contrast, is a synchronous mechanism that tracks modifications to a table but stores only the fact that a row has been modified and when. It does not keep track of how many times the row has changed or the values of any of the intermediate changes. However, having a mechanism that records that a row has changed, you can check to see whether data has changed and obtain the latest version of the row directly from the table itself rather than querying a change capture table.

NOTE

Unlike Change Data Capture, which is available only in the Enterprise, Datacenter, and Developer Editions of SQL Server, Change Tracking is available in all editions.

Change Tracking operates by using tracking tables that store a primary key and version number for each row in a table that has been enabled for Change Tracking. Applications can then check to see whether a row has changed by looking up the row in the tracking table by its primary key and see if the version number is different from when the row was first retrieved.

One of the common uses of Change Tracking is for applications that have to synchronize data with SQL Server. Change Tracking can be used as a foundation for both one-way and two-way synchronization applications.

One-way synchronization applications, such as a client or mid-tier caching application, can be built to use Change Tracking. The caching application, which requires data from a SQL Server database to be cached in other data stores, can use Change Tracking to determine when changes have been made to the database tables and refresh the cache store by retrieving data from the modified rows only to keep the cache up-to-date.

Two-way synchronization applications can also be built to use Change Tracking. A typical example of a two-way synchronization application is the occasionally connected application—for example, a sales application that runs on a laptop and is disconnected from the central SQL Server database while the salesperson is out in the field. Initially, the client

application queries and updates its local data store from the SQL Server database. When it reconnects with the database later, the application synchronizes with the database, and data changes will flow from the laptop to the database and from the database to the laptop. Because data changes happen in both locations while the client application is disconnected, the two-way synchronization application must be able to detect conflicts. A conflict occurs if the same data is changed in both data stores in the time between synchronizations. The client application can use Change Tracking to detect conflicts by identifying rows whose version number has changed since the last synchronization. The application can implement a mechanism to resolve the conflicts so that the data changes are not lost.

Implementing Change Tracking

To use Change Tracking, you must first enable it for the database and then enable it at the table level for any tables for which you want to track changes. Change Tracking can be enabled via T-SQL statements or through SQL Server Management Studio.

To enable Change Tracking for a database in SSMS, right-click on the database in Object Explorer to bring up the Properties dialog and select the Change Tracking page. To enable Change Tracking, set the Change Tracking option to `True` (see Figure 42.6). Also on this page, you can configure the retention period for how long SQL Server retains the Change Tracking information for each data row and whether to automatically clean up the Change Tracking information when the retention period has been exceeded.

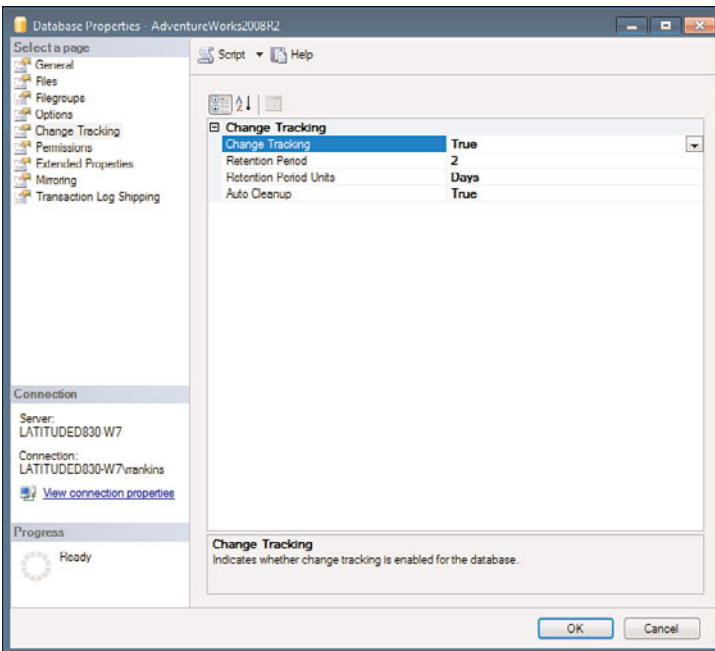

FIGURE 42.6 Enabling Change Tracking for a database.

Change Tracking can also be enabled with the ALTER DATABASE command:

```
ALTER DATABASE AdventureWorks2008R2
SET CHANGE_TRACKING = ON
(CHANGE_RETENTION = 2 DAYS, AUTO_CLEANUP = ON)
```

After enabling Change Tracking at the database level, you can then enable Change Tracking for the tables for which you want to track changes. To enable Change Tracking for a table in SSMS, right-click on the table in Object Explorer to bring up the Properties dialog and select the Change Tracking page. Set the Change Tracking option to True to enable Change Tracking (see Figure 42.7). The TRACK_COLUMNS_UPDATED option specifies whether SQL Server should store in the internal Change Tracking table any extra information about which specific columns were updated. Column tracking allows an application to synchronize only when specific columns are updated. This capability can improve the efficiency and performance of the synchronization process, but at the cost of additional storage overhead. This option is set to OFF by default.

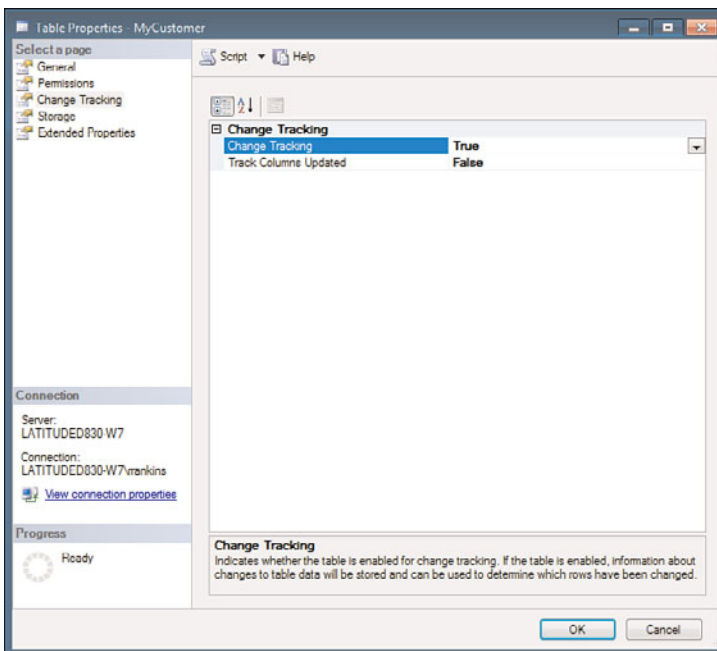

FIGURE 42.7 Enabling Change Tracking for a table.

Change Tracking can also be enabled via T-SQL with the ALTER TABLE command:

```
USE [AdventureWorks2008R2]
GO
ALTER TABLE [dbo].[MyCustomer]
    ENABLE CHANGE_TRACKING WITH(TRACK_COLUMNS_UPDATED = ON)
```

TIP

To determine which tables and databases have Change Tracking enabled, you can use the `sys.change_tracking_databases` and `sys.change_tracking_tables` catalog views.

Identifying Tracked Changes

After Change Tracking is enabled for a table, any data modification statements that affect rows in the table cause Change Tracking information for each modified row to be recorded. To query for the rows that have changed and to obtain information about the changes, you can use the built-in Change Tracking functions.

Unless you enabled the `TRACK_COLUMNS_UPDATED` option, only the values of the primary key column are recorded with the change information to allow you to identify the rows that have been changed. To identify the changed rows, use the `CHANGETABLE (CHANGES ...)` Change Tracking function. The `CHANGETABLE (CHANGES ...)` function takes two parameters: the first is the table name, and the second is the last synchronization version number.

If you pass `0` for the last synchronization version parameter, you get a list of all the rows that have been modified since version `0`, which means all the changes to the table since first enabling Change Tracking. Typically, however, you do not want all the rows that have changed from the beginning of Change Tracking, but only those rows that have changed since the last time you retrieved the changed rows.

Rather than having to keep track of the version numbers, you can use the `CHANGE_TRACKING_CURRENT_VERSION()` function to obtain the current version that will be used the next time you query for changes. The version returned represents the version of the last committed transaction.

Before an application can obtain changes for the first time, the application must first execute a query to obtain the initial data from the table and a query to retrieve the initial synchronization version using `CHANGE_TRACKING_CURRENT_VERSION()` function. The version number that is retrieved is passed to the `CHANGETABLE(CHANGES ...)` function the next time it is invoked.

The following example illustrates how to obtain the initial synchronization version and initial data set:

```
USE AdventureWorks2008R2
Go
declare @synchronization_version bigint

Select change_tracking_version = CHANGE_TRACKING_CURRENT_VERSION();
```

```
-- Obtain initial data set.
```

```
select CustomerID, TerritoryID, @synchronization_version as version
   from MyCustomer
  where CustomerID <= 5
go
```

```
change_tracking_version
```

```
-----
```

```
0
```

```
CustomerID  TerritoryID
```

```
-----
```

```
1           1
```

```
2           1
```

```
3           4
```

```
4           4
```

```
5           4
```

As you can see, because no updates have been performed since Change Tracking was enabled, the initial version is 0.

Now let's perform some updates on these rows to effect some changes:

```
update MyCustomer
   set TerritoryID = 5
   where CustomerID = 4
```

```
update MyCustomer
   set TerritoryID = 4
   where CustomerID = 5
```

Now you can use the `CHANGETABLE(CHANGES ...)` function to find the rows that have changed since the last version (0):

```
declare @last_synchronization_version bigint
set @last_synchronization_version = 0
SELECT
   CT.CustomerID as CustID, CT.SYS_CHANGE_OPERATION,
   CT.SYS_CHANGE_COLUMNS, CT.SYS_CHANGE_CONTEXT
FROM
   CHANGETABLE(CHANGES MyCustomer, @last_synchronization_version) AS CT
Go
```

```
CustID SYS_CHANGE_OPERATION SYS_CHANGE_COLUMNS SYS_CHANGE_CONTEXT
```

```
-----
```

```

4      U      0x0000000004000000 NULL
5      U      0x0000000004000000 NULL

```

You can see in these results that this query returns the CustomerIDs of the two rows that were changed. However, most applications also want the data from these rows as well. To return the data, you can join the results from `CHANGETABLE(CHANGES ...)` with the data in the user table. For example, the following query joins with the `MyCustomer` table to obtain the values for the `PersonID`, `StoredID`, and `TerritoryID` columns. Note that the query uses an `OUTER JOIN` to make sure that the change information is returned for any rows that may have been deleted from the user table. Also, at the same time you are retrieving the data rows, you also want to retrieve the current version as well to use the next time the application comes back to retrieve the latest changes:

```

declare @last_synchronization_version bigint
set @last_synchronization_version = 0
select current_version = CHANGE_TRACKING_CURRENT_VERSION()

SELECT
    CT.CustomerID as CustID,
    C.PersonID,
    C.StoreID,
    C.TerritoryID,
    CT.SYS_CHANGE_OPERATION,
    CT.SYS_CHANGE_COLUMNS, CT.SYS_CHANGE_CONTEXT
FROM
    MyCustomer C
    RIGHT OUTER JOIN
    CHANGETABLE(CHANGES MyCustomer, @last_synchronization_version) AS CT
    on C.CustomerID = CT.CustomerID

go

current_version
-----
2

CustID      PersonID      StoreID      TerritoryID
SYS_CHANGE_OPERATION SYS_CHANGE_COLUMNS SYS_CHANGE_CONTEXT
-----
4           NULL          932          5
U           0x0000000004000000 NULL
5           NULL          1026         4
U           0x0000000004000000 NULL

```

You can see in the output from this query that the current version is now 2. The next time the application issues a query to identify the rows that have been changed since this

query, it will pass the value of 2 as the `@last_synchronization_version` to the `CHANGETABLE(CHANGES ...)` function.

CAUTION

The version number is NOT specific to a table or user session. The Change Tracking version number is maintained across the entire database for all users and change tracked tables. Whenever a data modification is performed by any user on any table that has Change Tracking enabled, the version number is incremented.

For example, immediately after running an update on change tracked table A in the current application and incrementing the version to 3, another application could run an update on change tracked table B and increment the version to 4, and so on. This is why you should always capture the current version number whenever you are retrieving the latest set of changes from the change tracked tables.

If an application has not synchronized with the database in a while, the stored version number could no longer be valid if the Change Tracking retention period has expired for any row modifications that have occurred since that version. To validate the version number, you can use the `CHANGE_TRACKING_MIN_VALID_VERSION()` function. This function returns the minimum valid version that a client can have and still obtain valid results from `CHANGETABLE()`. Your client applications should check the last synchronization version obtained against the value returned by this function and if the last synchronization version is less than the version returned by this function, that version is invalid. The client application has to reinitialize all the data rows from the table. The following T-SQL code snippet can be used to validate the `last_synchronization_version`:

```
-- Check individual table.
IF (@last_synchronization_version <
    CHANGE_TRACKING_MIN_VALID_VERSION(OBJECT_ID('MyCustomer')))
BEGIN
    -- Handle invalid version and do not enumerate changes.
    -- Client must be reinitialized.
END
```

Identifying Changed Columns

In addition to information about which rows were changed and the operation that caused the change (insert, update, or delete—reported as I, U, or D in the `SYS_CHANGE_OPERATION`), the `CHANGETABLE(CHANGES ...)` function also provides information on which columns were modified if you enabled the `TRACK_COLUMNS_UPDATED` option. You can use this information to determine whether any action is needed in your client application based on which columns changed.

To identify whether a specific column has changed, you can use the `CHANGE_TRACKING_IS_COLUMN_IN_MASK` (*column_id*, *change_columns*) function. This func-

tion interprets the SYS_CHANGE_COLUMNS bitmap value returned by the CHANGETABLE(CHANGES ...) function and returns a 1 if the column was modified or 0 if it was not:

```
declare @last_synchronization_version bigint
set @last_synchronization_version = 0

SELECT
    CT.CustomerID as CustID,
    TerritoryChanged = CHANGE_TRACKING_IS_COLUMN_IN_MASK
        (COLUMNPROPERTY(OBJECT_ID('MyCustomer'),
            'TerritoryID', 'ColumnId'),
        CT.SYS_CHANGE_COLUMNS),
    CT.SYS_CHANGE_OPERATION,
    CT.SYS_CHANGE_COLUMNS
FROM
    CHANGETABLE(CHANGES MyCustomer, @last_synchronization_version) AS CT
go
```

CustID	TerritoryChanged	SYS_CHANGE_OPERATION	SYS_CHANGE_COLUMNS
4	1	U	0x0000000004000000
5	1	U	0x0000000004000000

In the query results, you can see that both update operations (SYS_CHANGE_OPERATION = 'U') modified the TerritoryID column (TerritoryChanged = 1).

Change Tracking Overhead

Although Change Tracking has been optimized to minimize the performance overhead on DML operations, it is important to know that there are some performance overhead and space requirements within the application databases when implementing Change Tracking.

The performance overhead associated with using Change Tracking on a table is similar to the index maintenance overhead incurred for insert, update, and delete operations. For each row changed by a DML operation, a row is added to the internal Change Tracking table. The amount of overhead incurred depends on various factors, such as

- ▶ The number of primary key columns
- ▶ The amount of data being changed in the user table row
- ▶ The number of operations being performed in a transaction
- ▶ Whether column Change Tracking is enabled

Change Tracking also consumes some space in the databases where it is enabled as well. Change Tracking data is stored in the following types of internal tables:

- ▶ **Internal change tables**—There is one internal change table for each user table that has Change Tracking enabled.

- ▶ **Internal transaction table**—There is one internal transaction table for the database.

These internal tables affect storage requirements in the following ways:

- ▶ For each change to each row in the user table, a row is added to the internal change table. This row has a small fixed overhead plus a variable overhead equal to the size of the primary key columns. The row can contain optional context information set by an application. In addition, if column tracking is enabled, each changed column requires an additional 4 bytes per row in the tracking table.
- ▶ For each committed transaction, a row is added to an internal transaction table.

If you are concerned about the space usage requirements of the internal Change Tracking tables, you can determine the space they use by executing the `sp_spaceused` stored procedure. The internal transaction table is called `sys.syscommittab`. The names of the internal change tables for each table are in the form `change_tracking_object_id`. The following example returns the size of the internal transaction table and internal change table for the `MyCustomer` table:

```
exec sp_spaceused 'sys.syscommittab'
declare @tablename varchar(128)
set @tablename = 'sys.change_tracking_'
                + CONVERT(varchar(16), object_id('MyCustomer'))
exec sp_spaceused @tablename
```

Summary

Transact-SQL has always been a powerful data access and data modification language, providing additional features, such as functions, variables, and commands, to control execution flow. SQL Server 2008 further expands the power and capabilities of T-SQL with the addition of a number of new features. These new T-SQL features can be incorporated into the building blocks for creating even more powerful SQL Server database components, such as views, stored procedures, triggers, and user-defined functions.

In addition to the powerful features available in T-SQL for developing SQL code and stored procedures, triggers, and user-defined functions, SQL Server 2008 also enables you to define custom-managed database objects such as stored procedures, triggers, functions, data types, and custom aggregates using .NET code. The next chapter, “Creating .NET CLR Objects in SQL Server 2008,” provides an overview of using the .NET common language runtime (CLR) to develop these custom-managed objects.

CHAPTER 43

Transact-SQL Programming Guidelines, Tips, and Tricks

One of the things you'll discover with Transact-SQL (T-SQL) is that there are a number of different ways to write queries to get the same results, but some approaches are more efficient than others. This chapter provides some general guidelines and best practices for programming in the T-SQL language to ensure robust code and optimum performance. Along the way, it provides tips and tricks to help you solve various T-SQL problems as well.

NOTE

This chapter is not intended to be a comprehensive list of guidelines, tips, and tricks. The intent of this chapter is to provide a collection of some of our favorite guidelines, tips, and tricks that are not presented elsewhere in this book. A number of other T-SQL guidelines, tips, and tricks are provided throughout many of the other chapters in this book. For example, a number of performance-related T-SQL coding guidelines and tips are presented in Chapter 35, "Understanding Query Optimization," and additional T-SQL coding guidelines can be found in Chapter 28, "Creating and Managing Stored Procedures," and 44, "Advanced Stored Procedure Programming and Optimization."

IN THIS CHAPTER

- ▶ General T-SQL Coding Recommendations
- ▶ General T-SQL Performance Recommendations
- ▶ T-SQL Tips and Tricks
- ▶ In Case You Missed It: New T-SQL Features in SQL Server 2005
- ▶ The **xml** Data Type
- ▶ The **max** Specifier
- ▶ **TOP** Enhancements
- ▶ The **OUTPUT** Clause
- ▶ Common Table Expressions
- ▶ Ranking Functions
- ▶ **PIVOT** and **UNPIVOT**
- ▶ The **APPLY** Operator
- ▶ **TRY . . . CATCH** Logic for Error Handling
- ▶ The **TABLESAMPLE** Clause

General T-SQL Coding Recommendations

Writing good T-SQL code involves establishing and following T-SQL best practices and guidelines. The following sections provide some common recommendations for general T-SQL coding guidelines to help ensure reliable, robust SQL code.

Provide Explicit Column Lists

When writing `SELECT` or `INSERT` statements in application code or stored procedures, you should always provide the full column lists for the `SELECT` or `INSERT` statement. If you use `SELECT *` in your code or in a stored procedure, the column list is resolved each time the `SELECT` statement is executed. If the table is altered to add or remove columns, the `SELECT` statement returns a different set of columns. This can cause your application or SQL code to generate an error if the number of columns returned is different than expected. For example, consider the following sample table:

```
create table dbo.explicit_cols (a int, b int)
insert explicit_cols (a, b) values (10, 20)
```

Now, suppose there is a stored procedure with a cursor that references the `explicit_cols` table, using `SELECT *` in the cursor declaration, similar to the following:

```
create proc dbo.p_fetch_explicit_cols
as
declare @a int, @b int
declare c1 cursor for select * from explicit_cols
open c1
fetch c1 into @a, @b
while @@fetch_Status = 0
begin
    print 'the proc works!!'
    fetch c1 into @a, @b
end
close c1
deallocate c1
return
```

If you run the `p_fetch_explicit_cols` procedure, it runs successfully:

```
exec dbo.p_fetch_explicit_cols
go
```

```
the proc works!!
```

Now, if you add a column to the `explicit_cols` table and rerun the procedure, it fails:

```
alter table explicit_cols add c int null
go
```

```
exec dbo.p_fetch_explicit_cols
go
```

Msg 16924, Level 16, State 1, Procedure p_fetch_explicit_cols, Line 7
Cursorfetch: The number of variables declared in the INTO list must match that of selected columns.

The p_fetch_explicit_cols procedure fails this time because the cursor is now returning three columns of data, and the FETCH statement is set up to handle only two columns. If the cursor in the p_fetch_explicit_cols procedure were declared with an explicit list of columns a and b instead of SELECT *, this error would not occur.

Not providing an explicit column list for INSERT statements can lead to similar problems. Consider the following stored procedure:

```
create proc p_insert_explicit_cols (@a int, @b int, @c int)
as
insert explicit_cols
    output inserted.*
    values (@a, @b, @c)
return
go
```

```
exec dbo.p_insert_explicit_cols 10, 20, 30
go
```

```
a          b          c
-----
10         20         30
```

With three columns currently on the explicit_cols table, this procedure works fine. However, if you alter the explicit_cols table to add another column, the procedure fails:

```
alter table explicit_cols add d int null
go
exec dbo.p_insert_explicit_cols 10, 20, 30
go
```

Msg 213, Level 16, State 1, Procedure p_insert_explicit_cols, Line 4
Insert Error: Column name or number of supplied values does not match table definition.

If the procedure were defined with an explicit column list for the INSERT statement, it would still execute successfully:

```
alter proc p_insert_explicit_cols (@a int, @b int, @c int)
as
insert explicit_cols (a, b, c)
```

```

output inserted.*
values (@a, @b, @c)
return
go
exec dbo.p_insert_explicit_cols 11, 12, 13
go

```

a	b	c	d
-----	-----	-----	-----
11	12	13	NULL

NOTE

If a procedure specifies fewer columns for an INSERT statement than exist in the table, the INSERT statement succeeds only if the columns not specified allow NULL values or have default values associated with them. Notice in the previous example that column d allows nulls, and the OUTPUT clause used in the procedure shows that the INSERT statement inserted a NULL value into that column.

Qualify Object Names with a Schema Name

In SQL Server 2005, the behavior of schemas was changed from earlier versions of SQL Server. SQL Server 2005 introduced definable schemas, which means schemas are no longer limited to database usernames only. Each schema is now a distinct namespace that exists independently of the database user who created it. Essentially, a schema is now simply a container for objects. A schema can be owned by any user, and the ownership of a schema is transferable to another user. This new feature provides greater flexibility in creating schemas and assigning objects to schemas that are not simply related to a specific database user. At the same time, it can create confusion if objects with the same name exist in multiple schemas.

By default, if a user has CREATE permission (or has the db_ddladmin role) in a database and that user creates an object without explicitly qualifying it with a schema name, the object is created in that user's default schema. If a user is added to a database with the CREATE USER command and a specific default schema is not specified, the default schema is the dbo schema.

NOTE

To further complicate matters, if you use the old sp_adduser system procedure to add a user to a database, sp_adduser also creates a schema that has the name of the user and makes that the user's default schema. However, sp_adduser is a deprecated feature that will be dropped in a future release of SQL Server. You should therefore instead use the CREATE USER command.

For example, consider the following SQL commands that create a user called `testuser43` in the `bigpubs2008` database:

```
use bigpubs2008
go
sp_addlogin testuser43, 'TestUser#43', bigpubs2008
go
create user testuser43
go
exec sp_addrolemember 'db_ddladmin', testuser43
exec sp_addrolemember 'db_datareader', testuser43
exec sp_addrolemember 'db_datawriter', testuser43
go
```

If you then log in and create a table under the `testuser43` account without qualifying the table with a schema name, it is created in the default `dbo` schema:

```
--Verify name of current schema
select schema_name()
go

-----
dbo

create table test43(a varchar(10) default schema_name() null)
go
insert test43 (a) values (DEFAULT)
go
select * from test43
go

a
-----
dbo
```

From these commands, you can see that the default schema for the `testuser43` user is `dbo`, and the `test43` table gets created in the `dbo` schema.

Now, if you create a `schema43` schema and want to create the `test43` table in the `schema43` schema, you need to fully qualify it or change the default schema for `testuser43` to `schema43`. To demonstrate this, you run the following commands while logged in as the `testuser43` user:

```
create schema schema43
go
alter user testuser43 with default_schema = schema43
go
```

```

create table test43(a varchar(10) default schema_name() null)
go
insert test43 (a) values (DEFAULT)
go
select * from test43
go

```

```

a
-----
schema43

```

As you can see from this example, now the same CREATE TABLE and INSERT commands as entered before create and insert into a table in the schema43 schema.

When the user testuser43 runs a query against the test43 table, which table the SELECT statement runs against depends on the current default schema for testuser43. The first query runs in the schema43 schema:

```

alter user testuser43 with default_schema = schema43
go
select * from test43
go

```

```

a
-----
schema43

```

The next query runs from the dbo schema:

```

alter user testuser43 with default_schema = dbo
go
select * from test43
go

```

```

a
-----
dbo

```

You can see that the current schema determines which table is queried when the table name is not fully qualified in the query. There are two ways to avoid this ambiguity. The first is to create objects only in the dbo schema and not to have additional schemas defined in the database. If you are working with a database that has multiple schemas, the only other way to avoid ambiguity is to always fully qualify your object names with the explicit schema name. In the following example, because you fully qualify the table name, it doesn't matter what the current schema is for user testuser43; the query always retrieves from the dbo.test43 table:

```

alter user testuser43 with default_schema = dbo

```

```

go
select * from dbo.test43
go

a
-----
dbo

alter user testuser43 with default_schema = schema43
go
select * from dbo.test43
go

a
-----
dbo

```

Along these same lines, when you are creating objects in a database, it is recommended that you specify the schema name in the `CREATE` statement to ensure that the object is created in the desired schema, regardless of the user's current schema.

Avoid SQL Injection Attacks When Using Dynamic SQL

The `EXEC ()` (or `EXECUTE ()`) command in SQL Server enables you to execute queries built dynamically into a character string. This is a great feature for building queries on the fly in your T-SQL code when it may not be possible to account for all possible search criteria in a stored procedure or when static queries may not optimize effectively.

However, when coding dynamic SQL, it's important to make sure your code is protected from possible SQL injection attacks. A SQL injection attack is, as its name suggests, an attempt by a hacker to inject T-SQL code into the database without permission. Typically, the hacker's goal is to retrieve confidential data such as Social Security or credit card numbers or to possibly vandalize or destroy data in the database.

SQL injection is usually the result of faulty application design—usually an unvalidated entry field in the application user interface. For example, this could be a text box where the user would enter a search value. A hacker may attempt to inject SQL statements into this entry field to try to gain access to information in the database.

Although SQL injection is essentially an application flaw, you can minimize the possibility of SQL injection attacks by following some coding practices in your stored procedures that make use of the `EXEC()` statement to dynamically build and execute a query. For example, consider the stored procedure shown in Listing 43.1, which might support a search page in a web application where the user is able to enter one or more optional search parameters.

LISTING 43.1 Sample Procedure to Demonstrate SQL Injection

```

use bigpubs2008
go
create proc dbo.get_titles @type varchar(12) = null,
                        @pubdate varchar(10) = null,
                        @price varchar(6) = null,
                        @title varchar(80) = null

as
declare @where varchar(4000)
set @where = ' WHERE 1 = 1 '
if @type is not null
    set @where = @where + ' AND type = ''' + @type + ''''
if @pubdate is not null
    set @where = @where + ' AND pubdate = ''' + @pubdate + ''''
if @price is not null
    set @where = @where + ' AND price = ' + @price
if @title is not null
    set @where = @where + ' AND title like ''' + @title + ''''

exec ('select left(title, 60) as title,
        convert (char(10), pubdate, 101) as pubdate from dbo.titles ' + @where)

return

```

Following is an example of a typical execution of this procedure if the end user enters business in the book type search field:

```

exec dbo.get_titles @type = 'business'
go

```

title	pubdate

Straight Talk About Computers	06/22/2004

To understand how to prevent SQL injection attacks, let's look at a way that a hacker might attempt a SQL injection attack. What a hacker attempting a SQL injection attack might typically do with a web application is to seek out a search field and try to inject some SQL code into it to see if the application is susceptible to an attack. This would typically be done by inserting a single quotation mark into the search field to close out the string and appending a SQL statement after it. For example, the hacker may enter the string ' OR 1 = 1 -- into the search field. This search condition contains a single quotation mark and an end comment marker (--). The quotation mark would have the effect of closing the search string, and the comment marker would comment out the rest of the query to prevent syntax errors caused by the SQL injection. The additional search condi-

tion appended to the query would cause the query to return all rows from the table, and the hacker would know he's found a susceptible text box:

```
exec dbo.get_titles @title = '' OR 1 = 1 --'
go
```

title	pubdate
-----	-----
Samuel Johnson	09/19/2008
Freud, Dora, and Vienna 1900	02/25/2008
Freud: A Life for Our Time	06/21/2008
For Love of the World	01/06/2006
Freud: A Life for Our Time	10/16/2007
The Riddle of Anna Anderson	02/21/2007
Final Analysis	05/31/2006
...	

When the hacker sees the results of this query, he knows he's found a susceptible text field and may try to query the system catalogs. Typically, this is done with a UNION ALL statement because the application would likely generate an error if multiple result sets were returned. With UNION, the hacker's SQL injection statement would have to return the same number of columns as the original query, and the columns would need to be of compatible data types. It might take the hacker some trial and error, but eventually, he might come up with a query string such as

```
UNION ALL select TABLE_NAME, NULL from INFORMATION_SCHEMA.TABLES --
```

to append to the following search value:

```
exec dbo.get_titles @title = '' UNION ALL select TABLE_NAME, NULL
from INFORMATION_SCHEMA.TABLES --'
go
```

title	pubdate
-----	-----
sales_big	NULL
roysched	NULL
titleauthor	NULL
PARTS	NULL
titleview	NULL
publishers	NULL
top_sales	NULL
sales_archive	NULL
authors	NULL
jobs	NULL

pub_info	NULL
sales	NULL
sales_qty_rollup	NULL
stores	NULL
titles	NULL
discounts	NULL
employee	NULL
sales_noclust	NULL

With this information, the hacker has a list of all the tables defined in the database. At this point, the hacker might try to probe deeper into the database to look for sensitive data. For example, the hacker might decide to try to query the authors table to see if there is any sensitive data, such as Social Security numbers, in it. To do so, the hacker would use a trial-and-error approach of entering various SQL injection queries against the system catalogs to get column information, possibly eventually coming up with the SQL injection statements used in the following queries:

```
exec dbo.get_titles @title = ''' UNION ALL select name, str(id) from sysobjects
where name = 'authors'--'
go
```

title	pubdate
-----	-----
authors	1253579504

```
exec dbo.get_titles @title = ''' UNION ALL select name, null from syscolumns
where id = 1253579504--'
go
```

title	pubdate
-----	-----
au_id	NULL
au_lname	NULL
au_fname	NULL
phone	NULL
address	NULL
city	NULL
state	NULL
zip	NULL
contract	NULL

At this point, the hacker has an idea what fields are in the authors table and could attempt to view data in those columns to try to uncover personal information such as Social Security numbers, credit card numbers, addresses, and so on:

```
exec dbo.get_titles @title = ''' UNION ALL select au_id + au_lname,
au_fname from authors--'
```

```
go
```

```

title                                     pubdate

```

The hacker could continue the SQL injection attack by attempting to view data in other tables. Or, worse, he could attempt to destroy data by attempting updates, deletes, or inserts of his own data, or, even worse, truncate tables or drop tables entirely. Depending on the account that the application runs under and the rights assigned to that account, the hacker might even be able to run system stored procedures or extended stored procedures such as `xp_cmdshell`.

So what can be done to help avoid SQL injection attacks? The best solution is to make sure the application itself performs validation on the user input fields to prevent the injection of SQL commands. Also, the application should keep any input fields as small as possible to reduce the likelihood of a hacker being able to squeeze SQL code into the field without it being truncated (which usually leads to a T-SQL syntax error). In addition, there are precautions you can take in your databases and T-SQL code as a secondary mechanism to prevent SQL injection.

On the database side, one thing you can do is to make sure the application runs under a user account with the minimal permissions necessary. You should avoid giving the application user account either `dbo` or, worse, `sa` permissions. (It's frightening how many applications are out there running under the `dbo` or `sa` account!) Restricting the permissions restricts the amount of damage a hacker might possibly inflict on a database.

Another way you can help avoid SQL injection is to check for common SQL injection methods in your stored procedure code. For example, you could recode the procedure shown in Listing 43.1 to look for the `UNION` statement (one common method used in SQL injection attacks) and to strip out any text from an input string from the point where the `UNION` statement is found. Listing 43.2 shows an example of this.

LISTING 43.2 Stripping Out the **UNION** Clause to Help Avoid SQL Injection

```

alter proc get_titles @type varchar(12) = null,
                    @pubdate varchar(10) = null,
                    @price varchar(6) = null,
                    @title varchar(80) = null

as
declare @where varchar(4000),
        @query varchar(8000)
set @query = 'select left(title, 60) as title,
            convert (char(10), pubdate, 101) as pubdate from dbo.titles '
set @where = ' WHERE 1 = 1 '
if @type is not null
    set @where = @where + ' AND type = ''' + @type + ''''
if @pubdate is not null
    set @where = @where + ' AND pubdate = ''' + @pubdate + ''''
if @price is not null
    set @where = @where + ' AND price = ' + @price
if @title is not null
    set @where = @where + ' AND title like ''' + @title + ''''

-- The following statement truncates the @where clause at the point where
-- it finds the UNION statement
select @query = @query + left(@where, charindex('UNION', @where) - 1)
exec (@query)

return

```

When this query is executed, the UNION statement is stripped out. The WHERE clause ends up looking like the following:

```
WHERE 1 = 1 AND title like ''
```

With the UNION stripped out, leaving only an empty string, the query now returns an empty result set:

```
exec dbo.get_titles @title = ''' UNION ALL select name,null from syscolumnswhere id
= 1253579504--'
```

```

title
-----
pubdate
-----

```

In addition to having the stored procedure code look for the UNION clause, you could further expand on this to look for other common SQL injection methods. One other, possibly more reliable, way to help avoid SQL injection attacks is to parameterize your dynamic queries by using `sp_executesql`. When you embed parameters in the dynamic SQL string rather than build it on the fly, it is much harder for a hacker to insert SQL statements into the dynamic query. Listing 43.3 shows an example of this approach.

LISTING 43.3 Using `sp_executesql` to Help Avoid SQL Injection

```

alter proc get_titles @type varchar(12) = null,
                    @pubdate varchar(10) = null,
                    @price varchar(6) = null,
                    @title varchar(80) = null
as
declare @where nvarchar(2000),
        @query nvarchar(2000)
set @query = 'select left(title, 60) as title,
              convert (char(10), pubdate, 101) as pubdate from dbo.titles '
set @where = ' WHERE 1 = 1 '
if @type is not null
    set @where = @where + ' AND type = @type '
if @pubdate is not null
    set @where = @where + ' AND pubdate = @pubdate '
if @price is not null
    set @where = @where + ' AND price = convert(money, @price) '
if @title is not null
    set @where = @where + ' AND title like @title '
-- Build the final query
select @query = @query + @where
exec sp_executesql @query,
    N'@type varchar(12), @pubdate varchar(10),
    @price varchar(6), @title varchar(80)',
    @type, @pubdate, @price, @title

return

```

With this version of the procedure, the query that gets built looks like the following:

```

select left(title, 60) as title,
        convert (char(10), pubdate, 101) as pubdate from dbo.titles
WHERE 1 = 1 AND title like @title

```

With the query written this way, the value passed in for `@title` when `sp_executesql` is invoked is the following:

```
'' UNION ALL select name, null from syscolumns where id = 1253579504--
```

With this value passed in as the argument to the `@title` variable in the where clause, the search condition eventually becomes this:

```

AND title like
''' UNION ALL select name, null from syscolumns where id = 1253579504--"

```

As you might surmise, this string matches no actual titles in the titles tables, so an empty result set is returned.

There is another alternative approach to preventing SQL injection attacks. Instead of searching for possible injection methods within the parameters used to build the query, you can make sure the dynamic SQL code fragments contain only allowable keywords and values. For example, consider a variation of the stored procedure in Listing 43.3 that allows for the specification of a dynamic sort on the query:

```
alter proc get_titles @type varchar(12) = null,
                    @pubdate varchar(10) = null,
                    @price varchar(6) = null,
                    @title varchar(80) = null,
                    @sort varchar(1000) = ''
as
declare @where nvarchar(2000),
        @query nvarchar(2000)
set @query = 'select left(title, 60) as title,
              convert(char(10), pubdate, 101) as pubdate from dbo.titles '
set @where = ' WHERE 1 = 1 '
if @type is not null
    set @where = @where + ' AND type = @type '
if @pubdate is not null
    set @where = @where + ' AND pubdate = @pubdate '
if @price is not null
    set @where = @where + ' AND price = convert(money, @price) '
if @title is not null
    set @where = @where + ' AND title like @title '
-- Build the final query
select @query = @query + @where
        + case when @sort <> '' then 'ORDER BY ' + @sort
              else '' end

exec sp_executesql @query,
    N'@type varchar(12), @pubdate varchar(10),
    @price varchar(6), @title varchar(80)',
    @type, @pubdate, @price, @title
```

Return

Although the use of parameterized SQL with `sp_executesql` avoids issues with SQL injection via the `@type`, `@pubdate`, `@price`, and `@title` parameters, the code opens itself up again to SQL injection with the `@sort` variable being tacked onto the end of the query. Instead of trying to find all the possible commands that could be embedded in the `@sort` variable, an alternative approach is to make sure it contains only allowable keywords and

columns. The ORDER BY clause is reasonably simple; the only allowable values are the keywords DESC and ASC, column position numbers, and column names. In this example, you set up the code in the procedure to allow only the DESC and ASC keywords and a limited set of column names. The code strips out all the allowable values, and if anything else is left, you know that the @sort parameter contains something that it shouldn't and can disallow it. An example using this approach is shown in Listing 43.4.

LISTING 43.4 Checking for Only Allowable Values to Prevent SQL Injection

```

alter proc get_titles @type varchar(12) = null,
                    @pubdate varchar(10) = null,
                    @price varchar(6) = null,
                    @title varchar(80) = null,
                    @sort varchar(1000) = ''
as
declare @where nvarchar(2000),
        @query nvarchar(2000) ,
        @sort_check varchar(1000)
set @query = 'select left(title, 60) as title,
            convert (char(10), pubdate, 101) as pubdate from dbo.titles '

-- Replace all allowable terms/syntax in @sort with empty strings
-- Allowable terms are ASC, DESC, title, pubdate, price, type and comma (,)
Set @sort_check = replace(@sort, 'ASCENDING', '')
Set @sort_check = replace(@sort_check, 'DESCENDING', '')
Set @sort_check = replace(@sort, 'ASC', '')
Set @sort_check = replace(@sort_check, 'DESC', '')
Set @sort_check = replace(@sort_check, ',,', '')
Set @sort_check = replace(@sort_check, 'title', '')
Set @sort_check = replace(@sort_check, 'pubdate', '')
Set @sort_check = replace(@sort_check, 'price', '')
Set @sort_check = replace(@sort_check, 'type', '')

If @sort_check <> '' -- the @sort column contains a disallowed term
Begin
    Raiserror ('Invalid sort specified', 16, 1)
    Return -101
end

set @where = ' WHERE 1 = 1 '
if @type is not null
    set @where = @where + ' AND type = @type '
if @pubdate is not null
    set @where = @where + ' AND pubdate = @pubdate '
if @price is not null

```

```

    set @where = @where + ' AND price = convert(money, @price) '
if @title is not null
    set @where = @where + ' AND title like @title '
-- Build the final query
select @query = @query + @where
    + case when @sort <> '' then 'ORDER BY ' + @sort
        Else '' end
exec sp_executesql @query,
    N'@type varchar(12), @pubdate varchar(10),
    @price varchar(6), @title varchar(80)',
    @type, @pubdate, @price, @title

return
go

-- execute with a valid @sort value
exec get_titles @pubdate = '2/21/2007',
    @sort = 'type ASC, price DESC'

-- execute with an attempted SQL injection in @sort parameter
exec get_titles @pubdate = '2/21/2007',
    @sort = 'type ASC, price DESC; select * from sysobjects'
go

```

title	pubdate
-----	-----
The Riddle of Anna Anderson	02/21/2007

Later the Same Day	02/21/2007

(3 row(s) affected)

Msg 50000, Level 16, State 1, Procedure get_titles, Line 26
Invalid sort specified

Dynamic SQL is a great feature in SQL Server that provides considerable flexibility in building queries in stored procedures. However, it also presents a risk if you are not careful to prevent possible SQL injection attacks.

Comment Your T-SQL Code

Anyone who has ever had to review or change some code recognizes the importance of comments. Even if it seems obvious what the code does when you're writing it, the meaning will most certainly not be as obvious later, especially if someone other than the original author is looking at it.

When you are working with large code blocks, a good technique to follow is to add a comment at the beginning and end of the code block:

```
while (...) /* Begin loop1 */
begin
...
end /* End loop1 */
...
if (@price > 1) /* if (@price > 1) */
begin
...
end /* if (@price > 1) */
```

Another recommendation is to include a comment header at the beginning of compiled objects such as stored procedures, functions, and triggers. Following is a sample comment header you might want to use as a template:

```
/******
-- Procedure Name:    p_proc_name
--
-- Purpose:           Describe the purpose of the procedure here. Include any
--                   special notes on usage or code logic
--
-- Input Parameters:
--                   @param1    numeric(12,0) Not Required
--                   @param2    tinyint      Not required
--
-- Output Parameters:
--                   None
--
-- Return Values:     0      Success
--                   Other    Error
--
-- Written By:       Joe Developer, 7/1/08
-- Modified By:     Joe Developer, 7/5/08
--                   Describe changes made to the proc here

```

General T-SQL Performance Recommendations

How you write T-SQL queries can often have an effect on the performance of those queries. The following sections provide some general guidelines to keep in mind to help ensure that you are getting optimal performance from your queries.

UNION Versus UNION ALL Performance

You should use `UNION ALL` instead of `UNION` if there is no need to eliminate duplicate result rows from the result sets being combined with the `UNION` operator. The `UNION` statement has to combine the result sets into a worktable to remove any duplicate rows from the result set. `UNION ALL` simply concatenates the result sets together, without the overhead of putting them into a worktable to remove duplicate rows.

Use IF EXISTS Instead of SELECT COUNT (*)

You should use `IF EXISTS` instead of `SELECT COUNT(*)` when checking only for the existence of any matching data values and when determining the number of matching rows is not required. `IF EXISTS` stops the processing of the `select` query as soon as the first matching row is found, whereas `SELECT COUNT(*)` continues searching until all matches are found, wasting I/O and CPU cycles. For example, you could replace

```
if (SELECT count(*) FROM dbo.sales WHERE stor_id = '6380') > 0
```

with an `IF EXISTS` check similar to

```
if exists (SELECT * FROM dbo.sales WHERE stor_id = '6380')
```

Avoid Unnecessary ORDER BY or DISTINCT Clauses

When a T-SQL query contains an `ORDER BY` or `DISTINCT` clause, a worktable is often required to process the final result of the query if it cannot determine that the rows will already be retrieved in the desired sort order or that a unique key in the result makes the rows distinct. If a query requires a worktable, that adds extra overhead and I/O to put the results into the worktable in `tempdb` and do the sorting necessary to order the results or to eliminate duplicate rows. This can result in extended processing time for the query, which can delay the time it takes for the final result to be returned to the client application.

If it is not absolutely necessary for the rows returned to the application to be in a specific order (for example, returning rows to a grid control where the contents can be re-sorted by any column in the grid control itself), you should leave off the `ORDER BY` clause in your queries.

Likewise, you should not arbitrarily include the `DISTINCT` clause in all your queries unless it is absolutely necessary to eliminate any duplicate rows from the result set.

Temp Tables Versus Table Variables Versus Common Table Expressions

SQL Server 2008 provides multiple options for working with temporary result sets in T-SQL code:

- ▶ Temporary tables
- ▶ Table variables

- ▶ Derived tables
- ▶ Common table expressions

One of the questions you may consider is “Which method should I use and when?” Whether you use a temporary table, table variable, derived table, or common table expression depends, in part, on how often and for how long you intend to use it. This section provides some general recommendations to consider.

You should use table variables instead of temporary tables in stored procedures whenever possible or feasible. Table variables are memory resident and do not incur the I/O overhead and system table and I/O contention that can occur in `tempdb` with normal temporary tables. However, remember that table variables exist only for the duration of the SQL batch or stored procedure in which they are defined.

In SQL Server 2005 and later, you also have the option of using derived tables or common table expressions in your queries to generate and hold intermediate result sets that can be further processed by the main query. A derived table is a subquery contained in a `FROM` clause that can be referred to by an alias and used as a table in the query. Derived tables and common table expressions can be thought of as sort of dynamic views that exist only for the duration of the query. Derived tables are handy if you don’t need to use a result set more than once in multiple queries. You should consider using derived tables or common table expressions when possible to completely avoid the use of table variables or temporary tables, especially if the temporary table or table variable is used only once by a single query.

NOTE

For more information on common table expressions and how to use them, see the section “Common Table Expressions” later in this chapter.

You should generally consider using temporary tables only when you need to share data between an application and stored procedures or between stored procedures. Also, if the temporary result set is going to be very large (that is, larger than can be held in SQL Server cache memory), you should consider storing it in a temporary table rather than a table variable.

NOTE

In SQL Server 2008, you can define `table` data types, which makes it possible to pass table variables to stored procedures as table parameters, so temp tables aren’t the only way to share data between stored procedures. However, there are some limitations: primarily, the contents of a table parameter passed to a stored procedure are read only and cannot be modified within the stored procedure. If you want to share data between stored procedures and have the ability to add, remove, or modify rows in any of the stored procedures, temporary tables are still the best solution.

If you need to use temporary tables, you can follow these general guidelines to help improve their performance:

- ▶ Select only the columns actually required by the subsequent SQL statements into the temp table (that is, avoid using `select *`). This helps reduce the size of the temp table, thereby reducing the number of writes to `tempdb` and also speeding up access of the data within the temp table because more rows will fit on a data page, reducing the number of data pages that need to be accessed by the query.
- ▶ Select only the rows needed by the subsequent queries, again to help limit the size of the temp table and reduce the amount of I/O in `tempdb`.
- ▶ If the temporary table will be accessed multiple times by queries using search arguments (SARGs), consider creating an index on the temporary table if it can be used to speed up the queries against the temp table and reduce I/O. Of course, this option should be considered only if the time and I/O saved by having an index on the temporary table significantly exceeds the time and I/O required to create the index.

Avoid Unnecessary Function Executions

If you call a SQL Server function (for example, `user_name()`, `getdate()`) repeatedly within a procedure or in T-SQL code, you should consider using a local variable to hold the value returned by the function and use the local variable repeatedly throughout your SQL statements rather than repeatedly executing the SQL Server function. This saves CPU cycles within your stored procedure and T-SQL code.

NOTE

For additional performance-related query recommendations related specifically to how queries are optimized, see Chapter 35.

Cursors and Performance

In contrast to most other programming languages, SQL is a set-based processing language. You retrieve sets of rows, update sets of rows, and delete sets of rows. The set of rows affected is determined by the search conditions specified in the query. Unfortunately, most programmers are used to doing record-oriented operations on data and often want to apply the same technique to SQL Server data. Admittedly, at times, processing rows as a single result set with a single query can seem difficult or impossible. However, because of the performance implications, cursors should not be used just because it's easier to program that way.

NOTE

SQL Server 2008 introduces the new `MERGE` statement, which provides another set-oriented option for processing a set of input rows and making a row-by-row determination which rows to ignore or which to insert, update, or delete in the target table. For more information on using the `MERGE` statement, see Chapter 42, "What's New for Transact-SQL in SQL Server 2008."

When to Use Cursors

Application performance can sometimes be slow due to the improper use of cursors. You should always try to write your T-SQL code so SQL Server can perform what it is good at: set-based operations. It makes little sense to have an advanced relational database management system (RDBMS) and use it only for one-row-at-a-time retrievals. For example, many update operations performed using cursors can be performed with a single UPDATE statement using the CASE expression. Consider the cursor shown in Listing 43.5.

LISTING 43.5 Updating the **titles** Table by Using a Cursor

```

/* This is a SQL script to update book prices dependent on current price and
ytd_sales */

/*declare cursor*/
declare titles_curs cursor for
    select ytd_sales, price from dbo.titles
    for update of price

declare @ytd_sales int, @price money
open titles_curs
fetch next from titles_curs into @ytd_sales, @price

if (@@fetch_status = -1)
begin
    print 'No books found'
    close titles_curs
    deallocate titles_curs
    return
end
while (@@fetch_status = 0)
begin
    if @ytd_sales < 500
        update titles set price = @price * .75
        where current of titles_curs
    else
        if @price > $15
            update titles set price = @price * .9
            where current of titles_curs
        else
            update titles set price = @price * 1.15
            where current of titles_curs
        fetch next from titles_curs into @ytd_sales, @price
end
if (@@fetch_status = -2)
    raiserror ('Attempt to fetch a row failed', 16, 1)
close titles_curs
deallocate titles_curs

```

This cursor can be replaced with a simple, single UPDATE statement, using the CASE expression, as shown in Listing 43.6

LISTING 43.6 The **titles** Cursor Example Performed with a Single **UPDATE** Statement Using the **CASE** Expression

```
update titles
    set price = case when ytd_sales < 500 then price *.75
                  when price > $15 then price * .90
                  else price * 1.15
    end
```

The advantages with this approach are significant performance improvement and much cleaner and simpler code. In testing the performance of the single update versus the cursor using the `bigpubs2008` database, the cursor required on average around 100 milliseconds (ms) to complete. The single update statement required, on average, about 10 ms. (Your results may vary depending on hardware capabilities.) Although both of these completed within a subsecond response time, consider that the cursor took 10 times longer to complete than the single update. Factor that out over hundreds of thousands or millions of rows, and you could be looking at a significant performance difference.

Why is the cursor so much slower? Well, for one thing, a table scan performed by an UPDATE, a DELETE, or a SELECT uses internal, compiled C code to loop through the result set. A cursor uses interpreted SQL code. In addition, with a cursor, you are performing multiple lines of code per row retrieved. The `titles` cursor example is a relatively simple one; it performs one or two conditional checks and a single update per row, but it is still three or four times slower. Because of the overhead required to process cursors, set-oriented operations typically run much faster, even if multiple passes of the table are required.

Although set-oriented operations are almost always faster than cursor operations, the one possible disadvantage of using a single update is locking concurrency. Even though a single update runs faster than a cursor, while it is running, the single update might end up locking the entire table for an extended period of time. This would prevent other users from accessing the table during the update. If concurrent access to the table is more important than the time it takes for the update to complete, you might want to consider using a cursor. A cursor locks the data only a row at a time instead of locking the entire table (as long as each row is committed individually and the entire cursor is not in a transaction).

Another situation in which you might want to consider using cursors is for scrolling applications when the result sets can be quite large. Consider a customer service application. The customer representative might need to pull up a list of cases and case contacts associated with a customer. If the result sets are small, you can just pull the entire result set down into a list box and let the user scroll through them and not need to use a cursor.

However, if thousands of rows of information are likely, you might want to pull back only a block of rows at a time, especially if the user needs to look at only a few of the rows to get the information he or she needs. It probably wouldn't be worth pulling back all that data across the network just for a few rows.

In this type of situation, you might want to use a scrollable API server cursor. This way, you can retrieve the appropriate number of rows to populate the list box and then use the available scrolling options to quickly fetch to the bottom of the list, using the `LAST` or `ABSOLUTE n` options, or you can go backward or forward by using the `RELATIVE` option.

NOTE

You need to be careful using the scrollable API server cursor approach in a multitier environment. Many multitier architectures include a middle data layer that often uses connection sharing for multiple clients, and the users are typically assigned any available connection when they need to access SQL Server. Users do not necessarily use the same connection each time. Therefore, if a user created a cursor in one connection, the next time the user submitted a fetch through the data layer, he or she might get a different connection, and the cursor will not be available.

One solution for this problem is to go back to retrieving the entire result set down to the client application. Another possible solution is to use a global temp table as a type of homemade insensitive cursor to hold the result set and grab the data from the global temp table in chunks, as needed. With the temp table approach, you need to make sure a sequential key is on the table so you can quickly grab the block of rows you need. You need to be aware of the potential impact on tempdb performance and the size requirements of tempdb if the result sets are large and you have many concurrent users.

As a general rule, you should use cursors only as a last resort when no set-oriented solution is feasible. If you have decided that a cursor is the appropriate solution, you should try to make it as efficient as possible by limiting the number of commands to be executed within the cursor loop as much as possible. Also, you should try to keep the cursor processing on the server side within stored procedures. If you will be performing multiple fetches over the network (for example, to support a scrolling application), you should use an API server cursor. You should avoid using client-side cursors that will be performing many cursor operations in the client application; otherwise, you will find your application making excessive requests to the server, and the volume of network roundtrips will make for a sloth-like application.

Variable Assignment in UPDATE Statements

One commonly overlooked feature in T-SQL is the ability to assign values to local variables in the `SET` clause of the `UPDATE` statement. This capability can help improve query performance by reducing locking and CPU contention and reducing the number of statements required in a T-SQL batch.

The simplified syntax of the SET clause for assigning values to variables is as follows:

```
SET
  { column_name = { expression | DEFAULT | NULL }
    | @variable = expression
    | @variable = column = expression [ ,...n ]
  } [ ,...n ]
```

One common use of variable assignment in UPDATE statements is when you have a table that is used for storing and generating unique key values. To demonstrate this, you can create the keygen table and populate it as shown in Listing 43.7.

LISTING 43.7 Creating and Populating the **keygen** Table

```
create table keygen (keytype char(1), keyval int)
go
insert keygen(keytype, keyval) values ('x', 1)
go
```

The typical approach often used to perform the task of retrieving a key value and updating the keygen table to generate the next key is to issue a SELECT statement and UPDATE statement within a transaction. Listing 43.8 shows an example of this.

LISTING 43.8 Retrieving and Updating **keyval** with **SELECT** and **UPDATE**

```
begin tran
declare @newkey int
-- Select current keyval into @newkey
select @newkey = keyval
  from keygen (XLOCK)
  where keytype = 'x'
update keygen
  set keyval = keyval + 1
  where keytype = 'x'
commit
select @newkey as newkey
go

newkey
-----
1
```

TIP

In Listing 43.8, the XLOCK hint is specified in the SELECT statement. This prevents two separate user processes from running this T-SQL batch at the same time and both acquiring the same keyval. With the XLOCK hint, only one of the processes can acquire an exclusive lock, and the other process waits until the lock is released and acquires the next keyval.

The use of XLOCK is definitely preferable to HOLDLOCK because the use of HOLDLOCK in this type of scenario often leads to a deadlock situation.

By using variable assignment in an UPDATE statement, you can eliminate the SELECT statement altogether and capture the keyval in the same statement you use to update the keygen table, as shown in Listing 43.9.

LISTING 43.9 Using Variable Assignment in an **UPDATE** to Update and Retrieve **keyval**

```
declare @newkey int
update keygen
    set keyval = keyval + 1,
        @newkey = keyval
    where keytype = 'x'
select @newkey as newkey
go
```

```
newkey
-----
2
```

Notice that the value assigned to the local variable using the syntax shown in Listing 43.9 is the value of the keyval column *prior* to the update. If you prefer to assign the value of the column after the column is updated, you use the @variable = column = expression syntax, as shown in Listing 43.10.

LISTING 43.10 Using Variable Assignment in an **UPDATE** to Update and Retrieve **keyval** After Update

```
declare @newkey int
update keygen
    set @newkey = keyval = keyval + 1
    where keytype = 'x'
select @newkey as newkey
go
```

```
newkey
-----
4
```

You need to be aware that the variable assignment is performed for every row that qualifies in the update. The resulting value of the local variable is the value of the last row updated.

Another use for variable assignment in UPDATE statements is to accumulate the sum of a column into a local variable for all the rows being updated. The alternative approach would be to use a cursor, as shown in Listing 43.11.

LISTING 43.11 Using a Cursor to Accumulate a Sum of a Column for Each Row Updated

```
declare c1 cursor for
    select isnull(ytd_sales, 0)
        from titles where type = 'business'
        for update of price
go
declare @ytd_sales_total int,
        @ytd_sales int
select @ytd_sales_total = 0
open c1
fetch c1 into @ytd_sales
while @@fetch_status = 0
begin
    update titles
        set price = price
        where current of c1
    select @ytd_sales_total = @ytd_sales_total + @ytd_sales
    fetch c1 into @ytd_sales
end
select @ytd_sales_total as ytd_sales_total
close c1
deallocate c1
go

ytd_sales_total
-----
30788
```

By using variable assignment in an UPDATE statement, you can replace the cursor in Listing 43.11 with a single UPDATE statement, as shown in Listing 43.12.

LISTING 43.12 Using Variable Assignment in an **UPDATE** Statement to Accumulate a Sum of a Column for Each Row Updated

```

declare @ytd_sales_total int
set @ytd_sales_total = 0
update titles
    set price = price,
        @ytd_sales_total = @ytd_sales_total + isnull(ytd_sales, 0)
    where type = 'business'
select @ytd_sales_total as ytd_sales_total
go

ytd_sales_total
-----
30788

```

As you can see from the examples presented in this chapter, using variable assignment in UPDATE statements results in much more concise and efficient T-SQL code than using cursors or other alternatives. When your code is more concise and consistent, it will run faster, requiring fewer CPU resources. Also, faster, more efficient code reduces the amount of time locks are held, which reduces the chance for locking contention, which also helps improve overall application performance.

T-SQL Tips and Tricks

The following sections provide some general tips and tricks to help you get the most from your T-SQL code.

Date Calculations

Occasionally, you may find that you need to start with a date value and use it to calculate some other date. For example, your SQL code might need to determine what date is the first day of the month or last day of the month. As you may know, working with the datetime data type in SQL Server can be a bit of a challenge. You probably already know how to use the datepart() function to extract specific components of a date (for example, year, month, day). You can then use those components along with a number of functions to calculate a date that you might need. This section provides some examples of algorithms you can use to generate some commonly needed date values.

The DATEDIFF function calculates the difference between two dates, where the difference is based on an interval, such as hours, days, weeks, months, years, and so on. The DATEADD function calculates a date by adding an interval of time to a date. In this case, the intervals of time are the same as those used by the DATEDIFF function. Using the DATEADD and DATEDIFF functions to calculate specific dates requires thinking outside the box a bit to

convert the date value into a date you need. You need to start thinking in terms of date intervals—for example, how many date intervals it is from the current date to the date you want to calculate, or how many date intervals it is from today to some other date, such as "2000-01-01", and so on. You use the DATEADD and DATEDIFF functions to calculate your desired date by determining the appropriate date intervals from the current date and then adding or subtracting intervals to arrive at the desired calculated date. Understanding how to use the various date intervals helps you more easily understand how to calculate the desired dates.

Calculating the First Day of Month

Let's look at a method for determining the first day of the month for a given date. To do this, you start out with the initial date. (In this example, you can use `getdate()` to work with the current system date and time.) The next step is to figure out the number of months between the given date and the date "1/1/1900".

NOTE

The value "1/1/1900" is the default for a date if an empty string (' ') is used to represent a date.

You can use the DATEDIFF function to determine the number of months from "1/1/1900":

```
select DATEDIFF(mm, ' ',getdate())
go
```

```
-----
1321
```

Now, using the number of months, you can add that result to "1/1/1900" to obtain the first day of the month for the given date:

```
select DATEADD(mm, DATEDIFF(mm, ' ',getdate()), ' ')
```

By adding the number of months between the given date and "1/1/1900" to "1/1/1900", you are able to arrive at the first day of the current month. In addition, the time portion of the calculated date is set to "00:00:00.000".

This technique for calculating a date interval between the current date and the year, "1900-01-01", and then adding the calculated number of intervals to "1900-01-01" can be used to calculate many different dates. The next four examples use the same technique to generate different dates based on the current date.

Calculating the First Day of the Year

You can use the year interval (yy) to display the first day of the year:

```
select DATEADD(yy, DATEDIFF(yy, ' ',getdate()), ' ')
```

Calculating the First Day of the Quarter

To calculate the first day of the current quarter, you use the quarter (qq) interval:

```
select DATEADD(qq, DATEDIFF(qq, '',getdate()), '')
```

Calculating Midnight for the Current Day

If you need to truncate the time portion for a `datetime` value so it reflects the current date at midnight, you can use the date interval (dd) to get the midnight time stamp for the desired date:

```
select DATEADD(dd, DATEDIFF(dd, '',getdate()), '')
```

Calculating Monday of the Current Week

You can use the week interval (wk) to calculate what date is Monday of the current week:

```
select DATEADD(wk, DATEDIFF(wk, '',getdate()), '')
```

Calculating Other Dates

As you have seen, by using simple `DATEADD` and `DATEDIFF` calculations, you can come up with many different dates that might be valuable. All the examples so far have only calculated the number of date intervals between the current date and "1/1/1900" and then added the appropriate number of intervals to "1900-01-01" to arrive at the calculated date. If you have to calculate other date values, you can use this calculation as the basis and then add or subtract additional intervals to come up with other useful dates.

For example, to calculate the last day of the previous month for a given date, you can use the following calculation to determine the first day of the current month and subtract a day from it:

```
select DATEADD(dd, -1, DATEADD(mm, DATEDIFF(mm, '',getdate()), ''))
```

You can perform a similar calculation to determine the last day of the previous year, based on the formula to calculate the first date of the current year for the given date:

```
select DATEADD(dd, -1, DATEADD(yy, DATEDIFF(yy, '',getdate()), ''))
```

What if you need to determine the last day of the current month for a given date? One way to do this is to calculate the first date of the next month and subtract one day from that. To calculate the first day of the next month, you can use the formula to calculate the first day of the current month and add one to the number of intervals returned by `DATEDIFF` when comparing the given date to "1/1/1900" to get the first day of the next month:

```
select DATEADD(mm, DATEDIFF(mm, '',getdate()) + 1, '')
```

Now that you have the first date of the next month, you simply subtract one day from it to get the last day of the current month:

```
select DATEADD(dd, -1, DATEADD(mm, DATEDIFF(mm, '',getdate()) + 1, ''))
```

Similarly, you can modify the formula to calculate the first day of the year to return the last day of the previous year:

```
select DATEADD(dd, -1, DATEADD(yy, DATEDIFF(yy, '', getdate()) + 1, ''))
```

Now, let's try a little more advanced calculation: the first Monday of the current month. To find this, you start with the calculation for the Monday of the current week and modify it slightly. Rather than use `getdate()` as the date value, you use the calculation to get the first day of the month and add five days to it. Adding five days to the first day of the month ensures that you are in the first full week of the month (SQL Server treats Sunday as the first day of the week, so if the first day of the month was on a Monday, adding 5 days keeps you in the same week. If the first day is Tuesday or later, adding 5 days puts you into the next week). You can use the following calculation to get the first day of the month and add five days to it:

```
select DATEADD(dd, 5, DATEADD(mm, DATEDIFF(mm, '', getdate()), ''))
```

Now, you use this expression in place of the `getdate()` function in the calculation to get the date for Monday of the current week:

```
select DATEADD(wk, DATEDIFF(wk, '',
    DATEADD(dd, 5, DATEADD(mm, DATEDIFF(mm, '', getdate()), ''))), '')
```

The examples presented in this chapter should give you some insight into using the `DATEADD` and `DATEDIFF` functions for calculating dates using date intervals. You can use them as a basis for calculating other dates that your applications might need.

TIP

If you find yourself using any of these date calculations frequently, it might be a good idea to create one or more user-defined functions to encapsulate these calculations. It would save your having to reenter the sometimes complex formulas, which can be easily mistyped, leading to incorrect calculations. For information on creating user-defined functions, see Chapter 29, "Creating and Managing User-Defined Functions."

Converting Dates for Comparison

Because the `datetime` data type contains both time and date components, searching for data rows matching a specific date only, excluding the time component, can sometimes be a bit tricky—especially when you consider that SQL Server stores time values only down to 3/1,000 second. For example, if you want to find all rows where the date is for a certain day, you have to perform a range search for all times within that day. Because a date without a time specified defaults to a time of midnight (`00:00:00.000`) for that date, the following query doesn't return all matching rows if any of the data values contain a time other than midnight:

```
select title_id, pubdate from dbo.titles where pubdate = '2006-01-14'
```

To be sure to include all rows for a particular date, regardless of the time component stored, you could run a query similar to the following:

```
select title_id, pubdate from dbo.titles
  where pubdate between '2006-01-14 00:00:00.0' and '2006-01-14 23:59:59.997'
go
```

```
title_id pubdate
-----
FI3599  2006-01-14 00:00:00.000
```

Now you might be wondering, why use a time of "2006-01-14 23:59:59.997" as the last time of the day? You do so because SQL Server stores datetime values only down to 3/1,000 second. If you enter a time of "2006-01-14 23:59:59.999", SQL Server rounds it up to "2006-01-15 00:00:00.000", and it actually matches any rows with that datetime value, as in this example:

```
select title_id, pubdate from dbo.titles
  where pubdate between '2006-01-14 00:00:00.0' and '2006-01-14 23:59:59.999'
```

```
title_id pubdate
-----
FI3599  2006-01-14 00:00:00.000
FI5162  2006-01-15 00:00:00.000
```

This is one reason you have to be careful when performing date searches. Now you might be wondering why not just use the DATEDIFF function as in the following example:

```
select title_id, pubdate from dbo.titles
  where datediff(day, pubdate, '2006-01-14') = 0
go
```

```
title_id pubdate
-----
FI3599  2006-01-14 00:00:00.000
```

Although this query returns the correct result, the use of the function on the pubdate column may prevent SQL Server from using any indexes that exist on the pubdate column to optimize the query, and it is likely to end up performing a table scan. (For more information on query optimization and optimizable search arguments, see Chapter 35.) To help ensure that your queries are optimized effectively, you need to try to avoid using any functions or expressions on the column in the search argument, and you need to search against constant expressions.

Another way to write the preceding query would be to use the date calculations discussed previously in this section. For example, you could use the calculation to determine midnight of the desired date and use that as the inclusive lower bound, and you could use the calculation of midnight of the next day as the noninclusive upper bound and write a query similar to the following:

```
declare @date datetime
set @date = '2006-01-14'
select title_id, pubdate from dbo.titles
where pubdate >= DATEADD(dd, DATEDIFF(dd, '', @date), '')
    and pubdate < DATEADD(dd, DATEDIFF(dd, '', @date) + 1, '')
go
```

```
title_id pubdate
-----
FI3599  2006-01-14 00:00:00.000
```

SQL Server 2008 introduces the date and time data types, as well as the `datetime2` data type. The long-awaited date and time data types store just a date value or time value, respectively, making date-only or time-only comparisons much simpler. For example, the previous solution for finding all books published on a specific day can be simplified a bit using the date data type because there is no need to consider a time component:

```
declare @date date
set @date = '2006-01-14'
select title_id, pubdate from dbo.titles
where pubdate >= @date
    and pubdate < DATEADD(dd, 1, @date)
go
```

If the `pubdate` column were defined using the date data type instead of `datetime` (reasonable because the time of publication of a book is irrelevant), the comparison becomes even simpler:

```
alter table titles drop constraint DF__titles__pubdate__103673A0
drop statistics titles.pubdate
alter table titles alter column pubdate date null
alter table titles
    add constraint DF__titles__pubdate__103673A0
        default getdate() for pubdate
```

```
go
declare @date date
set @date = '2006-01-14'
select title_id, pubdate from dbo.titles
where pubdate = @date
go
```

```

title_id pubdate
-----
FI3599    2006-01-14 00:00:00.000

```

The `datetime2` data type stores the time value down to microseconds and avoids the 3/1,000 second rounding issue that was present with the `datetime` data type. For example, if you redefine the `pubdate` column using the `datetime2` data type, you avoid the rounding issue and get a single row as expected by the following query:

```

alter table titles drop constraint DF__titles__pubdate__103673A0
alter table titles alter column pubdate datetime2 null
alter table titles
    add constraint DF__titles__pubdate__103673A0
        default sysdatetime() for pubdate

go
select title_id, pubdate from dbo.titles
    where pubdate between '2006-01-14 00:00:00.0' and '2006-01-14 23:59:59.999999'
go

```

```

title_id pubdate
-----
FI3599    2006-01-14 00:00:00.000

```

Sorting Results with the GROUPING Function

When working with the `CUBE` or `ROLLUP` operator, SQL Server generates `NULL` values for the columns that are being rolled up to generate the aggregate values. When you are viewing the results, however, it can be difficult to determine whether the `NULL` value shown for a nonaggregate column is the result of a rollup or because the column itself contains a `NULL` value. Fortunately, SQL Server provides the `GROUPING` function, which you can use to distinguish between real `NULL` values and `NULL` values that represent a rollup of all values for a column in the result set.

The `GROUPING` function returns 1 when the value is grouped and 0 when the column contains a `NULL` value.

In Listing 43.13, the `GROUPING` function is used to replace `NULL` values for the rolled-up columns with `ALL`.

LISTING 43.13 Using the **GROUPING** Function

```

SELECT CASE when GROUPING(type) = 1 then 'ALL'
           else isnull(type, 'Other')
        END AS type,
        cast(CASE when (grouping(advance) = 1) then 'ALL'
                else isnull(convert(varchar(10), advance), 'Unknown')

```

```

        END as varchar(10)) as advance,
    count(*) AS number
FROM DBO.titles
where type like '%cook%' or type like 'p%'
GROUP BY type, advance
WITH rollup
go

```

type	advance	number

mod_cook	0.00	1
mod_cook	15000.00	1
mod_cook	ALL	2
popular_comp	Unknown	1
popular_comp	7000.00	1
popular_comp	8000.00	1
popular_comp	ALL	3
psychology	2000.00	1
psychology	2275.00	1
psychology	4000.00	1
psychology	6000.00	1
psychology	7000.00	1
psychology	ALL	5
trad_cook	4000.00	1
trad_cook	7000.00	1
trad_cook	8000.00	1
trad_cook	ALL	3
ALL	ALL	13

You can also use the `GROUPING` function to order the result sets to move all the rollups toward the bottom, as shown in Listing 43.14.

LISTING 43.14 Using the **GROUPING** Function to Order the Result Sets

```

SELECT CASE when GROUPING(type) = 1 then 'ALL'
        else isnull(type, 'Other')
        END AS type,
    cast(CASE when (grouping(advance) = 1) then 'ALL'
        else isnull(convert(varchar(10), advance), 'Unknown')
        END as varchar(10)) as advance,
    count(*) AS number
FROM DBO.titles
where type like '%cook%' or type like 'p%'
GROUP BY type, advance
WITH rollup

```

```
ORDER by GROUPING(type), GROUPING(advance)
go
```

type	advance	number
popular_comp	Unknown	1
popular_comp	7000.00	1
popular_comp	8000.00	1
psychology	2000.00	1

mod_cook	0.00	1
mod_cook	15000.00	1
mod_cook	ALL	2
trad_cook	ALL	3
psychology	ALL	5
popular_comp	ALL	3
ALL	ALL	13

Using CONTEXT_INFO

Although SQL Server enables you to define local variables within a T-SQL batch or stored procedure, local variables do not retain values between batches or stored procedures. Unfortunately, SQL Server 2008 does not enable you to create user-defined global variables. However, you can simulate global variables by using the `CONTEXT_INFO` setting, which allows you to store information in the `context_info` column in the `sys.sysprocesses` catalog view. A row in `sys.sysprocesses` exists for every connection to SQL Server, so the data remains there until you disconnect from SQL Server.

The `context_info` column is a binary (128) column. You can store any data value in it with the `SET CONTEXT_INFO` command, but you have to deal with hexadecimal data when retrieving it. If you are handy at manipulating hexadecimal data, you can store multiple values in the `context_info` column. The following example stores the average price from the `titles` table in the `context_info` column:

```
declare @avg_price money
select @avg_price = avg(price) from dbo.titles
set context_info @avg_price
```

You can retrieve the value stored in `context_info` by using a `SELECT` statement. You need to convert the binary data back to money when you retrieve it. Because `avg(price)` is the

only value stored in `context_info`, you can retrieve it by performing a substring on the first 8 bytes of the `context_info` column. (The money data type is 8 bytes in size.) Because SQL Server assigns a unique server process ID (SPID) to each connection, you use the `@@SPID` function to retrieve the information for the current connection:

```
select convert(money, substring(context_info, 1, 8)) as AVG_PRICE
from master..sysprocesses
where spid = @@spid
go
```

```
AVG_PRICE
-----
0.3751
```

If you don't use a substring to specify only the first 8 bytes of the `context_info` column, SQL Server assumes that the money data is stored in the last 8 bytes and returns a result of 0:

```
select convert(money, context_info) as AVG_PRICE
from master..sysprocesses
where spid = @@spid
go
```

```
AVG_PRICE
-----
0.00
```

Because money can be implicitly converted to binary, you don't need to convert it when setting `context_info`. For some other data types, such as `char` or `datetime`, you need to explicitly convert the data to binary because implicit conversions from those data types to binary is not supported. In the following example, you append a `datetime` value to the average price value already stored in `context_info`. You explicitly convert the `datetime` value to binary and append it to the 8 bytes you have already stored in `context_info`:

```
declare @max_date datetime,
        @context_info binary(128)
select @max_date = max(pubdate) from dbo.titles
select @context_info = substring(context_info, 1, 8)
                    + convert(binary(8), @max_date)
from master..sysprocesses
where spid = @@spid
set context_info @context_info
```

You now have two values stored in `context_info`. Using the appropriate substring, you can retrieve either the average price or the maximum `pubdate` from `context_info`:

```
declare @avg_price money,
        @max_pubdate datetime
```

```
select @avg_price = substring(context_info, 1, 8),
       @max_pubdate = substring(context_info, 9, 8)
from master..sysprocesses
where spid = @@spid
```

```
select @avg_price as 'Avg Price', @max_pubdate as 'Max PubDate'
go
```

```
Avg Price          Max PubDate
-----
0.3751            2009-05-31 00:00:00.000
```

Note that the binary data converts implicitly to money and datetime.

Working with Outer Joins

An outer join is used to return all the rows from the specified outer table (specified with LEFT OUTER, RIGHT OUTER, or FULL OUTER), even if the other table has no match. Rows returned from the outer table that have no corresponding match in the inner table display the value NULL for any columns retrieved from the inner table. For example, you might want to display the names of all authors along with the average royalty paid, if available:

```
select au_lname, au_fname, avg(royaltyper) as avg_royalty
from dbo.authors a left outer join dbo.titleauthor ta on a.au_id = ta.au_id
group by au_lname, au_fname
order by 3
go
```

au_lname	au_fname	avg_royalty
Greene	Morningstar	NULL
Greenfield	Tom	NULL
McBadden	Heather	NULL
Smith	Meander	NULL
Stringer	Dirk	NULL
Gringlesby	Burt	30
O'Leary	Michael	35
Ringer	Anne	37
Yokomoto	Akiko	40
MacFeather	Stearns	42
Hunter	Sheryl	50
Dull	Ann	50
Bennet	Abraham	60
Green	Marjorie	70
DeFrance	Michel	75
Karsen	Livia	75
Ringer	Albert	75

Panteley	Sylvia	100
White	Johnson	100
Straight	Dean	100
Locksley	Charlene	100
Carson	Cheryl	100
Blotchet-Halls	Reginald	100
del Castillo	Innes	100

Note that no real difference exists between left and right outer joins except for specifying which table on which side of the join condition is to be the controlling, or outer, table. For example, the previous query would provide the same result if you reversed the tables in the join clause and made it a right outer join:

```
select au_lname, au_fname, avg(royaltyper)
  from dbo.titleauthor ta right outer join dbo.authors a on ta.au_id = a.au_id
  group by au_lname, au_fname
  order by 3
```

A full outer join returns all matching rows from both tables, along with all rows from each table, without a corresponding match in the other table:

```
select a.au_fname, p.pub_name
  from dbo.authors a full outer join dbo.publishers p on a.state = p.state
go
```

au_fname	pub_name
-----	-----
James A.	NULL
Francine du Plessix	Kumquat Technical Publishing
Jean	NULL
E.L.	Nordome Titles
Justin	Algodata Infosystems
April	Sidney's Books and More
Ron	Algodata Infosystems
Jack	NULL
Matt	NULL
Josef	NULL
...	
Albert	Ramona Publishers
NULL	Gooseberry Titles
NULL	Binnet & Hardley
NULL	GGG&G
NULL	Lucerne Publishing
NULL	Tomato Books
NULL	Significant Titles Company

OUTER JOIN Versus WHERE Clause Matching

With the ANSI join syntax, you specify the join condition in the FROM clause. Additional search conditions can be specified in either the JOIN clause or WHERE clause. It's important to remember that in a left or right outer join, search conditions specified in the ON clause work differently than search conditions in the WHERE clause:

- ▶ Search conditions in the WHERE clause always exclude nonmatching rows.
- ▶ Search conditions in the ON clause sometimes exclude rows and sometimes do not.

Needless to say, it can be somewhat confusing to figure out which rows and data values will be returned. To demonstrate the use of search conditions in the WHERE clause versus the ON clause, the examples presented in this section make use of the two views shown in Listing 43.15.

LISTING 43.15 **CREATE VIEW** Statements for Outer Join Examples

```
CREATE VIEW dbo.STORES_V1 AS
    SELECT STOR_ID, CITY FROM DBO.STORES WHERE STOR_ID BETWEEN 'A001' AND 'A005'
go
CREATE VIEW dbo.STORES_V2 AS
    SELECT STOR_ID, STATE FROM DBO.STORES WHERE STOR_ID BETWEEN 'A002' AND 'A007'
    UNION ALL
    SELECT 'A004', 'MA'
go

select * from dbo.stores_v1
select * from dbo.stores_v2

STOR_ID CITY
-----
A001    Dublin
A002    Oakland
A003    Bisbee
A004    White Plains
A005    Thomaston

(5 row(s) affected)

STOR_ID STATE
-----
A002    NJ
A003    AZ
A004    NY
```

A005 GA
 A006 CA
 A007 CA
 A004 MA

Listing 43.16 provides an example of a left outer join query that includes the search condition in the ON clause. All rows are returned from STORES_V1, and NULL values are returned for STORES_V2 where there isn't a matching STOR_ID or where there is a matching STOR_ID but STATE is not equal to 'GA'.

LISTING 43.16 Specifying the Search Condition in the **ON** Clause

```
SELECT * FROM DBO.STORES_V1 V1
    LEFT OUTER JOIN DBO.STORES_V2 V2
        ON V1.STOR_ID = V2.STOR_ID
        AND V2.STATE <> 'GA'
    ORDER BY V1.STOR_ID ,V2.STATE

go
```

STOR_ID	CITY	STOR_ID	STATE
A001	Dublin	NULL	NULL
A002	Oakland	A002	NJ
A003	Bisbee	A003	AZ
A004	White Plains	A004	MA
A004	White Plains	A004	NY
A005	Thomaston	NULL	NULL

Now, if you put the search condition in the WHERE clause, as shown in Listing 43.17, the nonmatching rows from STORES_V2 are filtered out because the NULL value returned for STATE does not match the WHERE clause search criteria WHERE V2.STATE <> 'GA'. (Remember that NULL values are neither equal to nor not equal to other values.)

LISTING 43.17 Specifying a Search Condition in a **WHERE** Clause

```
SELECT * FROM DBO.STORES_V1 V1
    LEFT OUTER JOIN DBO.STORES_V2 V2
        ON V1.STOR_ID = V2.STOR_ID
        WHERE V2.STATE <> 'GA'
    ORDER BY V1.STOR_ID ,V2.STATE

go
```

STOR_ID	CITY	STOR_ID	STATE
A002	Oakland	A002	NJ

A003	Bisbee	A003	AZ
A004	White Plains	A004	MA
A004	White Plains	A004	NY

To include the nonmatching rows from STORES_V2, you need to add a check for NULL to the WHERE clause, as shown in Listing 43.18.

LISTING 43.18 Including Nonmatching Inner Table Rows That Do Not Match a **WHERE** Clause Search Condition

```
SELECT * FROM DBO.STORES_V1 V1
  LEFT OUTER JOIN DBO.STORES_V2 V2
    ON V1.STOR_ID = V2.STOR_ID
  WHERE (V2.STATE <> 'GA' or V2.STATE is NULL)
  ORDER BY V1.STOR_ID ,V2.STATE
```

go

STOR_ID	CITY	STOR_ID	STATE
-----	-----	-----	-----
A001	Dublin	NULL	NULL
A002	Oakland	A002	NJ
A003	Bisbee	A003	AZ
A004	White Plains	A004	MA
A004	White Plains	A004	NY

Notice that the row where `STOR_ID = 'A005'` is still not included in the result set. The query shown in Listing 43.18 also demonstrates another difference between specifying a search condition in the WHERE clause and the ON clause. In this case, the outer join is performed first, so that all rows and selected column values are returned from STORES_V2, including the row where `STOR_ID = 'A005'`, without considering the WHERE clause condition:

```
SELECT * FROM DBO.STORES_V1 V1
  LEFT OUTER JOIN DBO.STORES_V2 V2
    ON V1.STOR_ID = V2.STOR_ID
```

go

STOR_ID	CITY	STOR_ID	STATE
-----	-----	-----	-----
A001	Dublin	NULL	NULL
A002	Oakland	A002	NJ
A003	Bisbee	A003	AZ
A004	White Plains	A004	NY
A004	White Plains	A004	MA
A005	Thomaston	A005	GA

After the join result is returned, because the STATE value is equal to 'GA', the search condition in the WHERE clause (`V2.STATE <> 'GA'`) filters out that row.

In a left or right outer join, a search condition in the ON clause also works differently, depending on whether it refers to a field in the inner or outer table. If the ON clause search condition refers to a field in the outer table, it determines whether the related row finds a match. (The outer row is returned regardless.) For example, Listing 43.19 demonstrates a search condition in the ON clause that restricts which rows in STORES_V1 (the outer table) join to STORES_V2. The join is performed only for those rows in STORES_V1 where CITY is greater than N. However, all rows from STORES_V1 are still returned.

LISTING 43.19 Specifying an **ON** Clause Search Condition on the Outer Table

```
SELECT * FROM DBO.STORES_V1 V1
    LEFT OUTER JOIN DBO.STORES_V2 V2
    ON V1.STOR_ID = V2.STOR_ID
    AND V1.CITY > 'N'
ORDER BY V1.STOR_ID ,V2.STATE
go
```

STOR_ID	CITY	STOR_ID	STATE
A001	Dublin	NULL	NULL
A002	Oakland	A002	NJ
A003	Bisbee	NULL	NULL
A004	White Plains	A004	MA
A004	White Plains	A004	NY
A005	Thomaston	A005	GA

If the ON clause search condition refers to a field in the inner table, it determines whether the related row matches the join. Listing 43.20 shows an example of specifying the ON clause search condition on the inner table. Again, notice that all rows from STORES_V1 are returned, but only the matching rows are returned from STORES_V2, where `STOR_ID` is less than `A004`.

LISTING 43.20 Specifying an **ON** Clause Search Condition on the Inner Table

```
SELECT * FROM DBO.STORES_V1 V1
    LEFT OUTER JOIN DBO.STORES_V2 V2
    ON V1.STOR_ID = V2.STOR_ID
    AND V2.STOR_ID < 'A004'
ORDER BY V1.STOR_ID ,V2.STATE
go
```

STOR_ID	CITY	STOR_ID	STATE
---------	------	---------	-------

A001	Dublin	NULL	NULL
A002	Oakland	A002	NJ
A003	Bisbee	A003	AZ
A004	White Plains	NULL	NULL
A005	Thomaston	NULL	NULL

When you perform a left or right outer join, a search condition against the outer table in the `ON` clause works differently from the same search condition specified in the `WHERE` clause. As shown in Listing 43.19, when the search condition in the `ON` clause filters on a field in the outer table, the outer row is returned, regardless, with no matching rows returned from the inner table. However, if the search condition on the `OUTER` table is specified in the `WHERE` clause, the outer row is eliminated from the result set, as shown in Listing 43.21.

LISTING 43.21 Specifying an Outer Table Search Condition in the **WHERE** Clause

```
SELECT * FROM DBO.STORES_V1 V1
  LEFT OUTER JOIN DBO.STORES_V2 V2
    ON V1.STOR_ID = V2.STOR_ID
  WHERE V1.CITY > 'N'
ORDER BY V1.STOR_ID ,V2.STATE
go
```

STOR_ID	CITY	STOR_ID	STATE
-----	-----	-----	-----
A002	Oakland	A002	NJ
A004	White Plains	A004	MA
A004	White Plains	A004	NY
A005	Thomaston	A005	GA

Nested Outer Joins

When using the ANSI `JOIN` syntax, you must be careful about mixing outer joins with inner joins because the query may not generate the desired result if the outer join is not continued down to the lowest level. For example, consider the query shown in Listing 43.22. The intent of this query is to list all authors whose state equals `NE` and, for those authors, display the titles of their associated books, if any.

LISTING 43.22 An Outer Join Nested in an Inner Join

```
select left(au_lname, 20) as au_lname, au_fname, left(title, 20) as title
  from dbo.authors a
 left join dbo.titleauthor ta on a.au_id = ta.au_id
  join dbo.titles t on ta.title_id = t.title_id
 where a.state = 'NE'
```

```

go
au_lname          au_fname          title
-----
Patterson         Richard North     The Lasko Tangent
Patterson         Richard North     The Outside Man
Patterson         Richard North     Private Screening
Patterson         Richard North     Eyes of a Child
Patterson         Richard North     Degree of Guilt
Patterson         Richard North     Escape the Night

```

However, because the outer join is not carried to the titles table, the author with no matching row in the titleauthor table ends up getting filtered from the result set. The reason is that when the outer join is performed between authors and titleauthor, because no matching row is found, NULL is returned for title_id. Because a normal inner join is performed on the titles table, the NULL value for title_id does not match any rows in the titles table, so the author with no matching rows in titleauthor ends up getting filtered out. To see those authors, you need to modify the query in Listing 43.22 to carry the outer join down to the join between titleauthor and authors:

```

select left(au_lname, 20) as au_lname, au_fname, left(title, 20) as title
  from dbo.authors a
  left join dbo.titleauthor ta on a.au_id = ta.au_id
  left join dbo.titles t on ta.title_id = t.title_id
 where a.state = 'NE'
go

```

```

au_lname          au_fname          title
-----
Patterson         Richard North     The Lasko Tangent
Patterson         Richard North     The Outside Man
Patterson         Richard North     Private Screening
Patterson         Richard North     Eyes of a Child
Patterson         Richard North     Degree of Guilt
Patterson         Richard North     Escape the Night
McBadden         Heather           NULL

```

Working with Full Outer Joins

A full outer join selects rows from both tables and joins those rows that match on the join fields. In addition to the matching rows, one copy of each nonmatching row from each table is returned. Listing 43.23 shows an example of a full outer join.

LISTING 43.23 Full Outer Join Example

```
SELECT * FROM DBO.STORES_V1 V1
    FULL OUTER JOIN DBO.STORES_V2 V2
        ON V1.STOR_ID = V2.STOR_ID
    ORDER BY V1.STOR_ID ,V2.STOR_ID ,V2.STATE
```

```
go
```

STOR_ID	CITY	STOR_ID	STATE
NULL	NULL	A006	CA
NULL	NULL	A007	CA
A001	Dublin	NULL	NULL
A002	Oakland	A002	NJ
A003	Bisbee	A003	AZ
A004	White Plains	A004	MA
A004	White Plains	A004	NY
A005	Thomaston	A005	GA

As you can see from the results in Listing 43.23, all rows are returned from both STORES_V1 and STORES_V2.

In a full outer join, a search condition in the ON clause is handled differently from a search condition in the WHERE clause in that it never results in a row being excluded from the result set. All it does is categorize the input row as being either matching or nonmatching. In Listing 43.24, a search condition (`V1.STOR_ID > 'A003'`) is specified in the ON clause. As you can see, any rows that do not meet that search condition are returned as nonmatching rows.

LISTING 43.24 Specifying a Search Condition in a Full Outer Join **ON** Clause

```
SELECT * FROM DBO.STORES_V1 V1
    FULL OUTER JOIN DBO.STORES_V2 V2
        ON V1.STOR_ID = V2.STOR_ID
        AND V1.STOR_ID > 'A003'
    ORDER BY V1.STOR_ID ,V2.STOR_ID ,V2.STATE
```

```
go
```

STOR_ID	CITY	STOR_ID	STATE
NULL	NULL	A002	NJ
NULL	NULL	A003	AZ
NULL	NULL	A006	CA
NULL	NULL	A007	CA
A001	Dublin	NULL	NULL
A002	Oakland	NULL	NULL
A003	Bisbee	NULL	NULL
A004	White Plains	A004	MA
A004	White Plains	A004	NY
A005	Thomaston	A005	GA

As you can see, when you work with full outer joins, search arguments in the `ON` clause serve only to define which rows are used as matching rows for a join. Search arguments specified in the `WHERE` clause define which rows are returned. It's important to note that the `WHERE` clause conditions behave as if the join is an inner join and are applied *after* the join is done. Listing 43.25 shows an example.

LISTING 43.25 Specifying a Search Condition in a Full Outer Join **WHERE** Clause

```
SELECT * FROM dbo.STORES_V1 V1
    FULL OUTER JOIN dbo.STORES_V2 V2
        ON V1.STOR_ID = V2.STOR_ID
    WHERE V1.STOR_ID > 'A003'
    ORDER BY V1.STOR_ID ,V2.STOR_ID ,V2.STATE
go
```

STOR_ID	CITY	STOR_ID	STATE
A004	White Plains	A004	MA
A004	White Plains	A004	NY
A005	Thomaston	A005	GA

Generating T-SQL Statements with T-SQL

The system catalogs in SQL Server 2008 contain a wealth of information you can use to save a lot of time and effort when generating SQL statements that need to be run repeatedly on a large number of database objects or when trying to build a column list for a query. You can use T-SQL code to select information from the system catalogs, system tables, and system views to generate `SELECT` statements and the like. For example, say you want to grant `EXECUTE` permission to the user `fred` on each stored procedure in the `bigpubs2008` database. This can be a tedious task to perform using SSMS because in the `Securables` dialog for the user `fred`, you have to select each procedure, one at a time, and click the `Grant Execute` check box. If there were a large number of procedures, this could be pretty time-consuming, and your mouse-clicking finger would probably get pretty tired.

The quicker and easier way would be to build the SQL statements necessary to grant `EXECUTE` permission to `fred` on all the stored procedures. The following `SELECT` statement can be used to generate a SQL script with those commands:

```
select 'grant execute on ' + name + ' to fred'
    from sys.procedures
    order by name
go
```

```
-----
grant execute on byroyalty to fred
```

```

grant execute on cursor_proc to fred
grant execute on error_handler to fred
grant execute on find_books_by_type2 to fred
grant execute on gen_sequence to fred
grant execute on get_authors to fred
grant execute on get_next_item_from_queue to fred
grant execute on get_titles to fred
grant execute on p_explicit_cols to fred
grant execute on p_fetch_explicit_cols to fred
grant execute on p_insert_explicit_cols to fred
grant execute on reptq1 to fred
grant execute on reptq2 to fred
grant execute on reptq3 to fred
grant execute on SHOW_PARTS_LIST to fred
grant execute on title_authors to fred
grant execute on trantest to fred
grant execute on ytd_sales to fred
grant execute on ytd_sales2 to fred

```

You can copy and paste the output from this statement into a query window in SSMS and execute it to grant the desired permissions. When you get to know your system catalog views, you can begin to automate the generation of a number of SQL operations in this manner, freeing up your time to spend on more interesting projects.

Working with @@ERROR and @@ROWCOUNT

When you are writing T-SQL code that needs to check for both errors and the number of rows affected after your SQL statements, one of the common pitfalls is trying to get both the error status and the number of rows after a SQL statement runs. You have to remember that all SQL statements except the DECLARE statement reset the value of @@ROWCOUNT and @@ERROR to the status of the last command executed.

If after a SQL statement you check the value of @@ERROR, the statement used to check @@ERROR resets @@ROWCOUNT. If you check @@ROWCOUNT first, it resets the value of @@ERROR. To check both values, you need to use an assignment SELECT immediately after the SQL statement you are checking and capture both values into local variables. Note that you cannot accomplish this with the SET statement because the SET statement allows setting a value to only a single variable at a time.

The example in Listing 43.26 provides a way to capture and check both @@ROWCOUNT and @@ERROR after an UPDATE statement in a T-SQL batch.

LISTING 43.26 Capturing Both @@ROWCOUNT and @@ERROR After an UPDATE Statement

```

declare @rowcnt int,
        @error int
UPDATE dbo.titles set price = price * 1.10
       where type = 'fiction'

```

```

select @rowcnt = @@ROWCOUNT, @error = @@ERROR
if @rowcnt = 0
    print 'no rows updated'
if @error <> 0
    raiserror ('Update of titles failed', 16, 1)
return

```

NOTE

Error processing was improved in SQL Server 2005 with the introduction of the TRY...CATCH construct in T-SQL. It provides a much more robust method of error handling than checking @@ERROR for error conditions. The TRY...CATCH construct is discussed in more detail later in this chapter.

De-Duping Data with Ranking Functions

One common problem encountered with imported data is unexpected duplicate data rows, especially if the data is being consolidated from multiple sources. In previous versions of SQL Server, de-duping the data often involved the use of cursors and temp tables. Since the introduction of the ROW_NUMBER ranking function and common table expressions in SQL Server 2005, you are able to de-dupe data with a single statement.

To demonstrate this approach, Listing 43.26 shows how to create an authors_import table and populate it with some duplicate rows.

LISTING 43.27 Script to Create and Populate the **authors_import** Table

```

USE bigpubs2008
GO
CREATE TABLE dbo.authors_import(
    au_id dbo.id NOT NULL,
    au_lname varchar(30) NOT NULL,
    au_fname varchar(20) NOT NULL)
go

INSERT INTO dbo.authors_import(au_id, au_lname, au_fname)
VALUES('681-61-9588', 'Ahlberg', 'Allan')
INSERT INTO dbo.authors_import(au_id, au_lname, au_fname)
VALUES('739-35-5165', 'Ahlberg', 'Janet')
INSERT INTO dbo.authors_import(au_id, au_lname, au_fname)
VALUES('499-84-5672', 'Alexander', 'Lloyd')
INSERT INTO dbo.authors_import(au_id, au_lname, au_fname)
VALUES('499-84-5672', 'Alexander', 'Lloyd')
INSERT INTO dbo.authors_import(au_id, au_lname, au_fname)
VALUES('432-31-3829', 'Bate', 'W. Jackson')

```

```

INSERT INTO dbo.authors_import(au_id, au_lname, au_fname)
VALUES('432-31-3829', 'Bate', 'W. Jackson')
INSERT INTO dbo.authors_import(au_id, au_lname, au_fname)
VALUES('432-31-3829', 'Bate', 'W. Jackson')
INSERT INTO dbo.authors_import(au_id, au_lname, au_fname)
VALUES('437-99-3329', 'Bauer', 'Caroline Feller')
INSERT INTO dbo.authors_import(au_id, au_lname, au_fname)
VALUES('378-33-9373', 'Benchley', 'Nathaniel')
INSERT INTO dbo.authors_import(au_id, au_lname, au_fname)
VALUES('378-33-9373', 'Benchley', 'Nate')
INSERT INTO dbo.authors_import(au_id, au_lname, au_fname)
VALUES('409-56-7008', 'Bennet', 'Abraham')
GO

```

You can see in the data for Listing 43.27 that there are two duplicates for `au_id` 499-84-5672 and three for `au_id` 432-31-3829. To start identifying the duplicates, you can write a query using the `ROW_NUMBER()` function to generate a unique row ID for each data row, as shown in Listing 43.28.

LISTING 43.28 Using the **ROW_NUMBER()** Function to Generate Unique Row IDs

```

SELECT ROW_NUMBER() OVER (ORDER BY au_id, au_lname, au_fname) AS ROWID, *
FROM dbo.authors_import
go

```

ROWID	au_id	au_lname	au_fname
1	378-33-9373	Benchley	Nate
2	378-33-9373	Benchley	Nathaniel
3	409-56-7008	Bennet	Abraham
4	432-31-3829	Bate	W. Jackson
5	432-31-3829	Bate	W. Jackson
6	432-31-3829	Bate	W. Jackson
7	437-99-3329	Bauer	Caroline Feller
8	499-84-5672	Alexander	Lloyd
9	499-84-5672	Alexander	Lloyd
10	681-61-9588	Ahlberg	Allan
11	739-35-5165	Ahlberg	Janet

Now you can use the query shown in Listing 43.28 to build a common table expression to find the duplicate rows. In this case, we keep the first row found. To make sure it works correctly, write the query first as a `SELECT` statement to verify that it is identifying the correct rows, as shown in Listing 43.29.

LISTING 43.29 Using a Common Table Expression to Identify Duplicate Rows

```

WITH authors_import AS
(SELECT ROW_NUMBER() OVER (ORDER BY au_id, au_lname, au_fname) AS ROWID, *
  FROM dbo.authors_import)
select * FROM authors_import WHERE ROWID NOT IN
(SELECT MIN(ROWID) FROM authors_import
  GROUP BY au_id, au_fname, au_lname);
GO

```

ROWID	au_id	au_lname	au_fname
5	432-31-3829	Bate	W. Jackson
6	432-31-3829	Bate	W. Jackson
9	499-84-5672	Alexander	Lloyd

Now you simply change the final SELECT statement in Listing 43.29 into a DELETE statement, and it removes the duplicate rows from authors_import:

```

WITH authors_import AS
(SELECT ROW_NUMBER() OVER (ORDER BY au_id, au_lname, au_fname) AS ROWID, *
  FROM dbo.authors_import)
delete FROM authors_import WHERE ROWID NOT IN
(SELECT MIN(ROWID) FROM authors_import
  GROUP BY au_id, au_fname, au_lname);
GO
select * from authors_import
go

```

au_id	au_lname	au_fname
681-61-9588	Ahlberg	Allan
739-35-5165	Ahlberg	Janet
499-84-5672	Alexander	Lloyd
432-31-3829	Bate	W. Jackson
437-99-3329	Bauer	Caroline Feller
378-33-9373	Benchley	Nathaniel
378-33-9373	Benchley	Nate
409-56-7008	Bennet	Abraham

If you want to retain the last duplicate record and delete the previous ones, you can replace the MIN function with the MAX function in the DELETE statement.

Notice that the uniqueness of the duplication is determined by the columns specified in the GROUP BY clause of the subquery. Notice that there are still two records for au_id 378-33-9373 remaining in the final record set. The duplicates removed were based on au_id,

au_lname, and au_fname. Because the first name is different for each of the two instances of au_id 378-33-9373, both Nathaniel Benchley and Nate Benchley remain in the authors_import table. If you remove au_fname from the GROUP BY clause, the earlier record for Nathaniel Benchley would remain, and Nate Benchley would be removed. However, this result may or may not be desirable. You would probably want to resolve the disparity between Nathaniel and Nate and confirm manually that they are duplicate rows before deleting them. Running the query in Listing 43.27 with au_fname removed from the GROUP BY clause helps you better determine what your final record set would look like.

In Case You Missed It: New Transact-SQL Features in SQL Server 2005

43

SQL Server 2005 introduced some new features and changes to the Transact-SQL (T-SQL) language:

- ▶ The xml data type
- ▶ The max specifier for the varchar and varbinary data types
- ▶ TOP enhancements
- ▶ The OUTPUT clause
- ▶ Common table expressions (CTEs)
- ▶ Ranking functions
- ▶ PIVOT and UNPIVOT
- ▶ The APPLY operator
- ▶ TRY-CATCH logic for error handling
- ▶ The TABLESAMPLE clause

NOTE

Unless stated otherwise, all examples in this chapter make use of tables in the bigpubs2008 database.

The xml Data Type

SQL Server 2005 introduced a new xml data type that supports storing XML documents and fragments in database columns or variables. The xml data type can be used with local variable declarations, as the output of user-defined functions, as input parameters to stored procedures and functions, and much more. The results of a FOR XML statement can easily be stored in a column, stored procedure parameter, or local variable. XML data is stored in an internal binary format and can be up to 2GB in size. XML instances stored in xml columns can contain up to 128 levels of nesting.

xml columns can also be used to store code files such as XSLT, XSD, XHTML, and any other well-formed content. These files can then be retrieved by user-defined functions written in managed code hosted by SQL Server. (See Chapter 45, “SQL Server and the .NET Framework,” for a full review of SQL Server managed hosting.)

For more information and detailed examples on using the xml data type, see Chapter 47, “Using XML in SQL Server 2008.”

The max Specifier

In SQL Server 2000, the most data that could be stored in a varchar, nvarchar, or varbinary column was 8,000 bytes. If you needed to store a larger value in a single column, you had to use the large object (LOB) data types: text, ntext, or image. The main disadvantage of using the LOB data types is that they cannot be used in many places where varchar or varbinary data types can be used (for example, as local variables, as arguments to SQL Server string manipulation functions such as REPLACE, and in string concatenation operations).

SQL Server 2005 introduced the max specifier for varchar and varbinary data types. This specifier expands the storage capabilities of the varchar and varbinary data types to store up to 2^{31-1} bytes of data, which is the same maximum size of text and image data types. The main difference is that these large value data types can be used just like the smaller varchar, nvarchar, and varbinary data types. The large value data types can be used in functions where LOB objects cannot (such as the REPLACE function), as data types for Transact-SQL variables, and in string concatenation operations. They can also be used in the DISTINCT, ORDER BY, and GROUP BY clauses of a SELECT statement as well as in aggregates, joins, and subqueries.

The following example shows a local variable being defined using the varchar(max) data type:

```
declare @maxvar varchar(max)
go
```

However, a similar variable cannot be defined using the text data type:

```
declare @textvar text
go
```

Msg 2739, Level 16, State 1, Line 2

```
The text, ntext, and image data types are invalid for local variables.declare
  @maxvar varchar(max)
```

The remaining examples in this section make use of the following table to demonstrate the differences between a varchar(max) column and text column:

```
create table maxtest (maxcol varchar(max),
                    textcol text)
```

```

go
-- populate the columns with some sample data
insert maxtest
  select replicate('1234567890', 1000), replicate('1234567890', 1000)
go

```

In the following example, you can see that the substringing function works with both varchar(max) and text data types:

```

select substring (maxcol, 1, 10),
       substring (textcol, 1, 10)
  from maxtest
go
maxcol      textcol
-----
1234567890 1234567890

```

However, in this example, you can see that while a varchar(max) column can be used for string concatenation, the text data type cannot:

```

select substring('xxx' + maxcol, 1, 10) from maxtest
go
-----
xxx1234567

```

```

select substring('xxx' + textcol, 1, 10) from maxtest
go

```

Msg 402, Level 16, State 1, Line 1

The data types varchar and text are incompatible in the add operator.

With the introduction of the max specifier, the large value data types are able to store data with the same maximum size as the LOB data types, but with the ability to be used just as their smaller varchar, nvarchar, and varbinary counterparts. It is recommended that the max data types be used instead of the LOB data types because the LOB data types will be deprecated in future releases of SQL Server.

TOP Enhancements

The TOP clause allows you to specify the number or percentage of rows to be returned by a SELECT statement. SQL Server 2005 introduced the capability for the TOP clause to also be used in INSERT, UPDATE, and DELETE statements. The syntax was also enhanced to allow the use of a numeric expression for the number value rather than having to use a hard-coded number.

The syntax for the TOP clause is as follows:

```
SELECT [TOP (numeric_expression) [PERCENT] [WITH TIES]]
      FROM table_name ...[ORDER BY...]
DELETE [TOP (numeric_expression) [PERCENT]] FROM table_name ...
UPDATE [TOP (numeric_expression) [PERCENT]] table_name SET ...
INSERT [TOP (numeric_expression) [PERCENT]] INTO table_name ...
```

numeric_expression must be specified in parentheses. Specifying constants without parentheses is supported in SELECT queries only for backward compatibility. The parentheses around the expression are always required when TOP is used in UPDATE, INSERT, or DELETE statements.

If you do not specify the PERCENT option, the numeric expression must be implicitly convertible to the bigint data type. If you specify the PERCENT option, the numeric expression must be implicitly convertible to float and fall within the range of 0 to 100. The WITH TIES option with the ORDER BY clause is supported only with SELECT statements.

The following example shows the use of a local variable as the numeric expression for the TOP clause to limit the number of rows returned by a SELECT statement:

```
declare @rows int
select @rows = 5
select top (@rows) * from sales
go
```

stor_id	ord_num	ord_date	qty	payterms	title_id
6380	6871	2007-09-14 00:00:00.000	5	Net 60	BU1032
6380	722a	2007-09-13 00:00:00.000	3	Net 60	PS2091
6380	ONFFFFFFFFFFFFFFFF	2007-08-09 00:00:00.000	852	Net 30	FI1980
7066	A2976	2006-05-24 00:00:00.000	50	Net 30	PC8888
7066	ONAAAAAAAAA	2007-01-13 00:00:00.000	948	Net 60	CH2480

Allowing the use of a numeric expression rather than a constant for the TOP command is especially useful when the number of requested rows is passed as a parameter to a stored procedure or function. When you use a subquery as the numeric expression, it must be self-contained; it cannot refer to columns of a table in the outer query. Using a self-contained subquery allows you to more easily develop queries for dynamic requests, such as “calculate the average number of titles published per week and return that many titles which were most recently published”:

```
SELECT TOP(SELECT COUNT(*)/DATEDIFF(month, MIN(pubdate), MAX(pubdate))
          FROM titles)
      title_id, pub_id, pubdate
FROM titles
ORDER BY pubdate DESC
go
```

```

title_id pub_id pubdate
-----
CH9009  9903  2009-05-31 00:00:00.000
PC9999  1389  2009-03-31 00:00:00.000
FI0375  9901  2008-09-24 00:00:00.000
DR4250  9904  2008-09-21 00:00:00.000
BI4785  9914  2008-09-20 00:00:00.000

BI3224  9905  2008-09-18 00:00:00.000
FI0435  9917  2008-09-17 00:00:00.000
FI0792  9907  2008-09-13 00:00:00.000

```

NOTE

Be aware that the TOP keyword does not speed up a query if the query also contains an ORDER BY clause. The reason is that the entire result set is selected into a work-table and sorted before the top *N* rows in the ordered result set are returned.

When using the TOP keyword, you can also add the WITH TIES option to specify that additional rows should be returned from the result set if duplicate values of the columns specified in the ORDER BY clause exist within the last values returned. The WITH TIES option can be specified only if an ORDER BY clause is specified. The following query returns the top four most expensive books:

```

SELECT TOP 4 price, title
  FROM titles
  ORDER BY price DESC
go

```

```

price          title
-----
17.1675        But Is It User Friendly?
17.0884        Is Anger the Enemy?
15.9329        Emotional Security: A New Algorithm
15.894         You Can Combat Computer Stress!

```

If you use WITH TIES, you can see that there is an additional row with the same price (15.894) as the last row returned by the previous query:

```

SELECT TOP 4 WITH TIES price, title
  FROM titles
  ORDER BY price DESC
go

```

price	title
17.1675	But Is It User Friendly?
17.0884	Is Anger the Enemy?
15.9329	Emotional Security: A New Algorithm
15.894	The Gourmet Microwave
15.894	You Can Combat Computer Stress!

In versions of SQL Server prior to 2005, if you wanted to limit the number of rows affected by an UPDATE statement or a DELETE statement, you had to use the SET ROWCOUNT statement:

```
set rowcount 100
DELETE sales where ord_date < (select dateadd(year, 1, min(ord_date)) from sales)
set rowcount 0
```

SET ROWCOUNT often was used in this way to allow backing up and pruning of the transaction log during a purge process and also to prevent lock escalation. The problem with SET ROWCOUNT is that it applies to the entire current user session. You have to remember to set the rowcount back to 0 to be sure you don't limit the rows affected by subsequent statements. With TOP, you can more easily specify the desired number of rows for each individual statement:

```
DELETE top (100) sales
    where ord_date < (select dateadd(year, 1, min(ord_date)) from sales)

UPDATE top (100) titles
    set royalty = royalty * 1.25
```

You may be thinking that using TOP in INSERT statements is not really necessary because you can always specify it in a SELECT query, as shown in Listing 43.30.

LISTING 43.30 Limiting Rows for Insert with **TOP** in a **SELECT** Statement

```
CREATE TABLE top_sales
(stor_id char(4),
 ord_num varchar(20),
 ord_date datetime NOT NULL,
 qty smallint NOT NULL,
 payterms varchar(12) ,
 title_id dbo.tid NOT NULL)
go
insert top_sales
select top 100 * from sales
    where qty > 1700
    order by qty desc
```

However, you may find using the TOP clause in an INSERT statement useful when inserting the result of an EXEC command or the result of a UNION operation, as shown in Listing 43.31.

LISTING 43.31 Using **TOP** in an Insert with a **UNION ALL** Query

```

insert top (50) into top_sales
  select stor_id, ord_num, ord_date, qty, payterms, title_id from sales
     where qty >= 1800
union all
  select stor_id, ord_num, ord_date, qty, payterms, title_id from sales_big
     where qty >= 1800
order by qty desc

```

When a **TOP** (*n*) clause is used with **DELETE**, **UPDATE**, or **INSERT**, the selection of rows on which the operation is performed is not guaranteed. If you want the **TOP**(*n*) clause to operate on rows in a meaningful chronological order, you must use **TOP** together with **ORDER BY** in a subselect statement. The following query deletes the 10 rows of the **sales_big** table that have the earliest order dates:

```

delete from sales_big
  where sales_id in (select top 10 sales_id
                    from sales_big order by ord_date)

```

To ensure that only 10 rows are deleted, the column specified in the subselect statement (**sales_id**) must be the primary key of the table. Using a nonkey column in the subselect statement could result in the deletion of more than 10 rows if the specified column matched duplicate values.

NOTE

SQL Server Books Online states that when you use **TOP** (*n*) with **INSERT**, **UPDATE**, and **DELETE** operations, the rows affected should be a random selection of the **TOP**(*n*) rows from the underlying table. In practice, this behavior has not been observed. Using **TOP** (*n*) with **INSERT**, **UPDATE**, and **DELETE** appears to affect only the first *n* matching rows. However, because the row selection is not guaranteed, it is still recommended that you use **TOP** together with **ORDER BY** in a subselect to ensure the expected result.

The OUTPUT Clause

By default, the execution of a DML statement such as **INSERT**, **UPDATE**, or **DELETE** does not produce any results that indicate what rows changed except for checking **@@ROWCOUNT** to determine the number of rows affected.

In SQL Server 2005, the **INSERT**, **UPDATE**, and **DELETE** statements were enhanced to support an **OUTPUT** clause to be able to identify the actual rows affected by the DML statement. The **OUTPUT** clause allows you to return data from a modification statement (**INSERT**, **UPDATE**, or **DELETE**). This data can be returned as a result set to the caller or returned into a table variable or an output table. To capture information on the affected rows, the **OUTPUT** clause provides access to the inserted and deleted virtual tables that are normally accessible

only in a trigger. The inserted and deleted tables provide access to the new/old images of the modified rows; this is similar to how they provide the information in triggers. In an INSERT statement, you are allowed to access only the inserted table. In a DELETE statement, you are allowed to access only the deleted table. In an UPDATE statement, you are allowed to access both the inserted and deleted tables.

Following is the general syntax of the OUTPUT clause:

```
UPDATE [ TOP ( expression ) [ PERCENT ] ] tablename
    SET { column_name = { expression | DEFAULT | NULL }
        | @variable = expression
        | @variable = column = expression [ ,...n ]
    } [ ,...n ]
    OUTPUT
{ DELETED | INSERTED | from_table_name }.{* | column_name} | scalar_expression
    [ INTO { @table_variable | output_table } [ ( column_list ) ] ] }
[ FROM { table_name } [ ,...n ] ]
[ WHERE search_conditions ]

DELETE [ TOP ( expression ) [ PERCENT ] ] tablename
    OUTPUT { DELETED | from_table_name }.{* | column_name} | scalar_expression
        [ INTO { @table_variable | output_table } [ ( column_list ) ] ] }
[ FROM ] table_name
[ FROM table_name [ ,...n ] ]
[ WHERE search_conditions ]

INSERT [ TOP ( expression ) [ PERCENT ] ] [ INTO ] tablename
{
    [ ( column_list ) ]
    [ OUTPUT { INSERTED | from_table_name }.{* | column_name} | scalar_expression
        [ INTO { @table_variable | output_table } [ ( column_list ) ] ] ] }
{ VALUES ( { DEFAULT | NULL | expression } [ ,...n ] )
    | SELECT_statement
}
}
```

The output table (*output_table*) may be a table variable, permanent table, or temporary table. If *column_list* is not specified, the output table must have the same number of columns as the *OUTPUT* result set. If *column_list* is specified, any omitted columns must either allow *NULL* values or have default values assigned to them. Any identity or computed columns in the output table must be skipped. In addition, *output_table* cannot have any enabled triggers defined on it, participate on either side of a foreign key constraint, or have any check constraints or enabled rules.

One use of the OUTPUT clause is to verify the rows being deleted, updated, or inserted:

```
begin tran
delete from sales_big output deleted.*
where sales_id in (select top 10 sales_id from sales_big order by ord_date)
rollback
go
```

sales_id	stor_id	ord_num	ord_date	qty	payterms	title_id

21	7067	P2121	2005-06-15 00:00:00.000	20	Net 30	TC4203
22	7067	P2121	2005-06-15 00:00:00.000	20	Net 30	TC7777
337470	7067	P2121	2005-06-15 00:00:00.000	40	Net 30	TC3218
337471	7067	P2121	2005-06-15 00:00:00.000	20	Net 30	TC4203
337472	7067	P2121	2005-06-15 00:00:00.000	20	Net 30	TC7777
506195	7067	P2121	2005-06-15 00:00:00.000	40	Net 30	TC3218

Another possible use of the OUTPUT clause is as a purge/archive solution. Suppose you want to periodically purge historic data from the `sales_big` table but also want to copy the purged data into an archive table called `sales_big_archive`. Rather than writing a process that has to select the rows to be archived before deleting them, or putting a delete trigger on the table, you could use the OUTPUT clause to insert the deleted rows into the archive table.

One approach would be to implement a loop to delete historic data (for example, delete rows for the oldest month in the `sales_big` table) in chunks, using the TOP clause to specify the chunk size. The OUTPUT clause can be specified to copy the deleted rows into the `sales_big_archive` table, as shown in Listing 43.32.

LISTING 43.32 Implementing a Purge/Archive Scenario, Using the **OUTPUT** Clause

```
declare @purge_date datetime,
        @rowcount int
-- find the oldest month in the sales_big table
select @purge_date = dateadd(day, - (datepart(day, min(ord_date))) + 1,
                             dateadd(month, 1, min(ord_date))),
        @rowcount = 1000
from sales_big
while @rowcount = 1000
begin
    delete top (1000) sales_big
        output deleted.* into sales_big_archive
        where ord_date < @purge_date
    set @rowcount = @@rowcount
end
```

In addition to referencing columns in the table being modified by using the `INSERTED` or `DELETED` qualifier, you can also retrieve information from another table included in the `FROM` clause of a `DELETE` or an `UPDATE` statement used to specify the rows to update or delete:

```
begin tran
delete top (5) sales
  output t.title_id
  from sales s
  join titles t on t.title_id = s.title_id
  where t.pub_id = '9906'
rollback
go
```

```
title_id
-----
FI9620
CH2080
BI7178
CH8924
FI2680
```

When used with an `UPDATE` command, `OUTPUT` produces both a deleted and an inserted table. The deleted table contains the values before the `UPDATE` command, and the inserted table has the values after the `UPDATE` command. The `OUTPUT` clause is also useful for retrieving the value of identity or computed columns after an `INSERT` or an `UPDATE` operation. Listing 43.33 shows an example of `OUTPUT` being used to capture the computed column as the result of an `UPDATE`.

LISTING 43.33 Using **OUTPUT** to Capture a Computed Column

```
create table UpdateOutputTest
(col1 tinyint,
 col2 tinyint,
 computed_col3 as convert(float, col2/convert(float, col1)))
go

insert UpdateOutputTest (col1, col2)
  output inserted.computed_col3
  values (10, 20)
insert UpdateOutputTest (col1, col2)
  output inserted.computed_col3
  values (10, 25)
go

computed_col3
```

```

-----
2
computed_col3
-----
2.5

declare @output_table TABLE (del_col1 int, ins_col1 int,
                              del_col2 int, ins_col2 int,
                              del_computed_col3 float, ins_computed_col3 float,
                              mod_date datetime)
update UpdateOutputTest
  set col2 = col2/5.0
  output deleted.col1, inserted.col1,
         deleted.col2, inserted.col2,
         deleted.computed_col3, inserted.computed_col3,
         getdate()
  into @output_table
  output deleted.computed_col3,
         inserted.computed_col3,
         getdate() as mod_date
select del_col1, ins_col1, del_col2, ins_col2,
       del_computed_col3 as del_col3, ins_computed_col3 as ins_col3,
       mod_date from @output_table
go

computed_col3 computed_col3 mod_date
-----

10      10      25      5      2.5    0.5      2010-02-28 19:48:34.240

```

The UPDATE statement in Listing 43.33 also demonstrates the capability to use OUTPUT to both insert values into a table and return values to the caller.

Note that the OUTPUT clause is not supported in DML statements that reference local partitioned views, distributed partitioned views, remote tables, or INSERT statements that contain an *execute_statement*. Columns returned from OUTPUT reflect the data as it is after the INSERT, UPDATE, or DELETE statement has completed but before any triggers on the target table are executed.

Common Table Expressions

A common table expression (CTE) is an ANSI SQL-99 expression that produces a table that is referred to by name within the context of a single query. The general syntax for a CTE is as follows:

```
WITH expression_name [ ( column_name [ ,...n ] ) ]
    AS ( CTE_query_definition )
```

The WITH clause, in effect, defines a table and its columns. Note that the syntax of the WITH clause is similar to that of a view. You can think of a CTE as a temporary view that lasts only for the life of the query that defines the CTE. Listing 43.34 shows an example of a simple CTE. This CTE is used to return the average and maximum sales quantities for each store. The CTE is then joined to the sales table to return the average and maximum sales quantity for the store, along with sales records for a specific title_id.

LISTING 43.34 An Example of a Simple CTE

```
with sales_avg (stor_id, avg_qty, max_qty)
    as (select stor_id, avg(qty), max(qty)
        from sales
        group by stor_id)
select top 5 s.stor_id, s.ord_num,
    convert(varchar(10), ord_date, 101) as ord_date,
    qty, title_id, avg_qty, max_qty
    from sales s
    join sales_avg a on s.stor_id = a.stor_id
    where s.title_id = 'DR8514'
go
```

stor_id	ord_num	ord_date	qty	title_id	avg_qty	max_qty
A004	ONGGGGGGGGGGGGGGGGGGG	09/13/2006	1224	DR8514	1008	1716
A068	ONEEEEEEEEEEE	09/02/2007	1572	DR8514	961	1572
A071	ONWWWWWWWWWWWWWWWWWWW	08/20/2006	1728	DR8514	948	1728
A161	ONDDDDDDDDDDDD	05/25/2006	624	DR8514	829	1668
A203	ONGGGGGGGGGGGGGGGGGGG	11/16/2006	1572	DR8514	1056	1692

NOTE

If the WITH clause for a CTE is not the first statement in the batch, you should delimit it from the preceding statement by placing a semicolon (;) in front of it. The semicolon is used to avoid ambiguity with other uses of the WITH clause (for example, for table hints). Including a semicolon is not necessary in all cases, but it is recommended that you use it consistently to avoid problems.

It is also possible to define multiple CTEs in a single query, with each CTE delimited by a comma. Each CTE is able to refer to previously defined CTEs. Listing 43.35 shows an example of a nested CTE that calculates the minimum, maximum, and difference of counts of store orders.

LISTING 43.35 An Example of Multiple CTEs in a Single Query

```
WITH store_orders(stor_id, cnt)
AS ( SELECT stor_id, COUNT(*) FROM sales
      GROUP BY stor_id ),
MinMaxCTE(MN, MX, Diff)
AS ( SELECT MIN(Cnt), MAX(Cnt), MAX(Cnt)-MIN(Cnt)
      FROM store_orders )
SELECT * FROM MinMaxCTE
go
```

MN	MX	Diff
1	22	21

A CTE must be followed by a single SELECT, INSERT, UPDATE, or DELETE statement that references some or all of the CTE columns. A CTE can also be specified in a CREATE VIEW statement as part of the defining SELECT statement of the view.

Listing 43.36 shows an example of a CTE used in a DELETE statement.

LISTING 43.36 An Example of a CTE in a **DELETE**

```
with oldest_sales (stor_id, ord_num, ord_date)
as (select top 100 stor_id, ord_num, ord_date from sales_big order by ord_date)
delete sales_big from sales_big s, oldest_sales o
where s.stor_id = o.stor_id
and s.ord_num = o.ord_num
and s.ord_date = o.ord_date
go
```

Most valid SELECT statement constructs are allowed in a CTE, except the following:

- ▶ COMPUTE or COMPUTE BY
- ▶ ORDER BY (except when a TOP clause is specified)
- ▶ INTO
- ▶ OPTION clause with query hints

- ▶ FOR XML
- ▶ FOR BROWSE

Recursive Queries with CTEs

Nonrecursive CTEs are ANSI SQL-99 compliant expressions that provide T-SQL coding flexibility. However, for each nonrecursive CTE, there is usually another T-SQL construct that can be used to achieve the same results (for example, derived tables). The real power and capability of CTEs is revealed when you use them to create recursive queries.

A recursive CTE can help simplify the code required to run a recursive query within a SELECT, INSERT, UPDATE, DELETE, or CREATE VIEW statement. Recursive queries are often useful for expanding a hierarchy stored in a relational table (for example, displaying employees in an organizational chart). In previous versions of SQL Server, a recursive query usually required using temporary tables, cursors, and logic to control the flow of the recursive steps.

A CTE is considered recursive when it refers to itself within the CTE definition. Recursive CTEs are constructed from at least two queries. One is a nonrecursive query, also referred to as the anchor member (AM). The other is the recursive query, also referred to as the recursive member (RM). The queries are combined using the UNION ALL operator.

The following pseudocode defines the basic structure of a recursive CTE:

```
WITH cte_name ( column_name [,...n] )
AS
( CTE_query_definition1 -- Anchor member (AM) is defined.
UNION ALL
CTE_query_definition2 -- Recursive member (RM) is referencing cte_name.
)
-- Statement using the CTE
SELECT col_list FROM cte_name
...
```

Logically, you can think of the algorithm implementing the recursive CTE as follows:

1. The anchor member is activated, and the initial result set (R) is generated.
2. The recursive member is activated, using the initial result set (R_{*n*}) as input and generating result set R_{*n*+1}.
3. The logic of step 2 is run repeatedly, incrementing the step number (*n*) until an empty set is returned.
4. The outer query is executed, getting the cumulative (UNION ALL) result of all the previous steps when referring to the recursive CTE.

You can have more than two members in a recursive CTE, but only the UNION ALL operator is allowed between a recursive member and another recursive or nonrecursive member. Other operators, such as UNION, are allowed only between nonrecursive members.

Recursive CTEs also require an exact match of the columns in all members, including the same data type, length, and precision.

Listing 43.37 shows a simple recursive CTE that generates a list of sequential numbers. Note that the AM generates the base result, and the RM following the `UNION ALL` controls the recursion. It is important in this example that a valid endpoint be defined to avoid infinite recursion.

LISTING 43.37 An Example of a Simple Recursive CTE

```
with numlist (val)
  as (select 1
      union all
      select val + 1
      from numlist
      where val < 10)
select * from numlist
go

val
-----
1
2
3
4
5
6
7
8
9
10
```

The following sections present some examples and uses of recursive CTEs.

Using Recursive CTEs for Expanding a Hierarchy

For this hierarchy example, we use the `parts` table in the `bigpubs2008` database. This table contains a simplified hierarchy of car parts, as shown in Figure 43.1.

In the `parts` table, any part that is a subpart of another part has the parent part ID stored in the `parentpartid` column. The `parentpartid` column is a foreign key that references the `partid` column. Therefore, the `parentpartid` must either correspond to a valid `partid` within the table or be `NULL`. For example, the car itself has `NULL` in the `parentpartid` column.

Following are some common requests that might be run on the `parts` table:

- ▶ Return all the parts for the engine.

- ▶ Show me all parts that are two levels below the drivetrain.
- ▶ Show me all the parts in such a way that it is easy to see their hierarchical dependencies.

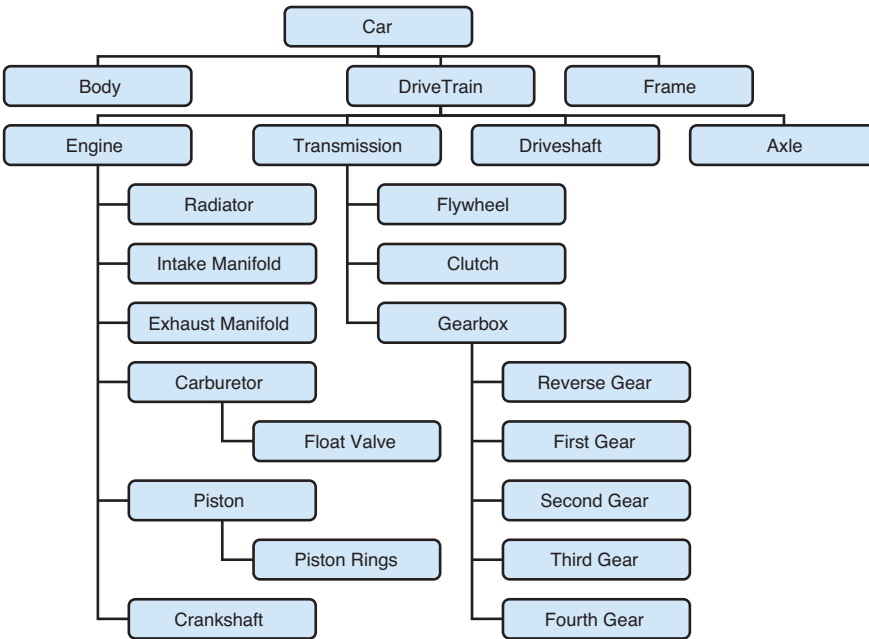

FIGURE 43.1 The **parts** table hierarchy.

The first request is probably the most common one: returning a part (for example, the engine, which has `partid = 2`) and all subparts. The recursive CTE shown in Listing 43.38 provides a solution to this request.

LISTING 43.38 A Recursive CTE to Return a Part and All Subparts

```

WITH PartsCTE(partid, partname, parentpartid, lvl)
AS
(
    SELECT partid, partname, parentpartid, 0
    FROM PARTS
    WHERE partid = 2 -- Engine
    UNION ALL

    SELECT P.partid, P.partname, P.parentpartid, PP.lvl+1
    FROM Parts as P
    JOIN PartsCTE as PP
    ON P.parentpartid = PP.Partid
)

```

```
SELECT PartID, Partname, ParentPartid, lvl
FROM PartsCTE
go
```

PartID	Partname	ParentPartid	lvl
2	Engine	1	0
5	Radiator	2	1
6	Intake Manifold	2	1
7	Exhaust Manifold	2	1
8	Carburetor	2	1
13	Piston	2	1
14	Crankshaft	2	1
21	Piston Rings	13	2
11	Float Valve	8	2

Notice that the lvl value is repeatedly incremented with each recursive invocation of the CTE. You can use this level counter to limit the number of iterations in the recursion. For example, Listing 43.39 shows an example of a CTE that returns all parts two levels below the drivetrain.

LISTING 43.39 A Recursive CTE to Return All Subparts Two Levels Below a Part

```
WITH PartsCTE(partid, partname, parentpartid, lvl)
AS
(
  SELECT partid, partname, parentpartid, 0
  FROM PARTS
  WHERE partid = 1 -- Drivetrain
  UNION ALL

  SELECT P.partid, P.partname, P.parentpartid, PP.lvl+1
  FROM Parts as P
  JOIN PartsCTE as PP
  ON P.parentpartid = PP.Partid
  where lvl < 2
)
SELECT PartID, Partname, ParentPartid, lvl
FROM PartsCTE
where lvl = 2
go
```

PartID	Partname	ParentPartid	lvl
9	Flywheel	3	2

10	Clutch	3	2
16	Gear Box	3	2
5	Radiator	2	2
6	Intake Manifold	2	2
7	Exhaust Manifold	2	2
8	Carburetor	2	2
13	Piston	2	2
14	Crankshaft	2	2

In Listing 43.39, the filter `WHERE lv1 < 2` in the recursive member is used as a recursion termination check; recursion stops when `lv1 = 2`. The filter on the outer query (`WHERE lv1 = 2`) is used to remove all parts up to the second level. Logically, the filter in the outer query (`lv1 = 2`) is sufficient by itself to return only the desired rows, but for performance reasons, you should include the filter in the recursive member to stop the recursion as soon as two levels below the drivetrain are returned.

SQL Server allows the use of local variables in a CTE to help make the query more generic. For example, you can use variables instead of constants for the part ID and level, as shown in Listing 43.40.

LISTING 43.40 Using Local Variables in a Recursive CTE

```

DECLARE @partid AS INT, @lv1 AS INT;
SET @partid = 22; -- Car
SET @lv1 = 2; -- two levels
WITH PartsCTE(partid, partname, parentpartid, lv1)
AS
(
    SELECT partid, partname, parentpartid, 0
    FROM PARTS
    WHERE partid = @partid
    UNION ALL

    SELECT P.partid, P.partname, P.parentpartid, PP.lv1+1
    FROM Parts as P
    JOIN PartsCTE as PP
    ON P.parentpartid = PP.Partid
    WHERE lv1 < @lv1
)
SELECT PartID, Partname, ParentPartid, lv1
FROM PartsCTE
Go

```

PartID	Partname	ParentPartid	lv1
22	Car	NULL	0

1	DriveTrain	22	1
23	Body	22	1
24	Frame	22	1
2	Engine	1	2
3	Transmission	1	2
4	Axle	1	2
12	Drive Shaft	1	2

You can also use recursive CTEs to perform aggregations, such as counting the total number of subparts that make up each parent part, as shown in Listing 43.41.

LISTING 43.41 Performing Aggregation with a Recursive CTE

```
WITH PartsCTE(parentpartid, lvl)
AS
(
  SELECT parentpartid, 0
  FROM PARTS
  WHERE parentpartid is not null
  UNION ALL
  SELECT P.parentpartid, lvl+1
  FROM Parts as P
  JOIN PartsCTE as PP
  ON PP.parentpartid = P.Partid
  WHERE P.parentpartid is not null
)
SELECT C.parentpartid, P.PartName, COUNT(*) AS cnt
FROM PartsCTE C
JOIN PARTS P on C.ParentPartID = P.PartID
GROUP BY C.parentpartid, P.PArtname
go
```

parentpartid	PartName	cnt

1	DriveTrain	20
2	Engine	8
3	Transmission	8
8	Carburetor	1
13	Piston	1
16	Gear Box	5
22	Car	23

In the example in Listing 43.41, the anchor member returns a row with the `parentpartid` for each part, being sure to filter out the `NULL` value in the `parentpartid` column because it is essentially the top of the hierarchy and represents no parent part. The recursive

member returns the parentpartid of each parent of the previously returned parts, again excluding any NULL values. Eventually, the CTE contains, for each part, as many occurrences as their direct or indirect number of subparts. The outer query is then left with the tasks of grouping the results by parentpartid and returning the count of occurrences. A join to Parts is included to get the corresponding partname for each parent part to provide more meaningful results.

Suppose you want to generate a report that is a bit more readable, with the subparts sorted and indented according to hierarchical dependencies. Listing 43.42 provides a way you could accomplish this.

LISTING 43.42 Generating a Formatted Report with a Recursive CTE

```

WITH PartsCTE(partid, partname, parentpartid, lvl, sortcol)
AS
(
    SELECT partid, partname, parentpartid, 0, cast(partid as varbinary(max))
    FROM Parts
    WHERE partid = 22
    UNION ALL
    SELECT P.partid, P.partname, P.parentpartid, PP.lvl+1,
           CAST(sortcol + CAST(P.partid AS BINARY(4)) AS VARBINARY(max))
    FROM Parts AS P
    JOIN PartsCTE AS PP
    ON P.parentpartID = PP.PartID
)
SELECT
    REPLICATE('-', lvl)
    + right('>', lvl)
    + partname AS partname
FROM PARTsCTE
order by sortcol
go

partname
-----
Car
-->DriveTrain
---->Engine
----->Radiator
----->Intake Manifold
----->Exhaust Manifold
----->Carburetor
----->Float Valve
----->Piston
----->Piston Rings

```

```

----->Crankshaft
---->Transmission
----->Flywheel
----->Clutch
----->Gear Box
----->Reverse Gear
----->First Gear
----->Second Gear
----->Third Gear
----->Fourth Gear
---->Axle
---->Drive Shaft
-->Body
-->Frame

```

In this example, you use a varbinary string as the `sortcol` to sort subparts according to the `partid` value. The anchor member is the starting point, generating a binary value for the `partid` of the root part. In each iteration, the recursive member appends the current part ID, converted to a binary value, to the parent part ID's `sortcol`. The outer query then sorts the result by `sortcol`, which groups the subparts under each immediate parent part.

Setting the MAXRECURSION Option

To help avoid infinite recursion in CTEs, SQL Server, by default, sets a `MAXRECURSION` value of `100`. If a recursive CTE attempts to perform more than 100 recursions, it is aborted, with the following error message:

```

Msg 530, Level 16, State 1, Line 1
The statement terminated. The maximum recursion 100 has been exhausted before
statement completion.

```

You can override the default `MAXRECURSION` setting by using the `OPTION(MAXRECURSION value)` query hint to force termination of the query after a specific number of recursive iterations have been invoked. Listing 43.43 shows an example.

LISTING 43.43 Controlling the Number of Recursions with **MAXRECURSION**

```

WITH PartsCTE(partid, partname, parentpartid, lvl)
AS
(
    SELECT partid, partname, parentpartid, 0
    FROM PARTS
    WHERE partid = 22 -- Car
    UNION ALL

    SELECT P.partid, P.partname, P.parentpartid, PP.lvl+1
    FROM Parts as P

```

```

JOIN PartsCTE as PP
  ON P.partid = PP.Partid
)
SELECT PartID, Partname, ParentPartid, lvl
FROM PartsCTE
OPTION (MAXRECURSION 10)
go

```

Msg 530, Level 16, State 1, Line 2

The statement terminated. The maximum recursion 10 has been exhausted before statement completion.

Keep in mind that if you use `MAXRECURSION` to control the number of levels of recursion in a CTE, your application receives the error message. It is not considered good programming practice to use code that returns errors in valid situations. Certain applications may discard query results if an error message is received. Instead, it is recommended that you use the level counter to limit recursion, as shown earlier in this chapter, in Listing 43.39. You should use the `MAXRECURSION` hint as a safeguard against infinite loops due to bad data or as a coding safeguard.

Ranking Functions

SQL Server 2005 introduced four new ranking functions: `ROW_NUMBER`, `RANK`, `DENSE_RANK`, and `NTILE`. These functions allow you to analyze data and provide ranking values to result rows of a query. For example, you might use these ranking functions for assigning sequential integer row IDs to result rows or for presentation, paging, or scoring purposes.

All four ranking functions follow a similar syntax pattern:

```

function_name() OVER(
  [PARTITION BY partition_by_list]
  ORDER BY order_by_list)

```

The `ROW_NUMBER` Function

The `ROW_NUMBER` function allows you to provide sequential integer values to the result rows of a query, based on the order of the rows in the result. The result set must be ordered using an `OVER` clause, with an `ORDER BY` clause as a variable.

The `ROW_NUMBER` function has been a feature long desired by SQL Server developers. For example, suppose you want to return the publishers and total number of titles per publisher and list the result rows, in descending order, with a numeric score assigned to each row. The query shown in Listing 43.44 generates the desired results by using the `ROW_NUMBER` function, specifying ordering over the `num_titles` column, in descending order.

LISTING 43.44 Using **ROW_NUMBER** to Rank Publishers by Number of Titles

```
select top 10 WITH TIES p.pub_id, pub_name, count(*) as num_titles,
ROW_NUMBER () OVER (order by count(*) DESC) as Rank
from publishers p join titles t on p.pub_id = t.pub_id
group by p.pub_id, p.pub_name
order by count(*) desc
go
```

pub_id	pub_name	num_titles	Rank
9911	Jones Jones and Johnson	44	1
9904	Strawberry Publications	34	2
9907	Incandescent Imprints	33	3
9905	Gooseberry Titles	32	4
9909	North American Press	30	5
9912	Landlocked Books	30	6
9913	Blackberry's	28	7
9914	Normanskill Printing Company	28	8
9910	Sidney's Books and More	28	9
9906	Tomato Books	28	10
9903	Kumquat Technical Publishing	28	11

In this example, the publishers with the highest number of titles got row number 1, and the publisher with the tenth-highest number of titles got row number 10. The **ROW_NUMBER** function always generates a distinct row number for each row, according to the requested sort.

If the **ORDER BY** list specified within the **OVER()** option is not on a unique key, the ordering of the row numbers is nondeterministic. For publishers that may have the same number of titles, each row would be assigned a different unique row number. The sequence of the row numbers assigned to those publishers could be different in different invocations of the query. In the results for Listing 43.44, for example, five different publishers have the same number of titles (28). Because SQL Server has to assign different row numbers to the different publishers, you should assume that the row numbers were assigned in arbitrary order among those publishers.

To ensure that the result is always deterministic, specify a unique **ORDER BY** list. For example, adding **pub_id** to the **ORDER BY** list ensures that in the case of a tie between publishers, the lowest **pub_id** is always assigned the lower row number, as shown in Listing 43.45.

LISTING 43.45 Using a Unique **ORDER BY** List for Deterministic **ROW_NUMBER** Results

```
select top 10 WITH TIES p.pub_id, pub_name, count(*) as num_titles,
ROW_NUMBER () OVER (order by count(*) DESC, p.pub_id) as Rank
```

```

from publishers p join titles t on p.pub_id = t.pub_id
group by p.pub_id, p.pub_name
order by count(*) desc
go

```

pub_id	pub_name	num_titles	Rank
9911	Jones Jones and Johnson	44	1
9904	Strawberry Publications	34	2
9907	Incandescent Imprints	33	3
9905	Gooseberry Titles	32	4
9909	North American Press	30	5
9912	Landlocked Books	30	6
9903	Kumquat Technical Publishing	28	7
9906	Tomato Books	28	8
9910	Sidney's Books and More	28	9
9913	Blackberry's	28	10
9914	Normanskill Printing Company	28	11

In the previous two examples, the sequence of row numbers is generated across the entire result set as one group. You can also have ranking values calculated independently within groups of rows as opposed to being calculated for all table rows as one group by using the **PARTITION BY** clause.

Partitioning by ROW_NUMBER ()

PARTITION BY allows you to specify a list of expressions that identify the groups of rows for which ranking values should be calculated independently. For example, the query in Listing 43.46 assigns row numbers within each type of book separately, in `num_titles` and `pub_id` order.

LISTING 43.46 Using **PARTITION BY** to Rank Rows Within Groups

```

select top 20 WITH TIES p.pub_id, pub_name, type, count(*) as num_titles,
ROW_NUMBER ( ) OVER (partition by type order by count(*) DESC, p.pub_id) as Rank
from publishers p join titles t on p.pub_id = t.pub_id
group by p.pub_id, p.pub_name, type
order by type, count(*) desc
go

```

pub_id	pub_name	type	num_titles	Rank
9906	Tomato Books	biography	4	1
9911	Jones Jones and Johnson	biography	4	2
9905	Gooseberry Titles	biography	2	3
9900	Boysenberry Books	biography	1	4

9903	Kumquat Technical Publishing	biography	1	5
9904	Strawberry Publications	biography	1	6
9909	North American Press	biography	1	7
9913	Blackberry's	biography	1	8
9914	Normanskill Printing Company	biography	1	9
9916	Nordome Titles	biography	1	10
9918	Significant Titles Company	biography	1	11
1389	Algodata Infosystems	business	3	1
0736	New Moon Books	business	1	2
9911	Jones Jones and Johnson	children	21	1
9914	Normanskill Printing Company	children	13	2
9905	Gooseberry Titles	children	12	3
9901	GGG&G	children	11	4
9903	Kumquat Technical Publishing	children	11	5
9915	Beanplant General	children	9	6
9900	Boysenberry Books	children	8	7
9913	Blackberry's	children	8	8

The RANK and DENSE_RANK Functions

The RANK and DENSE_RANK functions are similar to the ROW_NUMBER function in the sense that they also provide ranking values according to a specified sort. The difference is that rather than assign a unique ranking value to each row, RANK and DENSE_RANK assign the same ranking value to rows with the same values in the specified sort columns when the ORDER BY list is not unique.

The difference between RANK and DENSE_RANK is that with the DENSE_RANK function, there are no gaps in the ranking. The RANK function skips the next number if there is a tie in the ranking value. Listing 43.47 modifies the query shown in Listing 43.44 by replacing the ROW_NUMBER function with RANK and DENSE_RANK and provides a good example of the differences between the two.

LISTING 43.47 Using RANK and DENSE_RANK

```
select top 10 WITH TIES p.pub_id, pub_name, count(*) as num_titles,
RANK() OVER (order by count(*) DESC) as Rank,
DENSE_RANK() OVER (order by count(*) DESC) as Dense_Rank
from publishers p join titles t on p.pub_id = t.pub_id
group by p.pub_id, p.pub_name
order by count(*) desc
go
```

```
pub_id pub_name                num_titles Rank Dense_Rank
```

9911	Jones Jones and Johnson	44	1	1
9904	Strawberry Publications	34	2	2
9907	Incandescent Imprints	33	3	3
9905	Gooseberry Titles	32	4	4
9909	North American Press	30	5	5
9912	Landlocked Books	30	5	5
9913	Blackberry's	28	7	6
9914	Normanskill Printing Company	28	7	6
9910	Sidney's Books and More	28	7	6
9906	Tomato Books	28	7	6
9903	Kumquat Technical Publishing	28	7	6

Notice that in this result set, all publishers with the same number of titles get the same RANK and DENSE_RANK values.

NOTE

If the ORDER BY list for a ranking function is unique, ROW_NUMBER, RANK, and DENSE_RANK produce exactly the same values.

The NTILE Function

The NTILE function assigns a ranking value by separating the result rows of a query into a specified number of approximately even-sized groups. Each group of rows is assigned the same ranking number, starting with 1 for the first group, 2 for the second, and so on. You specify the number of groups you want the result set divided into as the argument to the NTILE function. The number of rows in a group is determined by dividing the total number of rows in the result set by the number of groups. If there's a remainder, *n*, the first *n* groups have an additional row assigned to them. Listing 43.48 provides an example of using the NTILE function, so you can compare it to the ROW_NUMBER function.

LISTING 43.48 Using the NTILE Function

```
select p.pub_id, pub_name, count(*) as num_titles,
NTILE(3) OVER (order by count(*) DESC) as NTILE,
ROW_NUMBER() OVER (order by count(*) DESC) as RowNum
from publishers p join titles t on p.pub_id = t.pub_id
group by p.pub_id, p.pub_name
order by count(*) desc
go
```

pub_id	pub_name	num_titles	NTILE	RowNum
9911	Jones Jones and Johnson	44	1	1
9904	Strawberry Publications	34	1	2

9907	Incandescent Imprints	33	1	3
9905	Gooseberry Titles	32	1	4
9909	North American Press	30	1	5
9912	Landlocked Books	30	2	6
9913	Blackberry's	28	2	7
9914	Normanskill Printing Company	28	2	8
9910	Sidney's Books and More	28	2	9
9906	Tomato Books	28	2	10
9903	Kumquat Technical Publishing	28	3	11
9902	Lemon Legal Publishing	27	3	12
9901	GGG&G	25	3	13
9908	Springfield Publishing	25	3	14
9900	Boysenberry Books	23	4	15
9916	Nordome Titles	22	4	16
9915	Beanplant General	21	4	17
9917	BFG Books	17	4	18
9918	Significant Titles Company	17	5	19
0877	Binnet & Hardley	6	5	20
1389	Algodata Infosystems	6	5	21
0736	New Moon Books	5	5	22

In this example, NTILE is used to divide the result set into five groups. Because there are 22 rows in the publishers table, there are 4 rows in each group, with 2 left over. The 2 extra rows are added to the first two groups.

The NTILE function provides a way to generate a histogram with an even distribution of items for each step. In the previous example, the first step represents the publishers with the highest number of titles, and the last step represents the publishers with the lowest number of titles. You can use this information in a CASE expression to provide descriptive meaningful alternatives to the ranking numbers, as shown in Listing 43.49.

LISTING 43.49 Using a **CASE** Expression to Provide Meaningful Labels to Ranking Values

```
select p.pub_id, pub_name, count(*) as num_titles,
       case NTILE(5) OVER (order by count(*) DESC)
         when 1 then 'Highest'
         when 2 then 'Above Average'
         when 3 then 'Average'
         when 4 then 'Below Average'
         when 5 then 'Lowest'
       end as Ranking
from publishers p join titles t on p.pub_id = t.pub_id
group by p.pub_id, p.pub_name
order by pub_id
go
```

pub_id	pub_name	num_titles	Ranking
0736	New Moon Books	5	Lowest
0877	Binnet & Hardley	6	Lowest
1389	Algodata Infosystems	6	Lowest
9900	Boysenberry Books	23	Below Average
9901	GGG&G	25	Average
9902	Lemon Legal Publishing	27	Average
9903	Kumquat Technical Publishing	28	Average
9904	Strawberry Publications	34	Highest
9905	Gooseberry Titles	32	Highest
9906	Tomato Books	28	Above Average
9907	Incandescent Imprints	33	Highest
9908	Springfield Publishing	25	Average
9909	North American Press	30	Highest
9910	Sidney's Books and More	28	Above Average
9911	Jones Jones and Johnson	44	Highest
9912	Landlocked Books	30	Above Average
9913	Blackberry's	28	Above Average
9914	Normanskill Printing Company	28	Above Average
9915	Beanplant General	21	Below Average
9916	Nordome Titles	22	Below Average
9917	BFG Books	17	Below Average
9918	Significant Titles Company	17	Lowest

Using Row Numbers for Paging Results

Typical uses for row numbers are for paging through the results of a query and for selecting a specific subset of rows from within the result set. Essentially, given a page size in terms of number of rows, and a page number, you can return the rows that belong to that given page.

For example, suppose you want to return the second page of rows from a query similar to the one shown in Listing 43.45. Assuming a page size of five rows, the query shown in Listing 43.50 uses a CTE to first calculate the row numbers according to the ranking by number of titles, and then only those rows with numbers 6 through 10, which belong to the second page, are returned.

LISTING 43.50 Using **ROW_NUMBER** to Page Through Results

```
with pub_titles as
(
select p.pub_id, pub_name, count(*) as num_titles,
ROW_NUMBER () OVER (order by count(*) DESC, p.pub_id) as Rank
from publishers p join titles t on p.pub_id = t.pub_id
```

```

group by p.pub_id, p.pub_name
)
select * from pub_titles
where Rank between 6 and 10
go

```

pub_id	pub_name	num_titles	Rank
9912	Landlocked Books	30	6
9903	Kumquat Technical Publishing	28	7
9906	Tomato Books	28	8
9910	Sidney's Books and More	28	9
9913	Blackberry's	28	10

You could make this query more generic by using local variables for the page number and page size and using them to calculate the proper set of rows to return, as shown in Listing 43.51.

LISTING 43.51 Using Local Variables for Determining Page Size When Paging Through Results

```

declare @pagesize tinyint,
        @pagenum tinyint;
set @pagesize = 6;
set @pagenum = 2;

with pub_titles as
(
select p.pub_id, pub_name, count(*) as num_titles,
ROW_NUMBER () OVER (order by count(*) DESC, p.pub_id) as Rank
from publishers p join titles t on p.pub_id = t.pub_id
group by p.pub_id, p.pub_name
)
select * from pub_titles
where Rank between ((@pagenum - 1) * @pagesize) + 1
                and @pagenum * @pagesize
go

```

pub_id	pub_name	num_titles	Rank
9903	Kumquat Technical Publishing	28	7
9906	Tomato Books	28	8
9910	Sidney's Books and More	28	9
9913	Blackberry's	28	10
9914	Normanskill Printing Company	28	11
9902	Lemon Legal Publishing	27	12

The example in Listing 43.51 is adequate for ad hoc requests when you're interested in retrieving only one specific page of the result set. However, this approach is not adequate for most applications that would issue multiple requests for individual pages of data because each invocation of the query would require a complete scan of the table to calculate the row numbers. A more efficient method for when the user might repeatedly request different pages would be to first populate a temporary table with all the base table rows, including the calculated row numbers, and then create a clustered index on the column in the temp table that contains the row numbers. An example is presented in Listing 43.52.

LISTING 43.52 Using a Temp Table for Paging Through Results

```
select p.pub_id, pub_name, count(*) as num_titles,
       ROW_NUMBER () OVER (order by count(*) DESC, p.pub_id) as Rank
into #paging_table
from publishers p join titles t on p.pub_id = t.pub_id
group by p.pub_id, p.pub_name
go
create unique clustered index idx1 on #paging_table(Rank)
go
declare @pagesize tinyint,
        @pagenum tinyint;
set @pagesize = 6;
set @pagenum = 2;
SELECT *
FROM #paging_table
WHERE Rank BETWEEN (@pagenum-1)*@pagesize+1 AND @pagenum*@pagesize
ORDER BY Rank
set @pagesize = 6;
set @pagenum = 4;
SELECT *
FROM #paging_table
WHERE Rank BETWEEN (@pagenum-1)*@pagesize+1 AND @pagenum*@pagesize
ORDER BY Rank
go
```

pub_id	pub_name	num_titles	Rank
9903	Kumquat Technical Publishing	28	7
9906	Tomato Books	28	8
9910	Sidney's Books and More	28	9
9913	Blackberry's	28	10
9914	Normanskill Printing Company	28	11
9902	Lemon Legal Publishing	27	12

pub_id	pub_name	num_titles	Rank
--------	----------	------------	------

9918	Significant Titles Company	17	19
0877	Binnet & Hardley	6	20
1389	Algodata Infosystems	6	21
0736	New Moon Books	5	22

If you are limiting the result set to a specific number of rows and are using a fixed page size, an alternative to using `ROW_NUMBER` would be to use the `NTILE` function to calculate the actual page numbers. For example, if you are using `TOP` to limit the result set to the first 500 rows and each page contains 10 rows, the total number of pages would be $500 / 10$, or 50 pages. If you use 50 as the argument to the `NTILE` function, the query generates 50 distinct ranking values with 10 rows each. An example of this solution is presented in Listing 43.53.

LISTING 43.53 Using **NTILE** to Generate Page Numbers

```
select TOP 500 t.title_id,
           left(title, 20) as title,
           sum(qty) as total_sales,
           NTILE(50) OVER(ORDER BY sum(qty) desc) AS pagenum
into #title_list
from titles t join sales s on t.title_id = s.title_id
group by t.title_id, title
go
create clustered index page_index on #title_list(pagenum)
go
select * from #title_list
where pagenum = 11
go
```

title_id	title	total_sales	pagenum
<hr/>

PIVOT and UNPIVOT

SQL Server 2005 added the PIVOT clause to T-SQL. A typical analytical use of the PIVOT command is to convert temporal data into categorized data to make the data easier to view and analyze.

The first, and simplest, option for returning the temporal data is to query the data, grouping the fact information in such a way that it answers the questions being asked. For example, Listing 43.54 retrieves data from the titles tables and provides the total number of business books sold, by year. Note that it's difficult to see trends of the number of titles sold between years. It is also even more difficult to answer questions about how sales of one title compared to sales of other titles in the same year.

LISTING 43.54 A Standard Query to Return Total Sales of Titles, by Year

```
select t.title_id,
       datepart(year, ord_date) as year,
       sum(qty) as total_sales
from sales s join titles t on s.title_id = t.title_id
where t.type = 'business'
group by t.title_id, datepart(year, ord_date)
go
```

title_id	year	total_sales
BU7832	2007	104616
BU1111	2007	88116
BU2075	2007	117888
BU1032	2006	95556
BU7832	2008	78240
BU1111	2006	104149
BU2075	2008	84588
BU7832	2006	102975
BU1032	2007	97131
BU2075	2006	108995
BU1032	2008	59772
BU1111	2008	72336

You could visualize and answer these questions more easily if you could pivot the YEAR column to create columns of TOTAL_SALES for each year. The resulting table is generally referred to as a *crossstab*. The PIVOT clause provides this capability.

The syntax of the PIVOT expression is as follows:

```
pivoted_table ::=
    table_source PIVOT ( aggregate_function ( value_column )
```

```

FOR pivot_column
IN ( column_list ) table_alias

```

To use the PIVOT feature, you first decide which column contains the important values for the query. In this example, the important piece of information is the `total_sales` amount. Next, you determine which field data becomes the columns you will pivot the data into. In this example, because you want to analyze sales over a period of time, you want to pivot the sales year field data into columns in the final result.

You start out by defining a CTE that returns the detail data on which you want to aggregate. This CTE might look like the following SQL code fragment:

```

with title_sales as
(select t.title_id,
      datepart(year, ord_date) as year,
      qty
from sales s join titles t on s.title_id = t.title_id
where t.type = 'business')

```

Drawing from the `title_sales` CTE, the value column is the `qty` column. Because you want to sum the `qty` values, you need to use the `SUM()` aggregate function in the PIVOT expression. The pivot column is `YEAR`. You need to define a list of `YEAR` columns that you want to see. For this example, the columns are `2006`, `2007`, and `2008`. You specify these values as column headings in the select list in the SQL expression and also as the column list in the PIVOT expression. Putting all the pieces together, you end up with the SQL statement shown in Listing 43.55.

LISTING 43.55 Using **PIVOT** to Return Total Sales by Year

```

with title_sales as
(select t.title_id,
      datepart(year, ord_date) as year,
      qty as total_sales
from sales s join titles t on s.title_id = t.title_id
where t.type = 'business')
select ts_pivot.title_id,
      isnull([2006], 0) as [2006],
      isnull([2007], 0) as [2007],
      isnull([2008], 0) as [2008]
from title_sales
pivot (sum(total_sales) for year in ([2006], [2007], [2008])
) as ts_pivot
go

```

```

title_id 2006      2007      2008
-----
BU1032   95556      97131      59772

```

BU1111	104149	88116	72336
BU2075	108995	117888	84588
BU7832	102975	104616	78240

Note that in this example, the `SUM` aggregate function is a required component of the `PIVOT` expression. If you think about it, the CTE could easily have been coded to perform the sum of the `qty` values, grouping them by year and simply have the `PIVOT` expression pivot using only the `total_sales`, without the need for the `SUM` function. Unfortunately, the `PIVOT` expression requires having an aggregate function included, so it must be coded this way.

Also note that the data specified in the `IN` column list for the `PIVOT` expression must explicitly include the names of all the values that will be pivoted into columns. Currently, the syntax does not allow for this column list to be dynamic.

The `UNPIVOT` expression is used to take data that is already in the form of a crosstab and rotate the data columns into data rows. You are likely to use `UNPIVOT` much less often than `PIVOT`.

For example, you can create a temporary table from the results of the `PIVOT` query in Listing 43.55:

```
with title_sales as
(select t.title_id,
       datepart(year, ord_date) as year,
       qty
 from sales s join titles t on s.title_id = t.title_id
 where t.type = 'business')
select ts_pivot.title_id,
       isnull([2006], 0) as [2006],
       isnull([2007], 0) as [2007],
       isnull([2008], 0) as [2008]
 into #title_sales_by_year
 from title_sales
 pivot (sum(qty) for year in ([2006], [2007], [2008])
 ) as ts_pivot
 go
select title_id, [2006], [2007], [2008]
       from #title_sales_by_year
 go
```

title_id	2006	2007	2008
BU1032	95556	97131	59772
BU1111	104149	88116	72336

BU2075	108995	117888	84588
BU7832	102975	104616	78240

To unpivot the #title_sales_by_year table, you start with the common table expression that returns the rows and columns you want to unpivot:

```
with title_sales as
(select title_id, [2006], [2007], [2008]
 from #title_sales_by_year)
```

Drawing from the title_sales CTE, the year columns become a single column called year, and you rotate the current total_sales columns into a single column. This time around, the year column is the unpivot column. For this example, the columns you want to unpivot are 2006, 2007, and 2008. You specify these values as the column list in the UNPIVOT expression and rename it as a single column called total_sales. Putting all the pieces together, you end up with the SQL statement shown in Listing 43.56.

LISTING 43.56 Using **UNPIVOT** to Rotate Pivoted Data

```
with title_sales as
(select title_id, [2006], [2007], [2008]
 from #title_sales_by_year)
select title_id,
       cast(ts_unpivot.year as smallint) as year,
       ts_unpivot.total_sales
 from title_sales
      UNPIVOT (total_sales for year in ([2006], [2007], [2008])
              ) as ts_unpivot
go
title_id year    total_sales
-----
BU1032  2006  95556
BU1032  2007  97131
BU1032  2008  59772
BU1111  2006  104149
BU1111  2007  88116
BU1111  2008  72336
BU2075  2006  108995
BU2075  2007  117888
BU2075  2008  84588
BU7832  2006  102975
BU7832  2007  104616
BU7832  2008  78240
```

NOTE

UNPIVOT is not the exact reverse of PIVOT. PIVOT performs an aggregation and, therefore, merges possible multiple rows into a single row in the output. UNPIVOT does not reproduce the original detail rows from the summary values.

The APPLY Operator

The APPLY relational operator allows you to invoke a table-valued function once per each row of an outer table expression. You specify APPLY in the FROM clause of a query, similarly to the way you use the JOIN operator. APPLY can take two forms: CROSS APPLY and OUTER APPLY.

CROSS APPLY

CROSS APPLY invokes a table-valued function for each row in an outer table expression, returning a unified result set out of all the results returned by the individual invocations of the table-valued function. The columns in the outer table are used as arguments to the table-valued function. If the table-valued function returns an empty set for a given outer row, that outer row is not returned in the result.

For example, the table-valued function in Listing 43.57 accepts stor_id and an integer as arguments and returns a list of the top N largest orders for that store. The number of rows returned is determined by the value passed to the second parameter. If you call this function with stor_id and a number of rows, it returns that many rows, ordered by the qty of the order, in descending order.

LISTING 43.57 A Table-Valued Function That Returns the Top N Orders for **stor_id**

```
CREATE FUNCTION dbo.fn_GetTopOrders(@stor_id AS char(4), @n AS INT)
    RETURNS TABLE
AS
RETURN
    SELECT TOP(@n) *
    FROM dbo.sales
    WHERE stor_id = @stor_id
    ORDER BY qty DESC
GO
```

Following is a sample invocation of the function in Listing 43.57:

```
select * from dbo.fn_GetTopOrders ('B251', 3)
go
```

```
stor_id ord_num          ord_date          qty  payterms  title_id
-----
```

```

B251    ONQQQQQQQQQQQQQQQ  2008-01-23 00:00:00.000 1740 Net 60      CH6808
B251    ONKKKKKKKKKKKKKKKK  2007-11-04 00:00:00.000 1704 Net 60      FI9420
B251    ONTTTTTTTTTTTTTTTT  2008-02-22 00:00:00.000 1560 Net 60      FI8000

```

If you want to generate a result set that shows each store name and the top three largest orders for each store, you can use the `CROSS APPLY` function to join to the `dbo.fn_GetTopOrders` function for each `stor_id` in the outer query, as shown in Listing 43.58.

LISTING 43.58 Using **CROSS APPLY**

```

select st.stor_id, stor_name, s.ord_date, s.qty
from stores st
cross apply
dbo.fn_GetTopOrders (st.stor_id, 3) as s
where st.state = 'MI'
and st.stor_name in ('Barnes & Noble', 'B Dalton BookSeller', 'Waldenbooks')
order by stor_id, s.qty DESC
go

```

stor_id	stor_name	ord_date	qty
B251	B Dalton Bookseller	2008-01-23 00:00:00.000	1740
B251	B Dalton Bookseller	2007-11-04 00:00:00.000	1704
B251	B Dalton Bookseller	2008-02-22 00:00:00.000	1560
B510	Barnes & Noble	2008-08-13 00:00:00.000	1464
B510	Barnes & Noble	2007-10-08 00:00:00.000	1200
B510	Barnes & Noble	2006-01-08 00:00:00.000	924
P963	Waldenbooks	2008-07-07 00:00:00.000	1668
P963	Waldenbooks	2006-12-30 00:00:00.000	1068
P963	Waldenbooks	2006-03-29 00:00:00.000	1032
Q017	Waldenbooks	2007-11-02 00:00:00.000	1776
Q017	Waldenbooks	2006-06-15 00:00:00.000	1704
Q017	Waldenbooks	2007-02-24 00:00:00.000	1548

`CROSS APPLY` returns only rows from the outer table that produce a result set from the table-valued function. If a store has no orders, it does not appear in the result set. To include all rows from the outer table, use `OUTER APPLY`.

OUTER APPLY

`OUTER APPLY` returns from the outer table both rows that produce a result set and rows that do not. Rows that do not produce a result set from the table-valued function return `NULL` values in the columns produced by the table-valued function.

The following example is similar to the query in Listing 43.58 but replaces `CROSS APPLY` with the `OUTER APPLY` clause:

```
select st.stor_id, stor_name, s.ord_date, s.qty
from stores st
outer apply
dbo.fn_GetTopOrders (st.stor_id, 3) as s
where st.state = 'MI'
and st.stor_name in ('Barnes & Noble', 'B Dalton BookSeller', 'Waldenbooks')
order by stor_id, s.qty DESC
go
```

stor_id	stor_name	ord_date	qty
B251	B Dalton Bookseller	2008-01-23 00:00:00.000	1740
B251	B Dalton Bookseller	2007-11-04 00:00:00.000	1704
B251	B Dalton Bookseller	2008-02-22 00:00:00.000	1560
B510	Barnes & Noble	2008-08-13 00:00:00.000	1464
B510	Barnes & Noble	2007-10-08 00:00:00.000	1200
B510	Barnes & Noble	2006-01-08 00:00:00.000	924
B511	Barnes & Noble	NULL	NULL
P963	Waldenbooks	2008-07-07 00:00:00.000	1668
P963	Waldenbooks	2006-12-30 00:00:00.000	1068
P963	Waldenbooks	2006-03-29 00:00:00.000	1032
Q017	Waldenbooks	2007-11-02 00:00:00.000	1776
Q017	Waldenbooks	2006-06-15 00:00:00.000	1704
Q017	Waldenbooks	2007-02-24 00:00:00.000	1548

TRY . . . CATCH Logic for Error Handling

SQL Server 2005 also introduced the `TRY . . . CATCH` construct, which you can use within T-SQL code to provide a more graceful mechanism for exception handling than was available in previous versions of SQL Server. In versions prior to 2005, error handling was typically done by checking `@@ERROR` after each SQL statement and often using the `GOTO` statement to branch to an error-handling routine.

A `TRY . . . CATCH` construct consists of two parts: a `TRY` block and `CATCH` block. When an error condition is detected in a T-SQL statement that is inside a `TRY` block, control is immediately passed to the `CATCH` block, where the error is processed. T-SQL statements in the `TRY` block that follow the statement that generated the error are not executed.

If an error occurs and processing is passed to the `CATCH` block, after the statements in the `CATCH` block are executed, control is transferred to the first T-SQL statement that follows the `END CATCH` statement. If there are no errors inside the `TRY` block, control is passed to the statement immediately after the associated `END CATCH` statement, essentially skipping over the statements in the `CATCH` block.

A TRY block is initiated with the `BEGIN TRY` statement and ended with the `END TRY` statement and can consist of one or more Transact-SQL statements between the `BEGIN TRY` and `END TRY` statements. The TRY block must be followed immediately by a `CATCH` block. A `CATCH` block is indicated with the `BEGIN CATCH` statement and ended with the `END CATCH` statement and can consist of one or more SQL statements. In SQL Server, each TRY block can be associated with only one `CATCH` block.

The syntax of the `TRY...CATCH` construct is as follows:

```
BEGIN TRY
    one_or_more_sql_statements
END TRY
BEGIN CATCH
    one_or_more_sql_statements
END CATCH
```

In a `CATCH` block, you can use the following error functions to capture information about the error that invoked the `CATCH` block:

- ▶ **ERROR_NUMBER()**—Returns the error number
- ▶ **ERROR_MESSAGE()**—Returns the complete text of the error message
- ▶ **ERROR_SEVERITY()**—Returns the error severity
- ▶ **ERROR_STATE()**—Returns the error state number
- ▶ **ERROR_LINE()**—Returns the line number inside the procedure that caused the error
- ▶ **ERROR_PROCEDURE()**—Returns the name of the stored procedure or trigger where the error occurred

Unlike `@@ERROR`, which is reset by each statement that is executed, the error information retrieved by the error functions remains constant anywhere within the scope of the `CATCH` block of a `TRY...CATCH` construct. Error functions can also be referenced from within a stored procedure invoked within a `CATCH` block. This allows you to modularize the error handling into a single stored procedure so you do not have to repeat the error-handling code in every `CATCH` block. Listing 43.59 shows an example of an error-handling procedure that you can use in your `CATCH` blocks.

LISTING 43.59 An Example of a Standard Error Handler Procedure

```
use bigpubs2008
go
create proc dbo.error_handler
as
begin
    Declare @errnum int,
           @severity int,
           @errstate int,
```

```

        @proc nvarchar(126),
        @line int,
        @message nvarchar(4000)
-- capture the error information that caused the CATCH block to be invoked
SELECT @errnum = ERROR_NUMBER(),
       @severity = ERROR_SEVERITY(),
       @errstate = ERROR_STATE(),
       @proc = ERROR_PROCEDURE(),
       @line = ERROR_LINE(),
       @message = ERROR_MESSAGE()
-- raise an error message with information on the error
RAISERROR ('Failed to add new publisher for the following reason:
Error: %d, Severity: %d, State: %d, in proc %s at line %d, Message: "%s"',
         16, 1, @errnum, @severity, @errstate, @proc, @line, @message)

Return
end

```

Listing 43.60 provides an example of the use of the TRY...CATCH construct in a T-SQL batch. Note that this CATCH block uses the `dbo.error_handler` procedure defined in Listing 43.59.

LISTING 43.60 Using a **TRY...CATCH** Construct for Error Handling in a T-SQL Batch

```

use bigpubs2008
go
BEGIN TRY
    INSERT INTO bigpubs2008.dbo.publishers
        (pub_id, pub_name, city, state, country)
        VALUES ('9950', 'Sams Publishing', 'Indianapolis', 'IN', 'USA')
-- if no error occurs, we should see this print statement
print 'New Publisher added'
END TRY
BEGIN CATCH
    -- invoke the error_handler procedure
    exec error_handler
    -- return a non-zero status code
END CATCH
-- if successful execution, return 0
go
Msg 50000, Level 16, State 1, Procedure error_handler, Line 18
Failed to add new publisher for the following reason:
Error: 2627, Severity: 14, State: 1, in proc (null) at line 2,
Message: "Violation of PRIMARY KEY constraint 'UPKCL_pubind'.
Cannot insert duplicate key in object 'dbo.publishers'."

```

If you want to capture and handle any errors that may occur within a CATCH block, you can incorporate another TRY...CATCH block within the CATCH block.

NOTE

Some errors with severity 20 or higher that would cause SQL Server to close the user connection cannot be handled by the TRY...CATCH construct. However, severity level 20 or higher errors that do not result in the connection being closed can be captured and handled by the CATCH block. Any errors with a severity level of 10 or less are considered only warnings or informational messages and not really errors, and thus they are not handled by the TRY...CATCH construct. Also, any compile errors (such as syntax errors) or object name resolution errors that happen during deferred name resolution also do not invoke a CATCH block. These errors are returned to the application or batch that called the error-generating routine.

The TABLESAMPLE Clause

The TABLESAMPLE clause lets you query a random sample of data from a table (either an exact number of rows or a percentage of rows). You can use TABLESAMPLE to quickly return a sample from a large table when the sample does not have to be a truly random sample at the level of individual rows. This clause is also useful when you want to test your code against a random subset of data that you copy from a production environment or when you just want to test the validity of your solutions against a subset of data as opposed to the entire data set.

To return a random sample of data using the TABLESAMPLE clause, you specify it in a query's FROM clause, right after the table name or table alias. The TABLESAMPLE clause has the following syntax:

```
TABLESAMPLE [SYSTEM] (sample_number [ PERCENT | ROWS ] )
[ REPEATABLE (repeat_seed) ]
```

Specifying the SYSTEM keyword is optional, but this option is currently the only sampling method available in SQL Server and is applied by default. SYSTEM specifies that an ANSI SQL implementation-dependent sampling method will be used. This means that individual database management system (DBMS) products can implement this method differently. In SQL Server, the same sampling method that it uses to sample data to create statistics is used to generate the results for TABLESAMPLE.

The result set returned by a query using TABLESAMPLE and a specified percentage is created by generating a random value for each physical page in the table. Based on the random value generated for a page, that page is either included in the sample or excluded. When a page is included in the sample, all rows on that page are returned in the result set. For

example, if you specify `TABLESAMPLE SYSTEM 10 PERCENT`, SQL Server returns all the rows from approximately 10% of the randomly selected data pages of the table.

When a specific number of rows rather than a percentage is specified, the requested number of rows is converted into a percentage of the total number of rows in the table and a percentage of the number of pages that should be returned. The `TABLESAMPLE` operation is then performed against the computed percentage of pages.

If the rows are evenly distributed on the pages of the table, the number of rows returned by a `TABLESAMPLE` query should be close to the requested sample size. However, if there is a mix of full and sparse pages in the table, the number of rows returned may vary widely for subsequent executions of the query. Consider the following query:

```
with sales_sample as
( select * from sales TABLESAMPLE (1 percent) )
select count(*) as numrows from sales_sample
go
```

```
numrows
-----
2055
```

There are 168,715 rows in the `sales` table in the `bigpubs2008` database. A 1% sample should return approximately 1,687 rows. However, as you can see from the preceding example, it returns 2,055 rows.

NOTE

Each time this query is run, it is likely to return a different set of rows, so your row counts may not match those presented in these examples.

If you invoke the query again, it could return a different number of rows:

```
with sales_sample as
( select * from sales TABLESAMPLE (1 percent) )
select count(*) as numrows from sales_sample
go
```

```
numrows
-----
1138
```

Note also that if you specify an actual number of rows, because the sampling is done at the page level, the pages sampled may have more or fewer rows than required to provide the requested sample size. For example, consider the following query, which requests a `TABLESAMPLE` of 1,000 rows:

```
with sales_sample as
( select * from sales TABLESAMPLE (1000 rows) )
select count(*) as numrows from sales_sample
go
```

```
numrows
-----
683
```

A subsequent execution of the same query could return a different number of rows:

```
with sales_sample as
( select * from sales TABLESAMPLE (1000 rows) )
select count(*) as numrows from sales_sample
go
```

```
numrows
-----
1371
```

If you run this query repeatedly, you are likely to get a different number of rows every time. However, the larger the table and the greater the number of rows you request, the more likely it is to get a closer percentage or number of requested rows returned. The smaller the table and the smaller the number or percentage of rows you request, the less likely the query is to return the number of rows close to the number or percentage you requested. With very small tables, you might not even get any rows.

To increase the likelihood of receiving the number of rows that you request, you should specify a greater number of rows than you actually need in the TABLESAMPLE clause and use the TOP option to specify the number of rows you actually want. For example, if you want a set of 1,000 random rows, you should request 2,000 rows in the TABLESAMPLE clause and then limit it to 1,000 rows with the TOP option, as in this example:

```
select top 1000 * from sales TABLESAMPLE (2000 rows)
```

When you do this, you may still get fewer than 1,000 rows returned, but the likelihood of that occurring is lower than if you request 1,000 rows in the TABLESAMPLE clause alone. Also, by specifying TOP(1000), you're guaranteed not to get *more* than 1,000 rows. When you use a combination of TABLESAMPLE and TOP, the data you obtain is a more representative sampling of the data in your table than if you use TOP alone.

If you want to generate the same random sample each time you use the TABLESAMPLE clause, you can specify the REPEATABLE option with a specified *repeat_seed* value. The REPEATABLE option causes a selected sample to be returned again. When REPEATABLE is specified with the same *repeat_seed* value, SQL Server returns the same subset of rows, as

long as no changes have been made to the table. For example, the following query uses *repeat_seed* of 1 and, in this case, returns 16,896 rows:

```
with sales_sample as
( select * from sales TABLESAMPLE (10 percent) repeatable (1) )
select count(*) as numrows from sales_sample
go
```

```
numrows
-----
16896
```

When REPEATABLE is specified with a different *repeat_seed* value, SQL Server typically returns a different sample of the rows in the table. For example, the following query uses *repeat_seed* of 2 and gets a different set and number of rows:

```
with sales_sample as
( select * from sales TABLESAMPLE (10 percent) repeatable (2) )
select count(*) as numrows from sales_sample
go
```

```
numrows
-----
19856
```

Running the query again with *repeat_seed* of 1 returns the same result rows as previously:

```
with sales_sample as
( select * from sales TABLESAMPLE (10 percent) repeatable (1) )
select count(*) as numrows from sales_sample
go
```

```
numrows
-----
16896
```

The types of actions that are considered changes and could affect the repeatability of the TABLESAMPLE results include inserts, updates, deletes, index rebuilding, index defragmenting, restoration of a database, and attachment of a database.

You can use other techniques to request random data samples, but most of those techniques require scanning the entire table, which can be time-consuming and I/O intensive for very large tables. Using TABLESAMPLE for a specific table limits the Query Optimizer to performing table scans only on that table, but physical I/Os are performed only on the actual sampled pages included in the result set. Because of this, using TABLESAMPLE is usually a faster way of generating a random sampling of your data.

Summary

Transact-SQL is a powerful data access and data modification language that provides a number of features and components to help you develop powerful and robust SQL Server–based applications. SQL Server 2005 further expanded the power and capabilities of T-SQL with the addition of a number of new features, and SQL Server 2008 provides even more (see Chapter 42 for details on the new T-SQL features introduced in SQL Server 2008). The guidelines, tips, and T-SQL features presented in this chapter provide you with some building blocks you can use to get the most out of your T-SQL code to help make your SQL Server–based applications even more powerful and robust.

CHAPTER 44

Advanced Stored Procedure Programming and Optimization

Chapter 28, “Creating and Managing Stored Procedures,” introduced the basic syntax and features for creating, viewing, and maintaining stored procedures. This chapter delves into more advanced stored procedure features and programming methods and provides guidelines on how to develop more robust and better optimized stored procedures.

It is important to understand the various capabilities and limitations of stored procedures before writing much stored procedure code. Poorly written procedures can make the server appear to run sluggishly and inefficiently. Well-written procedures run efficiently and solidly. Following the guidelines and tips presented in this chapter should help you write more efficient and robust stored procedures.

T-SQL Stored Procedure Coding Guidelines

Transact-SQL (T-SQL) stored procedures should be treated just like reusable application code. You should follow these suggested guidelines to ensure that your stored procedures are solid and robust:

- ▶ Check all parameters for valid values and return an error message if a problem exists.
- ▶ Be sure that the parameter data types match the column data types they are compared against to avoid data type mismatches and poor query optimization.

IN THIS CHAPTER

- ▶ T-SQL Stored Procedure Coding Guidelines
- ▶ Using Cursors in Stored Procedures
- ▶ Nested Stored Procedures
- ▶ Using Temporary Tables in Stored Procedures
- ▶ Using Remote Stored Procedures
- ▶ Stored Procedure Performance
- ▶ Using Dynamic SQL in Stored Procedures
- ▶ Installing and Using .NET CLR Stored Procedures
- ▶ Using Extended Stored Procedures

- ▶ Check the @@error system function after each SQL statement, especially insert, update, and delete, to verify that the statements executed successfully. Return a status code other than 0 if a failure occurs.
- ▶ Be sure to comment your code so that when you or others have to maintain it, the code is self-documenting.
- ▶ Consider using a source code management system, such as Microsoft Visual Studio SourceSafe, CVS, or Subversion, to maintain versions of your stored procedure source code.

You should avoid using `select *` in your stored procedure queries. If someone were to add columns to or remove columns from a table, the stored procedure would generate a different result set, which could cause errors with the applications.

Whenever using `INSERT` statements in stored procedures, you should always provide the column list associated with the values being inserted. This allows the procedure to continue to work if the table is ever rebuilt with a different column order or additional columns are added to the table. Listing 44.1 demonstrates what happens if the column list is not provided and a column is added to the referenced table.

LISTING 44.1 Lack of Column List in **INSERT** Statement Causing Procedure to Fail

```

use bigpubs2008
go
IF EXISTS ( SELECT * FROM sys.procedures
            WHERE schema_id = schema_id('dbo')
            AND name = N'insert_publishers')
    DROP PROCEDURE dbo.insert_publishers
GO
create proc insert_publishers @pub_id char(4),
                             @pub_name varchar(40),
                             @city varchar(20),
                             @state char(2),
                             @country varchar(30)
as
INSERT INTO bigpubs2008.dbo.publishers
VALUES(@pub_id, @pub_name, @city, @state, @country)
if @@error = 0
    print 'New Publisher added'
go

exec insert_publishers '9950', 'Sams Publishing', 'Indianapolis', 'IN', 'USA'
go

New Publisher added

```

```
alter table publishers add street varchar(80) null
go
```

```
exec insert_publishers '9951', 'Pearson Education', 'Indianapolis', 'IN', 'USA'
go
```

```
Msg 213, Level 16, State 1, Procedure insert_publishers, Line 7
Insert Error: Column name or number of supplied values does not match table
definition.
```

A stored procedure cannot directly create schemas, views, triggers, defaults, rules, aggregates, functions, or stored procedures. You can, however, execute dynamic SQL that creates the object:

```
CREATE PROC create_other_proc AS
EXEC ('CREATE PROC get_au_lname AS
      SELECT au_lname from authors
      RETURN')
```

TIP

If you are using dynamic SQL to create objects in stored procedures, be sure to qualify each object with the name of the object schema if users other than the stored procedure owner will be executing the stored procedure.

You can create tables in stored procedures. Generally, only temporary tables are created in stored procedures. Temporary tables created in stored procedures are dropped automatically when the procedure terminates. Global temporary tables, however, exist until the connection that created them terminates.

If you don't qualify object names within a stored procedure, they default to the schema of the stored procedure. It is recommended that objects in stored procedures be qualified with the appropriate schema name to avoid confusion.

You cannot drop a table and re-create another table with the same name within the procedure unless you use dynamic SQL to execute a string that creates the table.

A stored procedure cannot issue the `USE` statement to change the database context in which it is running; the database context for execution is limited to a single database. If you need to reference an object in another database, you should qualify the object name with the database name in your procedure code.

Calling Stored Procedures from Transactions

Stored procedures can be called from within a transaction, and they can also initiate transactions. SQL Server notes the transaction nesting level, which is available from the `@@trancount` function, before calling a stored procedure. If the value of `@@trancount`

when the procedure returns is different from the value of @@trancount when it was executed, SQL Server displays error message 266: Transaction count after EXECUTE indicates that a COMMIT or ROLLBACK TRAN is missing. This message indicates that transaction nesting is out of balance. Because a stored procedure does not abort the batch on a rollback transaction statement, a rollback transaction statement inside the procedure could result in a loss of data integrity if subsequent statements are executed and committed.

A rollback transaction statement rolls back all statements to the outermost transaction, including any work performed inside nested stored procedures that have not been fully committed. A commit tran within the stored procedure decreases the value of @@trancount by only one. Because the transaction is not fully committed until @@trancount returns to zero, the work can be completely rolled back at any time prior to that. Essentially, the nested transaction inside the stored procedure is largely ignored. The modifications within the procedure are committed or rolled back based on the final action taken for the outermost transaction.

To avoid transaction nesting issues, you need to develop a consistent error-handling strategy for failed transactions or other errors that occur in transactions within your stored procedures and implement that strategy consistently across all procedures and applications. Within stored procedures that might be nested, you need to check whether the procedure is already being called from within a transaction before issuing another begin tran statement. If a transaction is already active, you can issue a save tran statement so that the procedure can roll back only the work that it has performed and allow the calling procedure that initiated the transaction to determine whether to continue or abort the overall transaction.

To maintain transaction integrity when calling procedures that involve transactions, follow these guidelines:

- ▶ Make no net change to @@trancount within your stored procedures.
- ▶ Issue a begin tran only if no transaction is already active.
- ▶ Set a savepoint if a transaction is already active so that a partial rollback can be performed within the stored procedure.
- ▶ Implement appropriate error handling and return an error status code if something goes wrong and a rollback occurs.
- ▶ Issue a commit tran only if the stored procedure issued the begin tran statement.

Listing 44.2 provides a template for a stored procedure that can ensure transactional integrity whether it is run as part of an ongoing transaction or independently.

LISTING 44.2 Template Code for a Stored Procedure That Can Run as Part of a Transaction or Run as Its Own Transaction

```
/* proc to demonstrate no net change to @@trancount
** but rolls back changes within the proc
** VERY IMPORTANT: return an error code
```

```

** to tell the calling procedure rollback occurred */

create proc ptran1
as
declare @trncnt int

select @trncnt = @@trancount  -- save @@trancount value

if @trncnt = 0  -- transaction has not begun
    begin tran ptran1  -- begin tran increments nest level to 1

else  -- already in a transaction
    save tran ptran1  -- save tran doesn't increment nest level

/* do some processing */

if (@@error != 0) -- check for error condition
begin
    rollback tran ptran1  -- rollback to savepoint, or begin tran
    return 25  -- return error code indicating rollback
end

/* more processing if required */

if @trncnt = 0  -- this proc issued begin tran
    commit tran ptran1  -- commit tran, decrement @@trancount to 0
                        -- commit not required with save tran

return 0 /* successful return */

```

Listing 44.3 provides a template for the calling batch that might execute the stored procedure shown in Listing 44.2. The main problem you need to solve is handling return codes properly and responding with the correct transaction handling.

LISTING 44.3 Template Code for a Calling Batch or Stored Procedure That Might Execute a Stored Procedure Built with the Template in Listing 44.2

```

/* Retrieve status code to determine if proc was successful */

declare @status_val int, @trncnt int

select @trncnt = @@trancount  -- save @@trancount value

if @trncnt = 0  -- transaction has not begun
    begin tran t1  -- begin tran increments nest level to 1

```

```

else          -- otherwise, already in a transaction
  save tran t1 -- save tran doesn't increment nest level

/* do some processing if required */

if (@@error != 0) -- or other error condition
begin
  rollback tran t1 -- rollback to savepoint, or begin tran
  return          -- and exit batch/procedure
end

execute @status_val = ptran1 --exec procedure, begin nesting

if @status_val = 25 -- if proc performed rollback
begin              -- determine whether to rollback or continue
  rollback tran t1
  return
end

/* more processing if required */

if @trncnt = 0    -- this proc/batch issued begin tran
  commit tran t1 -- commit tran, decrement @@trancount to 0
return          -- commit not required with save tran

```

Handling Errors in Stored Procedures

SQL Server 2008 provides the TRY...CATCH construct, which you can use within your T-SQL stored procedures to provide a more graceful mechanism for exception handling than was available in previous versions of SQL Server by checking @@ERROR (and often the use of GOTO statements) after each SQL statement.

A TRY...CATCH construct consists of two parts: a TRY block and a CATCH block. When an error condition is detected in a T-SQL statement inside a TRY block, control is immediately passed to a CATCH block, where the error is processed. T-SQL statements in the TRY block that follow the statement that generated the error are not executed.

If an error occurs and processing is passed to the CATCH block, after the statements in the CATCH block are executed, control is then transferred to the first T-SQL statement that follows the END CATCH statement. If there are no errors inside the TRY block, control is passed to the statement immediately after the associated END CATCH statement, essentially skipping over the statements in the CATCH block.

A TRY is initiated with the BEGIN TRY statement and ended with the END TRY statement and can consist of one or more T-SQL statements between the BEGIN TRY and END TRY statements. The TRY block must be followed immediately by a CATCH block. A CATCH block

is indicated with the `BEGIN CATCH` statement and ended with the `END CATCH` statement and can consist of one or more SQL statements. In SQL Server, each `TRY` block can be associated with only one `CATCH` block.

The syntax of the `TRY...CATCH` construct is as follows:

```
BEGIN TRY
    one_or_more_sql_statements
END TRY
BEGIN CATCH
    one_or_more_sql_statements
END CATCH
```

When in a `CATCH` block, you can use the following error functions to capture information about the error that invoked the `CATCH` block:

- ▶ **ERROR_NUMBER()**—Returns the error number
- ▶ **ERROR_MESSAGE()**—Returns the complete text of the error message
- ▶ **ERROR_SEVERITY()**—Returns the error severity
- ▶ **ERROR_STATE()**—Returns the error state number
- ▶ **ERROR_LINE()**—Returns the line number inside the procedure that caused the error
- ▶ **ERROR_PROCEDURE()**—Returns the name of the stored procedure or trigger where the error occurred

Unlike @@error, which is reset by each statement that is executed, the error information retrieved by the error functions remains constant anywhere within the scope of the `CATCH` block of a `TRY...CATCH` construct. Error functions can also be referenced inside a stored procedure and can be used to retrieve error information when the stored procedure is executed within a `CATCH` block. This allows you to modularize the error handling into a single procedure so you do not have to repeat the error-handling code in every `CATCH` block. Listing 44.4 shows an example of an error-handling procedure that you can use in your `CATCH` blocks.

LISTING 44.4 An Example of a Standard Error-Handling Procedure

```
create proc dbo.error_handler
as
begin
    Declare @errnum int,
           @severity int,
           @errstate int,
           @proc nvarchar(126),
           @line int,
           @message nvarchar(4000)
    -- capture the error information that caused the CATCH block to be invoked
```

```

SELECT @errnum = ERROR_NUMBER(),
       @severity = ERROR_SEVERITY(),
       @errstate = ERROR_STATE(),
       @proc = ERROR_PROCEDURE(),
       @line = ERROR_LINE(),
       @message = ERROR_MESSAGE()
-- raise an error message with information on the error
RAISERROR ('Failed to add new publisher for the following reason:
Error: %d, Severity: %d, State: %d, in proc %s at line %d, Message: "%s"',
         16, 1, @errnum, @severity, @errstate, @proc, @line, @message)
Return
end

```

Listing 44.5 provides an example of the TRY...CATCH construct in a stored procedure, modifying the insert_publishers procedure created in Listing 44.1. Note that this CATCH block uses the dbo.error_handler procedure defined in Listing 44.4.

LISTING 44.5 Using a TRY...CATCH Construct for Error Handling in a Stored Procedure

```

use bigpubs2008
go
alter proc insert_publishers @pub_id char(4),
                             @pub_name varchar(40),
                             @city varchar(20),
                             @state char(2),
                             @country varchar(30)
as
BEGIN TRY
    INSERT INTO bigpubs2008.dbo.publishers
        (pub_id, pub_name, city, state, country)
        VALUES(@pub_id, @pub_name, @city, @state, @country)
    -- if no error occurs, we should see this print statement
    print 'New Publisher added'
END TRY
BEGIN CATCH
    -- invoke the error_handler procedure
    exec error_handler
    -- return a non-zero status code
    RETURN -101
END CATCH
-- if successful execution, return 0
RETURN 0
go

exec insert_publishers '9951', 'Pearson Education', 'Indianapolis', 'IN', 'USA'

```

```
exec insert_publishers '9950', 'Sams Publishing', 'Indianapolis', 'IN', 'USA'
go
```

New Publisher added

```
Msg 50000, Level 16, State 1, Procedure insert_publishers, Line 18
Failed to add new publisher for the following reason:
Error: 2627, Severity: 14, State: 1, in proc insert_publishers at line 8,
Message: "Violation of PRIMARY KEY constraint 'UPKCL_pubind'. Cannot insert
duplicate key in object 'dbo.publishers'."
```

If you want to capture and handle any errors that may occur within a `CATCH` block, you can incorporate another `TRY...CATCH` block within the `CATCH` block itself.

Also note that some errors with severity 20 or higher that cause SQL Server to close the user connection cannot be handled by the `TRY...CATCH` construct. However, severity level 20 or higher errors that do not result in the connection being closed are captured and handled by the `CATCH` block. Any errors with a severity level of 10 or less are considered warnings or informational messages and not really errors and thus are not handled by the `TRY...CATCH` construct. Also, any compile errors (such as syntax errors) or object name resolution errors that happen during deferred name resolution also do not invoke a `CATCH` block. These errors are returned to the application or batch that called the error-generating routine.

Using Source Code Control with Stored Procedures

When you can, it's generally a good idea to use source code control for your stored procedure scripts. Stored procedures are as much a part of an application as the application code itself and should be treated as such. When using source code control, you can link versions of your procedures and other object creation scripts with specific versions of your applications. Using source code control systems also provides a great way to keep track of the changes to your stored procedures and other object creation scripts, enabling you to go back to a previous version if the modifications lead to problems with the applications or data.

SQL Server Management Studio (SSMS) provides a feature similar to Visual Studio that lets you organize your SQL scripts into solutions and projects. A *project* is a collection of one or more script files stored in the Windows file system, usually in a folder with the same name as the project. A *solution* is a collection of one or more projects.

In addition to providing a way to manage and organize your scripts, SSMS can also integrate with source code control software if the source code control system provides a compatible plug-in. If you are using Visual Studio, it's likely that you are also using Visual SourceSafe. Visual SourceSafe provides a one-to-one mapping between SSMS projects and Visual SourceSafe projects. After you create an SSMS solution, you can check the entire SSMS solution into Visual SourceSafe and then check out individual script files or projects.

You can also specify that a solution be added to source code control when you create a new solution. In SSMS, you select File, New and then select New Project. In the New Project dialog, you can specify the name for the project and solution, and you can also specify whether to add the solution to source code control, as shown in Figure 44.1.

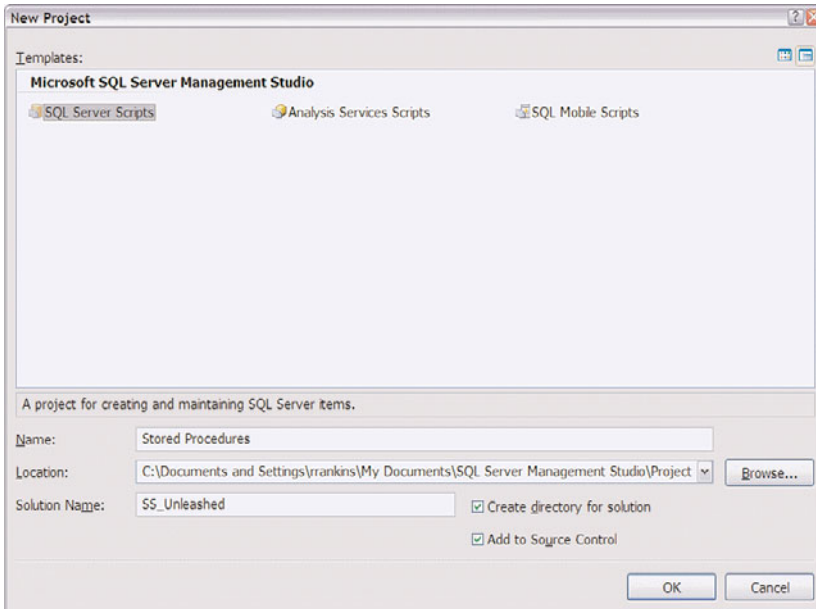

FIGURE 44.1 Creating a new project/solution and adding it to source control.

When you add a solution to Visual SourceSafe, it prompts you for the login ID and password to use to access Visual SourceSafe. After you provide that information, Visual SourceSafe then prompts you for the Visual SourceSafe project to add the SMSS project to, or it allows you to create a new project in Visual SourceSafe.

Within a project, you can specify the database connection(s) for the project and add SQL script files to the *Queries* folder. After creating a new script file, you can add it into the source code control system by right-clicking the script file in the Solutions Explorer and selecting Check In (see Figure 44.2).

After you check in a script file, you can right-click the file and perform source code control tasks such as checking out the script for editing, getting the current version, comparing versions, and viewing the check-in history. If you check out the script for editing, you can then open it in a new query window, where you can make changes to the script and then execute it in the database. When you are satisfied with the changes, you can check the new version back into the source code control system.

For more information on working with solutions and projects in SSMS, see Chapter 4, “SQL Server Management Studio.”

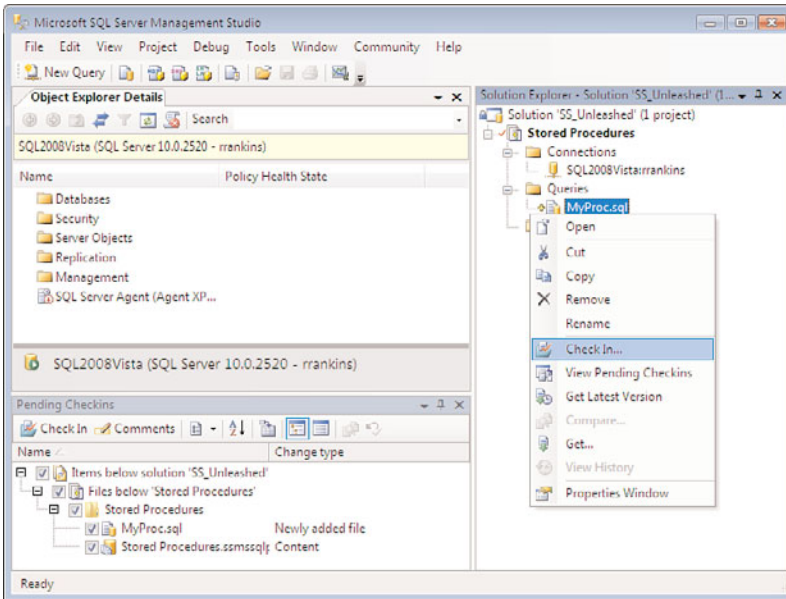

FIGURE 44.2 Checking in a new script file.

Using Cursors in Stored Procedures

When using cursors in stored procedures in SQL Server, you need to be aware of the scope of the cursor and how it can be accessed within calling or called procedures. Cursors in SQL Server can be declared as local or global. A global cursor defined in a stored procedure is available until it is deallocated or when the connection closes. A local cursor goes out of scope when the stored procedure that declared it terminates or the procedure scope changes.

If neither the `GLOBAL` nor `LOCAL` option is specified when the cursor is declared in a stored procedure, the default cursor type is determined by the database option `CURSOR_DEFAULT`, which you set with the `ALTER DATABASE` statement. The default value for the option `is_local_cursor_default` is `FALSE`, which defaults cursors as global, to match the behavior of earlier versions of SQL Server. If this value in the `sys.databases` catalog view is set to `TRUE`, T-SQL cursors default to local cursors.

TIP

If neither `GLOBAL` nor `LOCAL` is specified, the default scope setting for cursors in SQL Server 2008 is determined by the Default to Local Cursor database option. This option currently defaults to `OFF` to provide backward compatibility with versions of SQL Server prior to 7.0, in which all cursors were global. This default setting might change in future versions, so it is recommended that you explicitly specify the `LOCAL` or `GLOBAL` option when declaring your cursors so your code will not be affected by changes to the default setting.

If stored procedures are nested, they can access cursors declared in higher-level stored procedures in the call tree, but only if the cursors are declared as global. If the cursor is declared as local, it can be referenced only within the scope of the stored procedure in which it is declared. It cannot be accessed from a called or calling procedure. If the cursor is declared as global, it can be accessed within the declaring procedure, in a called procedure, or even from outside the declaring procedure if the cursor is not deallocated before the procedure returns.

In the following example, procedure p1 creates a cursor defined as global that can then be accessed by procedure p2:

```

if object_id('p1') is not null
    drop proc p1
go
if object_id('p2') is not null
    drop proc p2
go
create proc p2
as
set nocount on
-- fetch from global cursor defined in calling proc p1
fetch c1
return
go

create proc p1
as
set nocount on
-- Declare global cursor
declare c1 cursor global for
    select title_id, type from titles
open c1
fetch c1
exec p2
close c1
deallocate c1
go

exec p1
go

```

```

title_id type
-----
BI0194  biography

```

```
title_id type
-----
BI1408  biography
```

As you can see in the preceding example, the cursor `c1` is defined as global in procedure `p1` and can be accessed from within procedure `p2`.

TIP

To clean up the output when using cursors within stored procedures, specify the `set nocount on` option within the stored procedure to disable the *n rows(s) affected* that would normally be displayed after each invocation of the `fetch` statement.

Now, look what happens if you modify procedure `p1` to declare the cursor as local:

```
alter proc p1
as
set nocount on
-- Declare local cursor
declare c1 cursor local for
    select title_id, type from titles
open c1
fetch c1
exec p2
close c1
deallocate c1
go
exec p1
go

title_id type
-----
BI0194  biography
```

```
Msg 16916, Level 16, State 1, Procedure p2, Line 5
A cursor with the name 'c1' does not exist.
```

Notice in this example that the cursor `c1` is not available to the procedure `p2`. The reason is that the cursor is defined as local and is accessible only within the scope of procedure `p1`. Because the cursor is localized to the scope of `p1`, you are able to define a cursor with the same name within the scope of procedure `p2`:

```
alter proc p2
as
set nocount on
```

```
-- Declare another local cursor with same name 'c1'
declare c1 cursor local for
    select au_id, au_lname from authors
open c1
fetch c1
close c1
deallocate c1
return
go
exec p1
go
```

```
title_id type
-----
BI0194  biography

au_id      au_lname
-----
047-43-0360 Michener
```

Notice that when you define the scope of both cursors as local, each procedure can create a cursor with the same name without any conflict between them. You can take advantage of this feature if you have a recursive stored procedure that uses a cursor, as demonstrated in the “Recursive Stored Procedures” section, later in this chapter.

In addition to a global cursor defined in a calling procedure being available within a called procedure, the reverse is possible as well. A global cursor defined in a called procedure is available to the calling procedure as demonstrated in the following example:

```
alter proc p2
as
set nocount on
-- declare global cursor c2
declare c2 cursor global for
    select au_id, au_lname from authors
open c2
--do not close/deallocate cursor so it can be used by calling proc p1
return
go
alter proc p1
as
set nocount on
declare c1 cursor local for
    select title_id, type from titles
open c1
fetch c1
exec p2
```

```
-- fetch from global cursor declared in proc p2
fetch c2
close c1
deallocate c1
close c2
deallocate c2
return
go
exec p1
go
```

```
title_id type
-----
BI0194  biography

au_id      au_lname
-----
047-43-0360 Michener
```

As you can see in the preceding example, the global cursor defined in the called procedure p2 is available for use by the calling procedure p1 as long as the cursor is left open by the called procedure p2.

NOTE

Remember that global cursors persist beyond the scope of the procedure in which they are defined. If you are going to declare global cursors in called procedures to be accessed by the calling procedure, be sure the calling procedure closes and deallocates the cursor declared in the called procedure before it returns. Otherwise, the cursor will remain open and defined until the end of the user session. The following example demonstrates this behavior:

```
alter proc p1
as
set nocount on
declare c1 cursor local for
    select title_id, type from titles
open c1
fetch c1
exec p2
-- fetch from global cursor declared in proc p2
fetch c2
close c1
deallocate c1
```

```

-- Cursor c2 is not closed/deallocated before return
return
go
exec p1
go
--Cursor c2 should still be open here so the following fetch will work
fetch c2
go

title_id type
-----
BI0194  biography

au_id      au_lname
-----
047-43-0360 Michener

au_id      au_lname
-----
052-04-3539 Gray

```

Using CURSOR Variables in Stored Procedures

Another method available in SQL Server 2008 for passing cursor result sets between stored procedures is using the cursor data type. The cursor data type can be used to bind a cursor result set to a local variable, and that variable can then be used to manage and access the cursor result set. Cursor variables can be referenced in any of the cursor management statements: OPEN, FETCH, CLOSE, and DEALLOCATE.

A stored procedure can pass cursor variables as output parameters only; cursor variables cannot be passed as input parameters. When defining a CURSOR output parameter, you must also specify the VARYING keyword.

When assigning a cursor to a cursor variable, you must use the SET command because an assignment select is not allowed. Cursor data types can either be the source or the target in a SET statement.

The following stored procedure declares a cursor, opens it, and passes it back as an output parameter using the cursor data type:

```

IF EXISTS ( SELECT * FROM sys.procedures
            WHERE schema_id = schema_id('dbo')

```

```

        AND name = N'cursor_proc')
    DROP PROCEDURE dbo.cursor_proc
GO
create proc cursor_proc @cursor CURSOR VARYING OUTPUT
as
declare curs1 cursor global for
    select cast(title as varchar(30)) as title , pubdate from titles
set @cursor = curs1
open curs1
return

```

A cursor variable and the declared cursor name can be used interchangeably in cursor commands. You can use either the variable name or declared name to open, fetch, close, and deallocate the cursor. Fetching using either the cursor name or cursor variable fetches the next row in the cursor result set. Listing 44.6 illustrates how each fetch gets the next row in the result set.

LISTING 44.6 Fetching Cursor Rows by Using the Declared Cursor Name and a Cursor Variable

```

set nocount on
declare @curs CURSOR
exec cursor_proc @cursor = @curs output
fetch curs1
fetch @curs
fetch curs1
fetch @curs
go

```

One of the problems with a cursor declared as a global cursor in the procedure is that you cannot invoke the procedure again within the same session unless the cursor is closed and deallocated. This can be a problem if you need to get the cursor into a cursor variable again. If you try to invoke the procedure again, and the cursor hasn't been closed or deallocated, you get error messages, as shown in the following example:

```
set nocount on
declare @curs CURSOR
exec cursor_proc @cursor = @curs output
go
```

```
Msg 16915, Level 16, State 1, Procedure cursor_proc, Line 4
A cursor with the name 'curs1' already exists.
Msg 16905, Level 16, State 1, Procedure cursor_proc, Line 6
The cursor is already open.
```

```
close curs1
deallocate curs1
go
```

One way to work around this issue is to use the `CURSOR_STATUS` function in the procedure to check whether the cursor exists yet before declaring it and also to check whether the cursor is already open before opening it. Thus, the stored procedure declares the cursor only if it doesn't exist and opens the cursor only if it's closed, but the stored procedure always returns the cursor in the cursor output parameter. Keeping this in mind, take a look at a revised version of the `cursor_proc` stored procedure:

```
IF EXISTS ( SELECT * FROM sys.procedures
            WHERE schema_id = schema_id('dbo')
            AND name = N'cursor_proc' )
    DROP PROCEDURE dbo.cursor_proc
GO
go
create proc cursor_proc @cursor CURSOR VARYING OUTPUT
as
if CURSOR_STATUS('global', 'curs1') = -3 -- cursor does not exist
    declare curs1 cursor global for
        select cast(title as varchar(30)) as title , pubdate from titles
if CURSOR_STATUS('global', 'curs1') = -1 -- cursor is not open
    open curs1
set @cursor = curs1
return
```

When the procedure is written this way, you can now safely call the procedure at any time, even if the cursor is already open. If the cursor is open, it simply stores the cursor pointer into the cursor variable.

If you want to close the cursor, you can do so by using either the cursor variable or declared cursor name. When it is closed, however, you cannot fetch more rows from the cursor or cursor variable until it is reopened:

```
set nocount on
declare @curs CURSOR
exec cursor_proc @cursor = @curs output
fetch curs1
fetch @curs
-- close the cursor
close curs1
-- try to fetch from the cursor variable
fetch @curs
go
```

```
title                pubdate
-----
Samuel Johnson       2008-09-19 00:00:00.000
```

```
title                pubdate
-----
Freud, Dora, and Vienna 1900  2008-02-25 00:00:00.000
```

```
Msg 16917, Level 16, State 2, Line 7
Cursor is not open.
```

However, if the cursor has been assigned to a cursor variable, it cannot be fully deallocated until the last remaining reference to the cursor issues the DEALLOCATE command. Until all references to the cursor issue the DEALLOCATE command, the cursor can be reopened, but only by using the remaining cursor reference(s) that hasn't issued the DEALLOCATE command. An example of this behavior is shown in Listing 44.7. If the cursor has not been closed, only the last deallocation of the cursor closes it.

LISTING 44.7 Deallocating a Cursor by Cursor Name and Cursor Variable

```
declare @curs CURSOR
exec cursor_proc @cursor = @curs output

print 'FETCH VIA NAME:'
fetch curs1
print 'FETCH VIA VARIABLE:'
fetch @curs

print 'CLOSE BY NAME'
close curs1
print 'DEALLOCATE BY NAME'
```

```

deallocate curs1
print 'ATTEMPT FETCH VIA VARIABLE (CURSOR SHOULD BE CLOSED):'
fetch @curs
print 'ATTEMPT TO OPEN VIA VARIABLE (CURSOR SHOULD OPEN, NOT DEALLOCATED YET)'
open @curs
print 'ATTEMPT FETCH VIA VARIABLE (SHOULD START FROM BEGINNING AGAIN):'
fetch @curs
print 'CLOSE AND DEALLOCATE VIA VARIABLE'
close @curs
deallocate @curs
print 'ATTEMPT TO OPEN VIA VARIABLE (SHOULD FAIL, SINCE NOW FULLY DEALLOCATED):'
open @curs
go

```

```

FETCH VIA NAME:
TITLE                                PUBDATE
-----
SAMUEL JOHNSON                       2008-09-19 00:00:00.000

```

```

FETCH VIA VARIABLE:
TITLE                                PUBDATE
-----
FREUD, DORA, AND VIENNA 1900         2008-02-25 00:00:00.000
CLOSE BY NAME

```

DEALLOCATE BY NAME

```

ATTEMPT FETCH VIA VARIABLE (CURSOR SHOULD BE CLOSED):
MSG 16917, LEVEL 16, STATE 2, LINE 15
CURSOR IS NOT OPEN.

```

ATTEMPT TO OPEN VIA VARIABLE (CURSOR SHOULD OPEN, NOT DEALLOCATED YET)

```

ATTEMPT FETCH VIA VARIABLE (SHOULD START FROM BEGINNING AGAIN):
TITLE                                PUBDATE
-----
SAMUEL JOHNSON                       2008-09-19 00:00:00.000

```

CLOSE AND DEALLOCATE VIA VARIABLE

```

ATTEMPT TO OPEN VIA VARIABLE (SHOULD FAIL, SINCE NOW FULLY DEALLOCATED):
MSG 16950, LEVEL 16, STATE 2, LINE 27
The variable '@curs' does not currently have a cursor allocated to it.

```

If the cursor is declared as a local cursor within a stored procedure, it can still be passed back in an output variable to a cursor variable, but it is accessible only through the cursor variable, as shown in Listing 44.8.

LISTING 44.8 Assigning a Local Cursor to a Cursor Output Parameter

```

IF EXISTS ( SELECT * FROM sys.procedures
            WHERE schema_id = schema_id('dbo')
            AND name = N'cursor_proc2')
    DROP PROCEDURE dbo.cursor_proc2
GO
create proc cursor_proc2 @cursor CURSOR varying output
as
declare curs1 cursor local for
    select cast(title as varchar(30)) as title , pubdate from titles
set @cursor = curs1
open curs1
go
declare @curs CURSOR
exec cursor_proc2 @cursor = @curs output

print 'ATTEMPT FETCH VIA NAME:'
fetch next from curs1
print 'ATTEMPT FETCH VIA VARIABLE:'
fetch next from @curs
go

ATTEMPT FETCH VIA NAME:
Msg 16916, Level 16, State 1, Line 4
A cursor with the name 'curs1' does not exist.
ATTEMPT FETCH VIA VARIABLE:
title                pubdate
-----
Samuel Johnson       2008-09-19 00:00:00.000

```

Nested Stored Procedures

Stored procedures can call other stored procedures, and any of those procedures can call other procedures, up to a maximum nesting level of 32 levels deep. If you exceed the 32-level nesting limit, an error message is raised, the batch is aborted, and any open transaction in the session is rolled back. The nesting level limit prevents a recursive procedure from calling itself repeatedly in an infinite loop until a stack overflow occurs. To check the depth to which a procedure is nested, you use the system function @@NESTLEVEL (see Listing 44.9).

LISTING 44.9 Checking @@NESTLEVEL in Nested Stored Procedures

```

create proc main_proc
as
print 'Nesting Level in main_proc before sub_proc1 = ' + str(@@NESTLEVEL, 1)
exec sub_proc1
print 'Nesting Level in main_
proc after sub_proc1 = ' + str(@@NESTLEVEL, 1)
exec sub_proc2
print 'Nesting Level in main_proc after sub_proc2 = ' + str(@@NESTLEVEL, 1)
return
go

create proc sub_proc1
as
print 'Nesting Level in sub_proc1 before sub_proc2 = ' + str(@@NESTLEVEL, 1)
exec sub_proc2
print 'Nesting Level in sub_proc1 after sub_proc2 = ' + str(@@NESTLEVEL, 1)
return
go

create proc sub_proc2
as
print 'Nesting Level in sub_proc2 = ' + str(@@NESTLEVEL, 1)
return
go

print 'Nesting Level before main_proc = ' + str(@@NESTLEVEL, 1)
exec main_proc
print 'Nesting Level after main_proc = ' + str(@@NESTLEVEL, 1)
go

```

The module 'main_proc' depends on the missing object 'sub_proc1'. The module will still be created; however, it cannot run successfully until the object exists.

The module 'main_proc' depends on the missing object 'sub_proc2'. The module will still be created; however, it cannot run successfully until the object exists.

The module 'sub_proc1' depends on the missing object 'sub_proc2'. The module will still be created; however, it cannot run successfully until the object exists.

```

Nesting Level before main_proc = 0
Nesting Level in main_proc before sub_proc1 = 1
Nesting Level in sub_proc1 before sub_proc2 = 2
Nesting Level in sub_proc2 = 3
Nesting Level in sub_proc1 after sub_proc2 = 2

```

```

Nesting Level in main_proc after sub_proc1 = 1
Nesting Level in sub_proc2 = 2
Nesting Level in main_proc after sub_proc2 = 1
Nesting Level after main_proc = 0

```

Although a limit exists for the number of levels to which procedures can be nested, the number of stored procedures that can be called from within a single procedure is limitless. The main-level procedure can call potentially hundreds of other procedures. As long as the other procedures never invoke another procedure, the nesting level never exceeds two.

Any stored procedure that is called from within another procedure should return a status code if an error condition occurs. Depending on the severity of the error, failure within a nested procedure does not always cause the calling procedure or batch to be aborted. Checking the error condition from a nested procedure allows you to conditionally determine whether to continue processing.

Recursive Stored Procedures

A stored procedure can call itself up to the maximum nesting level of 32. This is referred to as *recursion*. When might you want a stored procedure to be recursive? One common example is when you need to expand a tree relationship. Although a common table expression (CTE) can be used to recursively expand a tree relationship, internally it builds the entire tree before applying any filters to display the tree, starting at a specific level. It is also somewhat limited in how the tree is displayed (see Listing 44.10).

LISTING 44.10 Using a Common Table Expression to Expand a Tree Relationship

```

WITH PartsTree (PartID, PartName, parentPartID, Level)
AS
(
-- Anchor member definition
  SELECT PartID, PartName, ParentPartID,
         0 AS Level
  FROM Parts AS parent
     where Parent.parentpartid is null
  UNION ALL
-- Recursive member definition
  SELECT child.PartID, child.PartName, child.ParentPartID,
         Level + 1
  FROM Parts AS Child
     INNER JOIN PartsTree AS parent
         ON child.ParentPartID = parent.PARTID
)
-- Statement that executes the CTE
select * from PARTsTree

```

```
go
```

PartID	PartName	parentPartID	Level
22	Car	NULL	0
1	DriveTrain	22	1
23	Body	22	1
24	Frame	22	1
2	Engine	1	2
3	Transmission	1	2
4	Axle	1	2
12	Drive Shaft	1	2
9	Flywheel	3	3
10	Clutch	3	3
16	Gear Box	3	3
15	Reverse Gear	16	4
17	First Gear	16	4
18	Second Gear	16	4
19	Third Gear	16	4
20	Fourth Gear	16	4
5	Radiator	2	3
6	Intake Manifold	2	3
7	Exhaust Manifold	2	3
8	Carburetor	2	3
13	Piston	2	3
14	Crankshaft	2	3
21	Piston Rings	13	4
11	Float Valve	8	4

A recursive procedure can provide a somewhat more elegant solution to expanding a tree relationship from any level in the tree. This solution also provides more control over formatting of the output. For example, the procedure in Listing 44.11 formats the output so that the child parts are indented within the parent part.

LISTING 44.11 Expanding a Tree Relationship by Using a Recursive Procedure

```
IF EXISTS ( SELECT * FROM sys.procedures
            WHERE schema_id = schema_id('dbo')
            AND name = N'SHOW_PARTS_LIST' )
    DROP PROCEDURE dbo.SHOW_PARTS_LIST
GO
CREATE PROC SHOW_PARTS_LIST @partid varchar(50)
as
set nocount on
```

```

declare @treelevel int,
        @partname varchar(50),
        @childpartid int,
        @parentpartid int

select @treelevel = @@NESTLEVEL -- keep track of nesting level for indenting

if @@nestlevel = 1 -- this is the top of the tree
begin
    select @partname = PArtName from Parts where Partid = @partid
    print 'Expanded parts list for ' + @partname
end

if @@NESTLEVEL < 32 -- Make sure we don't exceed the maximum nesting level
begin
    -- set up cursor to find all child parts for the current part
    declare c1 cursor local for
        select PartId, PartName from Parts
            where parentpartid = @partid
    open c1
    fetch c1 into @childpartid, @partname
    while @@fetch_Status = 0
    begin
        -- use the current tree level to set the indenting when
        -- we print out this record
        print replicate('-', @treelevel * 3) + '> '
            + @partname + ', Part Number: ' + ltrim(str(@childpartid))
        -- Now, call the procedure again to find all the child parts
        -- for the current part
        exec show_parts_list @childpartid
        fetch c1 into @childpartid, @partname
    end
    close c1
    deallocate c1
end
else
begin
    -- We are at maximum nesting level, print out message to indicate this
    print 'Nesting level at 32. Cannot expand tree further.'
end
return
go
-- show the whole parts tree
declare @car_partid int
select @car_partid = partid from Parts where PartName = 'Car'
exec show_parts_list @partid = @car_partid

```

```
go
```

```
Expanded parts list for Car
```

```

---> DriveTrain, Part Number: 1
-----> Engine, Part Number: 2
-----> Radiator, Part Number: 5

```

Using Temporary Tables in Stored Procedures

Temporary tables are commonly used in stored procedures when intermediate results need to be stored in a work table for additional processing. Local temporary tables created in a stored procedure are automatically dropped when the stored procedure exits. Global temporary tables created in a stored procedure still exist after the stored procedure exits until they are explicitly dropped (see Listing 44.12) or the user session in which they were created disconnects from SQL Server.

LISTING 44.12 Using Local and Global Temporary Tables in Stored Procedures

```

set nocount on
go
create proc temp_test2
as
select pub_id, pub_name, city, state
into ##temp
from publishers
where State in ('MA', 'DC', 'CA')

select pub_id, pub_name, city, state
into #temp
from publishers
where State in ('MA', 'DC', 'CA')
go

exec temp_test2
go

select * from ##temp
go

```

pub_id	pub_name	city	state
0736	New Moon Books	Boston	MA
0877	Binnet & Hardley	Washington	DC
1389	Algodata Infosystems	Berkeley	CA

9913	Blackberry's	Cambridge	MA

```

select * from #temp
go

```

Server: Msg 208, Level 16, State 0, Line 1

Invalid object name '#temp'.

Note what happens if you try to run the stored procedure again:

```
exec temp_test2
go
Server: Msg 2714, Level 16, State 6, Procedure temp_test2, Line 3
There is already an object named '##temp' in the database.
```

TIP

The general consensus is that there is not much need for using global temporary tables in stored procedures. The typical reason for using temporary tables in stored procedures is that you need a work area within the stored procedure only. You normally wouldn't want it sticking around after the procedure finishes. Creating a global temporary table in a stored procedure requires an explicit drop of the table before the procedure exits if you no longer need it. If that's the case, what's the benefit of using a global temporary table? Any subprocedures will be able to see and reference a local temporary table created in the calling procedure, so global temporary tables are not needed in that case.

Only if you need to create and populate a work table and have it available after the procedure exits should you consider using a global temporary table. However, you have to remember to explicitly drop it at some point before attempting to run the procedure again. But if an error occurs that aborts processing of the stored procedure, the explicit drop might not be executed.

You might want to include a check for the global temporary table in your stored procedure and drop it automatically before attempting to create it again, as in the following code snippet:

```
create proc myproc
as
if exists (select 1 from tempdb..sysobjects where name = '##global_temp'
          and type = 'U')
    drop table ##global_Temp

select * into ##global_temp from ...
```

Temporary Table Performance Tips

All users in SQL Server share the same tempdb database for work tables and temporary tables, regardless of the database in which they are working. This makes tempdb a potential performance bottleneck in any multiuser system. The primary bottleneck in tempdb is disk I/O, but locking contention may also occur between processes on the tempdb system catalogs.

SQL Server 2008 alleviates the disk I/O problem by logging just enough information to allow rollback of transactions without logging all the additional information that would be necessary to recover those transactions. The recovery information is needed only when recovering a database at system startup or when restoring from a backup. Because tempdb is rebuilt during SQL Server startup (and no one in his right mind would restore tempdb from a backup), you don't need to keep this recovery information. When you reduce the logging in tempdb, data modification operations on tables in tempdb can be up to four times faster than the same operations in other databases.

However, locking in tempdb is still a potential performance bottleneck. If you create a table in tempdb within a transaction, locks are held on rows in the system catalogs. These locks being held on the system catalogs could lead to locking contention with other processes trying to read or update the tempdb system catalogs.

To minimize the potential for locking contention on the system tables in tempdb, you should consider creating your temporary tables before starting a transaction so that locks are released immediately and not held on the system catalogs until the end of the transaction. If the table must be created in a transaction, you should commit your transaction as soon as possible.

Also, you need to be aware that even if it's not in a transaction, creating a temporary table by using `SELECT INTO` holds locks on the system catalogs in tempdb until the `SELECT INTO` completes. If locking contention in tempdb becomes a problem, you should consider replacing `SELECT INTO` with `CREATE TABLE`, followed by an `INSERT` using a `SELECT` statement. Although this statement might run a bit more slowly than `SELECT INTO`, the system table locks are held only for the brief moment it takes for `CREATE TABLE` to complete.

Another way to speed up temporary table creation/population is to keep temporary tables as small as possible so that they are created and populated more quickly. You should select only the required columns, rather than use `SELECT *`, and you should retrieve only the rows from the base table that you actually need to reference. The smaller the temporary table, the faster it is to create the table; smaller temporary tables also help speed up queries against the temporary table.

If a temporary table is of sufficient size and is going to be accessed multiple times within a stored procedure, it might be cost effective to create an index on it on the column(s) that will be referenced in the search arguments of queries against the temporary table. If the time it takes to create the index plus the time the queries take to run using the index is less than the sum total of the time it takes the queries against the temporary table to run without the index, you probably want to consider creating an index on the temporary table.

The following example demonstrates the creation of an index on a temporary table:

```
use bigpubs2008
go
create proc ptemp1 WITH RECOMPILE
as
select title_id, type, pub_id, ytd_sales
```

```

    into #temp_titles
    from titles

create index tmp on #temp_titles(pub_id)

select sum(ytd_sales)
    from #temp_titles
    where pub_id = '0736'
select min(ytd_sales)
    from #temp_titles
    where pub_id = '0736'

return
go

```

Following are some other final tips for using temporary tables in stored procedures:

- ▶ Don't use temporary tables to combine result sets together when a UNION or UNION ALL will suffice; internal worktables are faster due to less overhead than temporary tables. UNION ALL is the fastest because no worktable in tempdb is required to merge the result sets.
- ▶ Drop temporary tables as soon as possible to free up space in tempdb.
- ▶ Consider using the table data type to avoid using tempdb altogether.

Using the table Data Type

The table data type can be used to define table variables in stored procedures and elsewhere in SQL code. Table variables are defined similarly to regular tables, except you define them using a DECLARE statement, rather than using CREATE TABLE:

```

DECLARE @table_variable TABLE ({ column_definition | table_constraint }
                                [ ,...n ])

```

The following simple example shows how to use a table variable in a stored procedure:

```

-- proc to get year-to-date sales for all books published since specified date
-- with ytd_sales greater than specified threshold
create proc tab_var_test @pubdate datetime = null,
                        @sales_minimum int = 0
as

declare @ytd_sales_tab TABLE (title_id char(6),
                              title varchar(50),
                              ytd_sales int)

if @pubdate is null
    -- if no date is specified, set date to last year

```

```

set @pubdate = dateadd(month, -12, getdate())

insert @ytd_sales_tab
select title_id, convert(varchar(50), title), ytd_sales
  from titles
  where pubdate > @pubdate
     and ytd_sales > @sales_minimum
select * from @ytd_sales_tab
return
go

exec tab_var_test '6/1/2001', 10000
go

```

title_id	title	ytd_sales

MC3021	The Gourmet Microwave	22246
TC4203	Fifty Years in Buckingham Palace Kitchens	15096

44

You can use table variables in user-defined functions, stored procedures, and T-SQL batches. You should consider using table variables instead of temporary tables whenever possible because they provide the following benefits:

- ▶ Table variables are memory resident and require no space in tempdb.
- ▶ When table variables are used in stored procedures, fewer recompilations of the stored procedures occur than when temporary tables are used.
- ▶ Transactions involving table variables last only for the duration of an update on the table variable. Thus, table variables require fewer locking and no logging resources.
- ▶ A table variable behaves like a local variable, and its scope is limited to the stored procedure in which it is declared. It is cleaned up automatically at the end of the function, stored procedure, or batch in which it is defined.

A table variable can be used like a regular table in SELECT, INSERT, UPDATE, and DELETE statements. However, a table variable is not allowed in a SELECT INTO statement like the following:

```
SELECT select_list INTO table_variable ...
```

You need to keep a couple of other limitations in mind when considering using table variables in stored procedures. You cannot create indexes on table variables by using the CREATE INDEX command, and no statistics are kept on table variables. You can, however, define a primary or unique key on the table variable when it is declared to enforce uniqueness. However, because table variables are memory resident and typically not very large in size, the inability to define explicit indexes generally does not lead to any significant

performance issues. In some cases, (for example, if the result set is large and accessed repeatedly) performance may improve when you use temporary tables instead because they support indexes and statistics.

Using Remote Stored Procedures

You can execute a stored procedure residing on another server by using a four-part naming scheme:

```
EXEC server_name.db_name.owner_name.proc_name
```

This concept is called *remote stored procedures*. The name implies that the procedure called on the other server is a special type of stored procedure, but it is not. Any stored procedure can be called from another server, as long as the remote server has been configured and the appropriate login mapping has been done. The method used to set up servers to allow Remote Procedure Calls (RPCs) is described in Chapter 54, “Managing Linked and Remote Servers” (on the CD).

The processing done by the remote stored procedure is, by default, not done in the local transaction context. If the local transaction rolls back, modifications performed by the remote stored procedure are not undone. However, you *can* get the remote stored procedures to execute within the local transaction context by using distributed transactions, as in the following example:

```
BEGIN DISTRIBUTED TRANSACTION
EXEC purge_old_customers --A local procedure
EXEC LONDON.customers.dbo.purge_old_customers -- a remote procedure
COMMIT TRANSACTION
```

SQL Server also automatically promotes a local transaction to a distributed transaction if the `remote proc trans` option is enabled and a remote stored procedure is invoked in a transaction. This option can be configured globally in SQL Server via `sp_configure`, or it can be set explicitly at the connection level with the `SET REMOTE_PROC_TRANSACTIONS` command. If the `remote proc trans` option is enabled, remote stored procedure calls in local transactions are automatically protected as part of distributed transactions, without requiring you to rewrite applications to specifically issue `BEGIN DISTRIBUTED TRANSACTION` instead of `BEGIN TRANSACTION`.

Distributed transactions and the Microsoft Distributed Transaction Coordinator service are also discussed in Chapter 54.

Stored Procedure Performance

Using stored procedures can provide a number of benefits to SQL Server applications. One performance benefit is reduced network traffic because stored procedures minimize the number of round trips between client applications and SQL Server. Stored procedures can consist of many individual SQL statements but can be executed with a single statement.

This allows you to reduce the number and size of calls from the client to the server. If you have to take different actions based on data values, you can specify to have these decisions made directly in the procedure, avoiding the need to send data back to the application to determine what to do with the data values.

By default, SQL Server sends a message back to the client application after each statement is completed within the stored procedure to indicate the number of rows affected by the statement. To further reduce the amount of “chatter” between the client and server and to therefore further improve stored procedure performance, you can eliminate the `DONE_IN_PROC` messages that SQL Server sends to the client API by issuing the `set nocount on` command at the beginning of the stored procedure. Be aware that if you turn on this option, the number of rows affected by the commands in the procedure is not available to the client application. If you need this information, you can still issue `select @@rowcount` after a statement executes to determine the number of rows affected.

Another performance benefit of using stored procedures is potentially faster execution due to the caching of stored procedure query plans. Stored procedure query plans are kept in cache memory after the first execution. The code doesn't have to be reparsed and reoptimized on subsequent executions.

Query Plan Caching

When a batch of SQL statements is submitted to SQL Server, SQL Server performs a number of steps, including the following, before the data can be returned to the client:

1. Parse the SQL statements and build a query tree (the internal format on which SQL Server operates).
2. Check for a previous cached plan for the query/procedure. If one does not exist or is no longer valid, optimize the SQL statements and generate an execution plan.
3. Check for permissions for access to the underlying objects.
4. Execute the execution plan for the SQL statements.

The first time a stored procedure executes, SQL Server loads the SQL code for the stored procedure from the system catalog into the plan cache and optimizes and compiles an execution plan.

The optimization of SQL statements is based on the parameters passed, the index distribution statistics, the number of rows in each table, and other information available at the time of the first execution. The compiled plan is then saved in cache memory. For subsequent executions, all SQL Server has to do is find the plan in the cache and execute it, essentially skipping most of the work in steps 1 and 2. Parsing and compilation always add some overhead, and depending on the complexity of the stored procedure code, they can sometimes be as expensive as the actual execution. Just by skipping these two steps, you can achieve a performance gain by using stored procedures.

The SQL Server Plan Cache

SQL Server uses the same buffer area for storing data and index pages as it does for storing query execution plans. The portion of the buffer pool used to store execution plans is referred to as the *plan cache*. The percentage of the memory pool allocated to execution plans fluctuates dynamically, depending on the state of the system. SQL Server also can keep execution plans in cache for ad hoc queries. This means that even dynamic SQL queries might be able to reuse a cached execution plan and skip recompilation. The cache space is dynamically allocated as needed.

With the ability to keep query plans in memory for ad hoc queries, it is not as critical in SQL Server 2008 for applications to use stored procedures to achieve performance benefits of using precompiled plans. However, when and how the plans are stored and reused for ad hoc queries is not nearly as predictable as with stored procedures. The query plans for stored procedures remain in cache memory more persistently. In addition, you have less explicit control over the recompilation of ad hoc queries.

TIP

You can get information about what is currently in the plan cache via the `dm_exec_cached_plans`, `dm_exec_plan_attributes`, and `dm_exec_sql_text` dynamic management views. These views return the current server state information regarding the plan cache.

Shared Query Plans

SQL Server 2008 execution plans consist of two main components: a query plan and an execution context. The query plan is the bulk of the execution plan. Query plans are re-entrant, read-only data structures used by any number of users. There are at most ever only two copies of the query plan in memory: one copy for all serial executions and another for all parallel executions. The parallel copy covers all parallel executions, regardless of their degree of parallelism. When a SQL statement is executed, the Database Engine searches the plan cache to see whether an execution plan for the same SQL statement is already in the plan cache. If a query plan does exist, the Database Engine reuses it, saving the overhead of recompiling the SQL statement. However, if no existing query plan is found, SQL Server 2008 generates a new execution plan for the query and saves it into the plan cache.

For each user currently executing a query, there is a data structure that holds information specific to that user's execution, such as parameter values. This data structure is referred to as the *execution context*. Execution context data structures are also reusable if they are not currently in use. When a user executes a query, SQL Server looks for an execution context structure not being used, and it reinitializes the structure with the context for the new user. If no free execution context structures exist, SQL Server creates a new one. Thus, there can potentially be multiple execution context structures in the plan cache for the same query.

For more information on the `syscacheobjects` table and how query plans are cached and managed in SQL Server, see Chapter 35, “Understanding Query Optimization” and Chapter 36, “Query Analysis.”

Automatic Query Plan Recompilation

SQL Server attempts to reuse existing execution plans for stored procedures, but certain operations cause the execution plans to become inefficient or invalid. In these cases, a new execution plan needs to be recompiled on the next execution of the stored procedure. The following conditions cause a plan to be invalidated:

- ▶ Whenever there is a change to the schema of a referenced table or view
- ▶ When an index for a referenced table is dropped or changed
- ▶ When the statistics used by an execution plan have been updated, either explicitly or automatically
- ▶ When `sp_recompile` has been run on a table referenced by a stored procedure
- ▶ When a sufficient number of data changes have been made to a table that is referenced by the stored procedure
- ▶ For tables with triggers, when the number of rows in the inserted and deleted tables grows significantly

In addition to these reasons, other events that can cause stored procedures to recompile new query plans include the following:

- ▶ When SQL Server activity is heavy enough to cause execution plans to be flushed from cache memory
- ▶ When the `WITH RECOMPILE` option has been specified in the `CREATE PROCEDURE` or `EXEC` command
- ▶ When shutting down and restarting SQL Server, which flushes all query plans from memory

In SQL Server 2000 and prior versions, whenever an execution plan was invalidated, the entire batch or stored procedure was recompiled. In SQL Server 2005 and later, only the statement, batch, or stored procedure that caused the query plan to be invalidated has to be recompiled. Because often only a small number of statements in batches or stored procedures are the reason a plan becomes invalidated, statement-level recompilation improves performance in terms of CPU time and locks by avoiding the need to have to recompile all the other statements in the batch whose execution plans are still valid.

Monitoring Stored Procedure Recompilation

You can monitor when stored procedures or statements are automatically recompiled by using SQL Server Profiler. The two events you want to monitor are the `SP:Recompile` and `SQL:StmtRecompile` trace events (see Figure 44.3). In SQL Server 2008, the `TextData` column of these events is filled in with information about the query that caused the

recompile, so you do not need to also trace the SP:StmtStarting or SP:StmtCompleted events to be able to capture the query information.

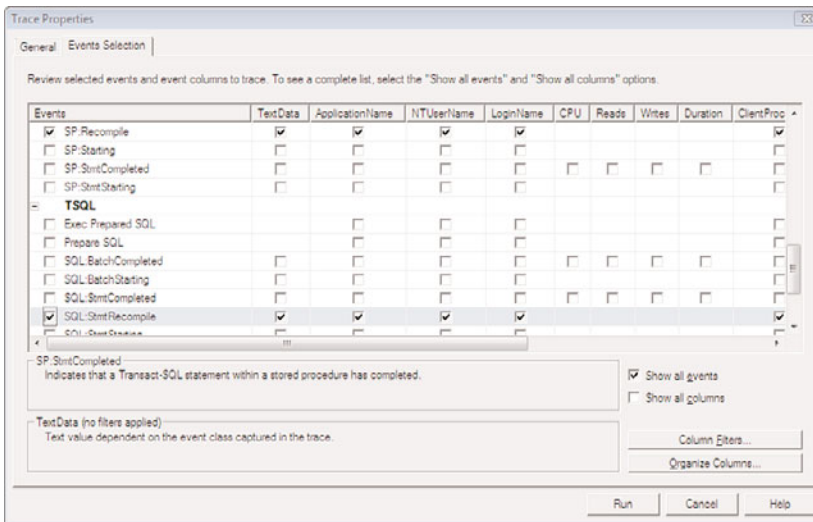

FIGURE 44.3 Adding events in SQL Server Profiler to monitor stored procedure recompilation.

If a stored procedure or statement is automatically recompiled during execution, SQL Server Profiler displays the SP:Recompile event and/or the SQL:StmtRecompile event. For example, you can create the following stored procedure to create and populate a temporary table:

```
create proc recomp_test
as
create table #titles (title_id varchar(6), title varchar(80), pubdate datetime)
insert #titles select title_id, title, pubdate from titles
where pubdate > '10/1/2001'
select * from #titles
go
```

Say you turn on SQL Server Profiler and then execute the following SQL, which executes the procedure (which in turn results in the initial compilation), and then add an index on pubdate to the titles table:

```
exec recomp_test
go
create index idx1 on titles (pubdate)
go
```

```
exec recomp_test
go
drop index titles.idx1
go
```

When you do this, you capture events similar to those shown in Figure 44.4.

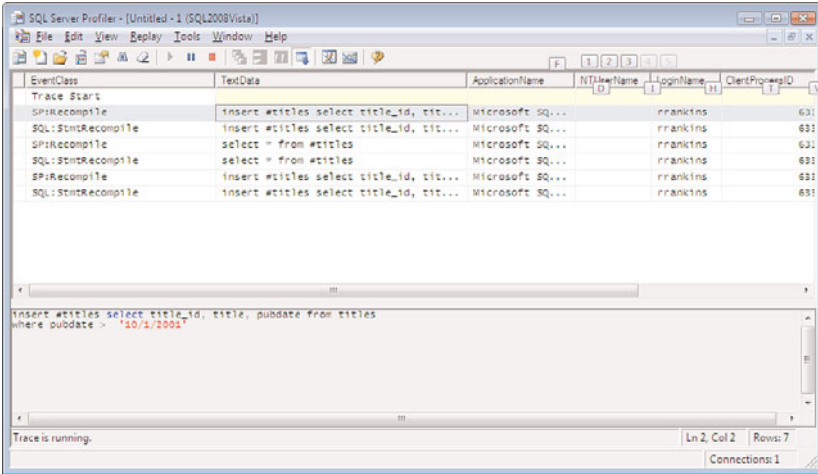

FIGURE 44.4 Recompile events captured for a stored procedure in SQL Server Profiler.

The key columns to focus on in the Profiler trace are ObjectName, EventSubclass, and TextData. The TextData column shows which statements were recompiled. You can see in Figure 44.4 that on the subsequent execution, only the statement affected by the new index on the titles table was recompiled. The EventSubclass column provides the reason for the recompile. These reasons are summarized in Table 44.1.

TABLE 44.1 SQL Server Profiler **EventSubClass** Values for Recompile Events

EventSubClass Value	Description
1	Schema changed.
2	Statistics changed.
3	Deferred compile.
4	SET option changed.
5	Temporary table changed.
6	Remote rowset changed.
7	FOR BROWSE permission changed.
8	Query notification environment changed.

TABLE 44.1 SQL Server Profiler **EventSubClass** Values for Recompile Events

EventSubClass Value	Description
9	Partitioned view changed.
10	Cursor options changed.
11	OPTION (RECOMPILE) requested.

For more information on using SQL Server Profiler to monitor SQL Server performance, see Chapter 6, “SQL Server Profiler.”

Forcing Recompilation of Query Plans

In some situations, a stored procedure might generate different query plans, depending on the parameters passed in. At times, depending on the type of query and parameter values passed in, it can be difficult to predict the best query plan for all executions. Consider the following stored procedure:

```
IF EXISTS ( SELECT * FROM sys.procedures
            WHERE schema_id = schema_id('dbo')
            AND name = N'advance_range' )
    DROP PROCEDURE dbo.advance_range
GO
create proc advance_range
    (@low money, @high money)
as
select * from dbo.titles
    where advance between @low and @high
return
```

Assume that a nonclustered index exists on the `advance` column in the `titles` table. A search in which `advance` is between 1,000 and 2,000 might be highly selective, and the index statistics might indicate that fewer than 5% of the rows fall within that range, and thus an index would be the best way to find the rows. If those were the values passed on the first execution, the cached query plan would indicate that the index should be used.

Suppose, however, that if on a subsequent execution, search values of 5,000 and 10,000 were specified. These values match against 90% of the rows in the table, and if optimized normally, SQL Server would likely use a table scan because it would have to visit almost all rows in the table anyway. Without recompiling, however, it would use the index as specified in the cached query plan, which would be a suboptimal query plan because it would likely be accessing more pages using the index than would a table scan.

When a lot of variance exists in the distribution of data values in a table or in the range of values passed as parameters, you might want to force the stored procedure to recompile and build a new execution plan during execution and not use a previously cached plan.

Although you incur the overhead of compiling a new query plan for each execution, it is typically much less expensive than executing the wrong query plan.

You can force recompilation of the query plan for a stored procedure by specifying the `WITH RECOMPILE` option when creating or executing a stored procedure. Including the `WITH RECOMPILE` option in the `create procedure` command causes the procedure to generate a new query plan for each execution:

```
IF EXISTS ( SELECT * FROM sys.procedures
           WHERE schema_id = schema_id('dbo')
           AND name = N'advance_range' )
    DROP PROCEDURE dbo.advance_range
GO
create proc advance_range
    (@low money, @high money)
    WITH RECOMPILE
as
select * from dbo.titles
    where advance between @low and @high
return
```

If the procedure is not created with the `WITH RECOMPILE` option, you can generate a new query plan for a specific execution by including the `WITH RECOMPILE` option in the `EXEC` statement:

```
exec advance_range 5000, 10000 WITH RECOMPILE
```

Because of the performance overhead of recompiling query plans, you should try to avoid using `WITH RECOMPILE` whenever possible. One approach is to create different subprocedures and execute the appropriate one based on the passed-in parameters. For example, you could have a subprocedure to handle small-range retrievals that would benefit from an index and a different subprocedure to handle large-range retrievals. The queries in each procedure would be identical; the only difference would be in the parameter values passed to them. This is controlled in the top-level procedure. An example of this approach is demonstrated in Listing 44.13.

LISTING 44.13 Using Multiple Stored Procedures as an Alternative to Using **WITH RECOMPILE**

```
IF EXISTS ( SELECT * FROM sys.procedures
           WHERE schema_id = schema_id('dbo')
           AND name = N'advance_range' )
    DROP PROCEDURE dbo.advance_range
GO
go

create proc get_titles_smallrange
```

```

    @low money, @high money
as
select * from titles
    where advance between @low and @high
return
go
create proc get_titles_bigrange
    @low money, @high money
as
select * from titles
    where advance between @low and @high
return
go
create proc advance_Range
    @low money, @high money
as
if @high - @low >= 1000
-- if the difference is over 5000
    exec get_titles_bigrange @low, @high
else
-- execute the small range procedure
    exec get_titles_smallrange @low, @high

```

Obviously, this solution would require substantial knowledge of the distribution of data in the table and where the threshold is on the range of search values that results in different query plans.

Another type of stored procedure that can sometimes generate different query plans based on initial parameters is a multipurpose procedure, which usually performs different actions based on conditional branching, as in the following example:

```

IF EXISTS ( SELECT * FROM sys.procedures
            WHERE schema_id = schema_id('dbo')
            AND name = N'get_titles_data')
    DROP PROCEDURE dbo.get_titles_data
GO
create proc get_titles_data (@flag tinyint, @value money)
as
if @flag = 1
    select * from titles where price = @value
else
    select * from titles where advance = @value

```

At query compile time, the Query Optimizer doesn't know which branch will be followed because the `if...else` construct isn't evaluated until runtime. On the first execution of

the procedure, the Query Optimizer generates a query plan for all SELECT statements in the stored procedure, regardless of the conditional branching, based on the parameters passed in on the first execution. A value passed in to the parameter intended to be used for searches against a specific table or column (in this example, price versus qty) might not be representative of normal values to search against another table or column.

Again, a better approach would be to break the different SELECT statements into separate subprocedures and execute the appropriate stored procedure for the type of query to be executed, as in the following example:

```
IF EXISTS ( SELECT * FROM sys.procedures
            WHERE schema_id = schema_id('dbo')
            AND name = N'get_titles_data')
    DROP PROCEDURE dbo.get_titles_data
GO
drop proc get_titles_data
go
create proc get_titles_data_by_price (@value money)
as
    select * from titles where price = @value
go
create proc get_titles_data_by_advance (@value money)
as
    select * from titles where advance = @value
go
create proc get_titles_data (@flag tinyint, @value money)
as
if @flag = 1
    exec get_titles_data_by_price @value
else
    exec get_titles_data_by_advance @value
```

Using sp_recompile

In versions of SQL Server prior to 7.0, it was necessary to use the `sp_recompile` system stored procedure when you wanted to force all stored procedures that referenced a specific table to generate a new query plan upon the next execution. This was necessary if you had added new indexes to a table or had run `UPDATE STATISTICS` on the table. However, the usefulness of this command in SQL Server 2008 is questionable because new query plans are generated automatically whenever new indexes are created or statistics are updated on a referenced table. It appears that `sp_recompile` is available primarily for backward compatibility or for times when you want the recompilations to occur explicitly for all procedures referencing a specific table.

Using Dynamic SQL in Stored Procedures

SQL Server allows the use of the EXEC statement in stored procedures to execute dynamic SQL statements. This capability allows you to do things such as pass in object names as parameters and dynamically execute a query against the table name passed in, as in the following example:

```
IF EXISTS ( SELECT * FROM sys.procedures
            WHERE schema_id = schema_id('dbo')
            AND name = N'get_order_data')
    DROP PROCEDURE dbo.get_order_data
GO
create proc get_order_data
(@table varchar(30), @column varchar(30), @value int)
as
declare @query varchar(255)

select @query = 'select * from ' + @table
            + ' where ' + @column
            + ' = ' + convert(varchar(10), @value)

EXEC (@query)

return
```

This feature can be useful when you have to pass a variable list of values into a stored procedure. The string contains a comma-separated list of numeric values or character strings, just as they would appear inside the parentheses of an IN clause. If you are passing character strings, you need to be sure to put single quotation marks around the values, as shown in Listing 44.14.

LISTING 44.14 Passing a Variable List of Values into a Stored Procedure

```
IF EXISTS ( SELECT * FROM sys.procedures
            WHERE schema_id = schema_id('dbo')
            AND name = N'find_books_by_type')
    DROP PROCEDURE dbo.find_books_by_type
GO
create proc find_books_by_type @typelist varchar(8000)
as

exec ('select title_id, title = substring(title, 1, 40), type, price
      from titles where type in ('
      + @typelist + ') order by type, title_id')
go
```

```
set quoted_identifier off
exec find_books_by_type "'business', 'mod_cook', 'trad_cook'"
go
```

When using dynamic SQL in stored procedures, you need to be aware of a few issues:

- ▶ Any local variables that are declared and assigned values in the constructed string within an EXEC statement are not available to the stored procedure outside the EXEC command. The lifespan of a local variable is limited to the context in which it is declared, and the context of the EXEC command ends when it completes. For a solution to passing values back out from a dynamic query, see the section “Using Output Parameters with `sp_executesql`,” later in this chapter.
- ▶ Any local variables that are declared and assigned values in the stored procedure can be used to build the dynamic query statement, but the local variables cannot be referenced by any statements within the EXEC string. The commands in the EXEC statement run in a different context from the stored procedure, and you cannot reference local variables declared outside the current context.
- ▶ Commands executed in an EXEC string execute within the security context of the user executing the procedure, not the execution context of the stored procedure. By default, if a user has permission to execute a stored procedure, that user also has implied permission to access all objects referenced in the stored procedure that are owned by the same person who created the stored procedure. However, if a user has permission to execute the procedure but hasn't explicitly been granted the permissions necessary to perform all the actions specified in the EXEC string, a permission violation occurs at runtime.
- ▶ If you issue a USE command to change the database context in an EXEC statement, it is in effect only during the EXEC string execution. It does not change the database context for the stored procedure (see Listing 44.15).

```

exec sp_executesql N'select title_id, title = substring(title, 1, 40),
    type, price from bigpubs2008.dbo.titles where type = @type',
    N'@type char(12)',
    @type = @type1
if @type2 is not null
    exec sp_executesql N'select title_id, title = substring(title, 1, 40),
        type, price from bigpubs2008.dbo.titles where type = @type',
        N'@type char(12)',
        @type = @type2
if @type3 is not null
    exec sp_executesql N'select title_id, title = substring(title, 1, 40),
        type, price from bigpubs2008.dbo.titles where type = @type',
        N'@type char(12)',
        @type = @type3
go

set quoted_identifier off
exec find_books_by_type2 'business', 'mod_cook', 'trad_cook'
go

```

title_id	title	type	price
BU1032	The Busy Executive's Database Guide	business	14.9532

TC7777	Sushi, Anyone?	trad_cook	14.3279

Note that the SQL command and parameter definition parameters to `sp_executesql` must be of type `nchar`, `nvarchar`, or `ntext`. Also, to ensure that the query plan is reused, make sure that the object names are fully qualified in the SQL command.

Using Output Parameters with `sp_executesql`

One important concept to remember about dynamic SQL is that it runs in a separate scope from the stored procedure that invokes it. This is similar to when a stored procedure executes another stored procedure. Because local variables are available only within the

current scope, a nested procedure cannot access a local variable declared in the calling procedure. Similarly, you cannot access a local variable declared outside the scope of a dynamic SQL statement. With stored procedures, you can work around this limitation by using input and output parameters to pass values into and out of a nested stored procedure.

If you use `sp_executesql` to execute dynamic SQL, you can use output parameters to pass values both into and out of the dynamic SQL query through local variables. As described in the previous section, the second parameter to `sp_executesql` is a comma-separated list that defines the parameters you will be using within the dynamic SQL statement. As with parameter definitions for a stored procedure, parameters passed to `sp_executesql` can also be defined as output parameters. To get the values back out, you define the parameter as an output parameter in the parameter list and then specify the `OUTPUT` keyword when passing the variable in the corresponding argument list for `sp_executesql`.

Listing 44.17 shows an example of a stored procedure that uses `sp_executesql` to execute a dynamic SQL query and return a value via an output parameter. You can use the parameters inside the dynamic SQL–like parameters inside a stored procedure. Any values assigned to output parameters within the dynamic SQL query are passed back to the local variable in the calling procedure.

LISTING 44.17 Using Output Parameters in **sp_executesql**

```

IF EXISTS ( SELECT * FROM sys.procedures
            WHERE schema_id = schema_id('dbo')
            AND name = N'get_avg_price')
    DROP PROCEDURE dbo.get_avg_price
GO
create proc get_avg_price @dbname sysname,
                        @type varchar(12) = '%'
as

declare @dsql nvarchar(500),
        @avgval float

/*****
** build the dynamic query using the @avg and @type as
** variables, which will be passed in via sp_executesql
*****/
select @dsql = 'select @avg = avg(isnull(price, 0)) from '
            + @dbname+ '..titles '
            + 'where type like @type'

/*****
** submit the dynamic query using sp_executesql, passing type
** as an input parameter, and @avgval as an output parameter
** The value of @avg in the dynamic query will be passed
** back into @avgval
*****/

```

```

*****/
exec sp_executesql @dsql, N'@avg float OUT, @type varchar(12)',
                  @avgval OUT, @type
print 'The avg value of price for the titles table'
      + ' where type is like ''' + @type
      + ''' in the ' + @dbname + ' database'
      + ' is ' + ltrim(str(@avgval, 9,4))

go

exec get_avg_price @dbname = 'bigpubs2008',
                  @type = 'business'

go

```

The avg value of price for the titles table where type is like 'business' in the bigpubs2008 database is 15.0988

```

exec get_avg_price @dbname = 'bigpubs2008',
                  @type = DEFAULT

go

```

The avg value of price for the titles table where type is like '%' in the bigpubs2008 database is 0.3744

Installing and Using .NET CLR Stored Procedures

Prior to SQL Server 2005, the only way to extend the functionality of SQL Server beyond what was available using the T-SQL language was to create extended stored procedures or COM components. The main problems with these types of extensions were that if not written carefully, they could have an adverse impact on the reliability and security of SQL Server. Besides extended stored procedures and COM components, in SQL Server, the only language the stored procedures could be written in was T-SQL. Unfortunately, T-SQL has a somewhat limited command set for things such as complex string comparison and manipulation and complex numeric computations.

In SQL Server 2005 and later, you can create stored procedures in any Microsoft .NET Framework programming language, such as Microsoft Visual Basic .NET or Microsoft Visual C#. Stored procedures written in the common language runtime (CLR) are much more secure and reliable than extended stored procedures or COM components.

For information on the methods and tools for actually creating and compiling CLR stored procedures, see Chapter 46, “Creating .NET CLR Objects in SQL Server 2008.” In this chapter, we focus only on how to install and use CLR procedures in a SQL Server database.

NOTE

The CLR procedure examples presented subsequently in this chapter are provided as illustrations only. The sample code will not execute successfully because the underlying CLR assemblies have not been provided.

Adding CLR Stored Procedures to a Database

If you've already created and compiled a CLR stored procedure, the next step is to install that CLR procedure in the database. The first step in this process is to copy the .NET assembly to a location that SQL Server can access and then load it into SQL Server by creating an assembly. The syntax for the `CREATE ASSEMBLY` command is as follows:

```
CREATE ASSEMBLY AssemblyName [AUTHORIZATION LoginName]
FROM StringPathToAssemblyDll
[WITH PERMISSION_SET (SAFE | EXTERNAL_ACCESS | UNSAFE) ]
```

AssemblyName is the name of the assembly, and *StringPathToAssemblyDll* is the path to the DLL. The path can be a local path, but often this path is a network share.

The `WITH` clause is optional, and it defaults to `SAFE`. Marking an assembly with the `SAFE` permission set indicates that no external resources (for example, the Registry, web services, file I/O) will be accessed.

The `CREATE ASSEMBLY` command fails if it is marked as `SAFE` and assemblies such as `System.IO` are referenced, and anything causing a permission demand for executing similar operations results in an exception being thrown at runtime.

Marking an assembly with the `EXTERNAL_ACCESS` permission set tells SQL Server that it will be using resources such as networking, files, and so forth. Assemblies such as `System.Web.Services` (but not `System.Web`) may be referenced with this set. To create an `EXTERNAL_ACCESS` assembly, the creator must have `EXTERNAL_ACCESS` permission.

Marking an assembly with the `UNSAFE` permission set tells SQL Server that not only might external resources be used, but unmanaged code may be invoked from managed code. An `UNSAFE` assembly can potentially undermine the security of either SQL Server or the CLR. Only members of the `sysadmin` role can create `UNSAFE` assemblies.

After an assembly has been created, the next step is to associate the method within the assembly with a stored procedure. This is done with the `CREATE PROCEDURE` command, using the following syntax:

```
CREATE PROCEDURE [ schema_name. ] procedure_name
    ( [ { @parameter_name [AS] [ schema_name. ]scalar_datatype [ = default ] }
      [ ,...n ] ] )
    [ AS ] EXTERNAL NAME assembly_name.class_name.method_name
```

After the CLR procedure has been created successfully, it can be used just like a T-SQL stored procedure. The following example shows how to manually deploy a CLR stored procedure:

```

CREATE ASSEMBLY pr_address_verify
FROM 'F:\assemblies\address_routines\address_procs.dll'
WITH PERMISSION_SET = SAFE
GO
CREATE PROCEDURE pr_address_verify (@address1 nvarchar(100),
                                   @address2 nvarchar(100),
                                   @city varchar(50),
                                   @state char(2),
                                   @zip char(9))
AS
EXTERNAL NAME [SQLCLR].[Routines.StoredProcedures].[address_verify]
go

```

NOTE

The preceding examples show the manual steps of registering an assembly and creating the CLR function. If you are using Visual Studio's Deploy feature, Visual Studio automatically issues the CREATE/ALTER ASSEMBLY and CREATE PROCEDURE commands. For more details on using Visual Studio to create and deploy user-defined CLR functions, see Chapter 46.

T-SQL or CLR Stored Procedures?

One question that often comes up is whether it's better to develop stored procedures in T-SQL or in the CLR. The best answer is that the method you choose really depends on the situation and what functionality the procedure needs to implement.

The general rule is that if the stored procedure will be performing data access or large set-oriented operations with little or no complex procedural logic, it's better to create the procedure in T-SQL for best performance. The reason is that T-SQL works more closely with the data and doesn't require multiple transitions between the CLR and the SQL OS.

However, most benchmarks have shown that the CLR performs better than T-SQL for procedures that require a high level of computation or text manipulation. The CLR offers much richer APIs that provide capabilities not available in T-SQL for operations such as text manipulation, cryptography, I/O operations, data formatting, and invocation of web services. For example, T-SQL provides only rudimentary string manipulation capabilities, whereas .NET supports capabilities such as regular expressions, which are much more powerful for pattern matching and replacement than the T-SQL `replace()` function.

In a nutshell, performance tests have shown that T-SQL generally performs better for standard CRUD (create, read, update, delete) operations, whereas CLR code performs better for complex math, string manipulation, and other tasks that go beyond data access.

Using Extended Stored Procedures

If you've worked with versions of SQL Server prior to SQL Server 2005, you are probably familiar with extended stored procedures. These stored procedures reside in the master database and have names that begin with `xp_`. Extended stored procedures are invoked and managed similarly to regular stored procedures. You can grant and revoke permissions on extended stored procedures as you do for normal stored procedures. Although extended stored procedures reside in the master database like system procedures, the procedure name has to be fully qualified with the master database name when it is invoked from a database other than master, as in the following example:

```
use bigpubs2008
go
exec master..xp_fixeddrives
```

Extended stored procedures are not built with T-SQL commands; instead, they map to a function stored in a DLL. Historically, extended stored procedures were the mechanism available to extend SQL Server functionality. However, the introduction of CLR procedures provides a much easier, safer way to extend the functionality of SQL Server 2008.

Extended stored procedures are typically written in Microsoft C or Visual C++, using the Microsoft Extended Stored Procedure API, and coding them can be quite complex. In addition, extended stored procedures run under the same security context as SQL Server and within the same address space. A poorly written extended stored procedure could bring down the SQL Server service. CLR procedures, in contrast, are written in .NET code that is type safe and runs within the Appdomain boundary so it cannot access random SQL Server memory locations. In other words, it is much easier and safer to create and deploy CLR procedures than extended stored procedures.

TIP

Because of the unsafe nature of extended stored procedures, and the greater security and capabilities of CLR stored procedures, extended stored procedures are a feature that will very likely be removed in some future version of Microsoft SQL Server. For new development efforts, you should use CLR procedures instead of extended stored procedures. In addition, you should make plans to convert any existing applications that currently use extended stored procedures to use CLR procedures instead.

Adding Extended Stored Procedures to SQL Server

If you happen to have a DLL that contains one or more extended stored procedures you need to add to SQL Server, you can use the `sp_addextendedproc` system stored procedure. Only SQL Server system administrators can add extended stored procedures to SQL Server. The syntax is as follows:

```
sp_addextendedproc [ @funcname = ] 'procedure' , [ @dllname = ] 'dll'
```

Extended stored procedures are added only in the master database. The `sp_addextended` procedure adds an entry for the extended stored procedure to the system catalogs and registers the DLL with SQL Server. You must provide the complete path for the DLL when registering it with SQL Server.

To remove an extended procedure from SQL Server, you use `sp_dropextendedproc`:

```
sp_dropextendedproc [ @funcname = ] 'procedure'
```

CAUTION

Because extended stored procedure DLLs and SQL Server share the same address space, poorly written extended procedure code can adversely affect SQL Server functioning. Any memory access violations or exceptions thrown by an extended stored procedure could possibly damage SQL Server data areas. For this reason, it is strongly recommended that CLR procedures be considered as an alternative to extended stored procedures. If there is some compelling reason to use extended stored procedures, they should be thoroughly tested and verified before they are installed.

Obtaining Information on Extended Stored Procedures

To obtain information on the extended stored procedures in SQL Server, you use `sp_helpextendedproc` as follows:

```
sp_helpextendedproc [ [ @funcname = ] 'procedure' ]
```

If the procedure name is specified, `sp_helpextendedproc` lists the procedure name along with the DLL invoked when the extended stored procedure is executed. If no procedure name is passed in, `sp_helpextendedproc` lists all extended stored procedures defined in SQL Server and their associated DLLs.

Extended Stored Procedures Provided with SQL Server

Most of the extended stored procedures that ship with SQL Server are undocumented. All extended stored procedures (or rather, the references to them) are stored in the master database. You can display them in SSMS under the master database. To do so, you open the Programmability folder for the master database and then open the Extended Stored Procedures folder. The provided extended stored procedures are listed in the System Extended Stored Procedures folder.

If you plan to use an undocumented extended stored procedure, be careful. First, you have to find out what it does and what parameters it takes. You should also be aware that Microsoft does not support the use of undocumented extended stored procedures. Moreover, an undocumented procedure might not be included in a later version of SQL Server, or if it is included, it might behave differently than it does now.

Table 44.2 lists the general categories of extended stored procedures.

TABLE 44.2 Extended Stored Procedures Categories

Category	Description
General extended procedures	Provide general functionality. Perhaps the most useful is <code>xp_cmdshell</code> , which executes external programs and returns the output from them as a result set.
SQL Mail extended procedures	Enable you to perform email operations from within SQL Server.
SQL Server Profiler extended procedures	Are used by SQL Server Profiler. They can also be used directly, for instance, to create a trace queue and start the trace from within a stored procedure.
OLE automation procedures	Allow SQL Server to create and use OLE automation objects.
API system stored procedures	Are undocumented extended stored procedures used by the API libraries. The server cursor functionality, for instance, is implemented as a set of extended stored procedures.

Using `xp_cmdshell`

One of the most useful, and potentially dangerous, extended stored procedures provided with SQL Server 2008 is `xp_cmdshell`. `xp_cmdshell` can execute any operating system command or program available on the SQL Server system, as long as it is a console program that doesn't require user input. `xp_cmdshell` accepts a `varchar(8000)` (or `nvarchar(4000)`) value as the command string to be executed, and it returns the results of the command as a single `nvarchar(255)` column. The full syntax of `xp_cmdshell` is as follows:

```
xp_cmdshell { 'command_string' } [ , no_output ]
```

If the `no_output` option is specified, the results from the command are not displayed.

The following example uses `xp_cmdshell` to list the files in a directory on the SQL Server computer's hard disk:

```
EXEC xp_cmdshell 'DIR c:\*.*'
```

`xp_cmdshell` runs synchronously. Control is not returned to the SQL Server user session until the shell command completes. This is why you have to ensure that the shell command invoked via `xp_cmdshell` does not prompt for user input. Commands invoked via `xp_cmdshell` do not run interactively, so there is no way to respond to the user input prompt. The SQL Server session waits indefinitely for a command invoked via `xp_cmdshell` to return.

CAUTION

After SQL Server passes off the `xp_cmdshell` command to the operating system, SQL Server cannot interact with the command. If the command requires user input, the process waits indefinitely, and it usually doesn't go away without a fight. Killing the process in SQL Server usually just leaves it in a KILLED/ROLLBACK state. Closing the session that invoked the `xp_cmdshell` statement doesn't help either. Sometimes, you might have to stop and restart SQL Server to make the process finally go away. Alternatively, you may be able to use Task Manager on the system where SQL Server is running to identify the system process that corresponds to the process invoked by `xp_cmdshell` and end the process.

If `xp_cmdshell` is invoked from another database, it has to be fully qualified as `master..xp_cmdshell`. Unlike with system procedures, SQL Server doesn't automatically look for extended stored procedures in the `master` database.

Because of the potentially dangerous nature of `xp_cmdshell` (it essentially allows a user to run operating system-level commands on the SQL Server machine), it is disabled by default. To enable `xp_cmdshell`, you must run the following commands:

```
EXEC sp_configure 'show advanced options', 1
GO
RECONFIGURE
GO
-- To enable the feature.
EXEC sp_configure 'xp_cmdshell', 1
GO
RECONFIGURE
GO
```

As an additional security measure in SQL Server 2008, by default, permission to execute `xp_cmdshell` is limited to users with `CONTROL SERVER` permission. The Windows process spawned by `xp_cmdshell` runs within the security context of the account under which the SQL Server service is running. Essentially, it has the same security rights as the SQL Server service account.

When `xp_cmdshell` is invoked by a user who is not a member of the `sysadmin` fixed server role, it fails unless a proxy account has been set up. A *proxy account* is a Windows account that a system administrator defines and sets a security context for within the Windows environment. When a user who is not a member of the `sysadmin` group runs `xp_cmdshell`, the commands are run within the security context of the defined proxy account.

The proxy account for `xp_cmdshell` can be created by executing `sp_xp_cmdshell_proxy_account`. The syntax of this command is as follows:

```
sp_xp_cmdshell_proxy_account [ NULL | { 'account_name' , 'password' } ]
```

For example, the following command creates a proxy credential for the Windows domain user Developer\tom that has the Windows password ss2k5Un1:

```
sp_xp_cmdshell_proxy_account 'Developer/tom' , 'ss2k5Un1'
```

If NULL is passed as *account_name*, the proxy credential is deleted.

CAUTION

Because of the potential havoc that could be wreaked on your database server if `xp_cmdshell` got into the wrong hands, it is recommended that the capability to run `xp_cmdshell` be left disabled. If you must use `xp_cmdshell`, be very careful about who has access to it by limiting it to only those with `sysadmin` permissions if at all possible. If for some reason `xp_cmdshell` must be made available to all users, be sure that the permissions granted to the proxy account are restricted to the minimum permissions required to perform the commands that need to be invoked via `xp_cmdshell`.

Summary

Stored procedures in SQL Server can be very powerful, especially when they take advantage of the many features of the T-SQL language. Very complex tasks can be simplified into a single stored procedure call. The guidelines and tips presented in this chapter should help you create more powerful, efficient, and robust stored procedures.

Additionally, with the ability to create .NET CLR stored procedures, you can write even more powerful stored procedures in languages other than T-SQL to further expand the capabilities and power of the stored procedures that reside in SQL Server.

CHAPTER 45

SQL Server and the .NET Framework

IN THIS CHAPTER

- ▶ What's New in SQL Server 2008 and the .NET Framework
- ▶ Getting Comfortable with ADO.NET 3.5 and SQL Server 2008
- ▶ Developing with LINQ to SQL
- ▶ Using ADO.NET Data Services
- ▶ Leveraging the Microsoft Sync Framework

This chapter examines the deep integration of the .NET Framework with SQL Server 2008. It first teaches the essentials of programming with ADO.NET 3.5, then it jump-starts your LINQ to SQL skills, and finally it delves into ADO.NET Data Services (formerly *Astoria*) and the Microsoft Sync Framework.

What's New in SQL Server 2008 and the .NET Framework

The release of the .NET Framework 3.5 includes a number of exciting new SQL Server features, the most compelling of which is Language-Integrated Query (LINQ). LINQ to SQL is a timesaving and powerful technology that enables developers to write code in either C# or VB .NET, rather than T-SQL, to query SQL Server databases.

ADO.NET Data Services is another new technology that makes it easy to work with SQL Server data in web applications, websites, Rich Internet Applications (RIAs), and other programs that need to consume data from the Web. This chapter shows you how to get started with a simple web application that exposes your data over HTTP.

Finally, this chapter covers the Microsoft Sync Framework and how to use it for your occasionally connected applications.

Getting Comfortable with ADO.NET 3.5 and SQL Server 2008

You need to familiarize yourself with the following primary .NET Framework namespaces to be able to program against SQL Server 2008:

- ▶ **System.Data** —This is the root namespace, which contains essential data access classes, such as `DataSet`, `DataTable`, and `DataRow`.
- ▶ **System.Data.SqlClient** —This namespace contains classes specialized for SQL Server access, such as `SqlConnection`, `SqlCommand`, and `SqlParameter`.
- ▶ **System.Xml** —This namespace holds most of the objects you need to be able to work with SQL Server XML.
- ▶ **System.Linq** and **System.Data.Linq** —These namespaces hold classes essential for working with LINQ to SQL (stored in the new `System.Core` assembly).

The easiest way to immerse yourself in the code is to walk through some typical usage scenarios, which we do in the following sections.

ADO.NET: Advanced Basics

To start coding with ADO.NET and SQL Server, you first need to connect to an instance of SQL Server. To do this, you need a connection string. A *connection string* is simply a string literal that contains all the parameters necessary to locate and log in to a server in a semi-colon-delimited format. The following is an example:

```
"Data Source=(SQLServer001);Initial Catalog=AdventureWorks2008;Integrated Security=True"
```

This connection string tells ADO.NET to connect to a server called `SQLServer001`, change to the `AdventureWorks2008` database context, and use integrated Windows security to connect, which means it should use the credentials of the currently authenticated user (in web applications, this is usually ASPNET, unless impersonation is used). You typically want to store this connection string in your application's `.config` file, preferably encrypted.

There are too many different connection string parameters to list here; you can check the MSDN "Connection Strings" topic for full information.

The managed object that represents a SQL Server connection is `System.Data.SqlClient.SqlConnection`.

This chapter takes you through a simple C# Windows application built with Visual Studio 2008 (VS). It contains every manager's dream: a form with a magic button on it that does everything with one click. To create this application, open Visual Studio and create a new C# Windows Forms application (illustrated in Figure 45.1). Right-click the file called `Form1.cs` in Solution Explorer (SE) and select `Rename`. Change the name to `MainForm.cs`

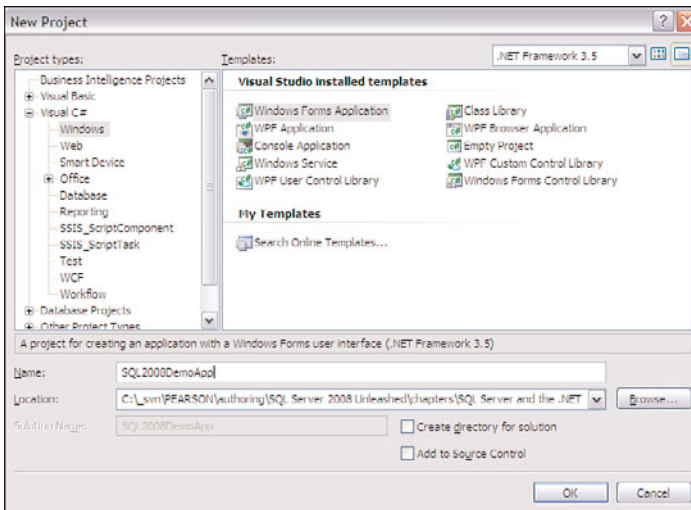

FIGURE 45.1 Creating a new C# Windows Forms application with Visual Studio 2008.

and accept the rename warning. Next, right-click `MainForm.cs` again and select `View Code`. Then type the following namespaces into the using area at the top left:

```
using System.Data.SqlClient;
using System.Configuration;
```

Next, right-click the `References` folder in the Solution Explorer and choose `Add Reference`. On the ensuing `Add Reference` dialog, click on the `.NET` tab and then scroll down until you find `System.Configuration`. Select this entry and click `OK`. Next, right-click the project in the Solution Explorer and choose `Add New Item`; then scroll through the choices that appear in the `Add New Item` dialog until you find `Application Configuration File`. This file is the place where you typically store connection strings and other configurable parameters. Open your new `App.Config` file and enter the following elements, substituting your server name for `(local)` in the connection string itself:

```
<?xml version="1.0" encoding="utf-8" ?>
<configuration>
  <appSettings>
    <add
      key="SqlConn"
      value="Data Source=(local);Initial Catalog=AdventureWorks2008;
Integrated Security=True"/>
    </appSettings>
  </configuration>
```

Switching back to `MainForm.cs`, right-click the file in Solution Explorer and then select View Designer, which launches the Visual Studio WinForms designer. Drag a Button control from the Toolbox onto the form and name it `btnGo`. Next, drag a `DataGridView` control onto the form and name it `GridView` (ignore the form designer's SmartTag); this control will be used to display the data returned when you execute your `SqlCommand`. The `SqlCommand` object allows you to execute T-SQL, including stored procedures, functions, and other expressions from within the context of an active SQL Server connection.

`SqlCommand` has several execution methods, each of which behaves differently and returns a different type of object:

- ▶ **ExecuteNonQuery**—Executes the T-SQL statements and returns an `Int32` that indicates the number of rows affected. It also populates any output parameters. This capability is especially useful when you are executing `INSERT` and `UPDATE` queries.
- ▶ **ExecuteScalar**—Executes the T-SQL statements and returns an object (of type **Object**) that contains the value of the first column of the first row returned. The object returned is castable to one of the native .NET types (for example, `Int32`, `String` [even for returned `xml` columns], `Boolean`).
- ▶ **ExecuteReader**—Executes the T-SQL statements and returns a `SqlDataReader` object. `SqlDataReader` objects are useful when you want to perform some behavior on the returned result set on a per-row and/or per-column basis (usually using a looping construct).
- ▶ **ExecuteXmlReader**—Executes the T-SQL statements and returns a `System.Xml.XmlReader`, which you can use to iterate through the nodes in selected XML (or to instantiate other `System.Xml` objects, such as `System.Xml.XPath.XPathDocument`), produced either via `SELECT...FOR XML` or from a column or variable of the new `xml` data type.

TIP

`System.Data.SqlClient` also provides asynchronous versions of the preceding method calls in begin-call/end-call pairs that take a handy callback method parameter, including `BeginExecuteReader`, `EndExecuteReader`, `BeginExecuteNonQuery`, and `EndExecuteNonQuery`. Note that there is no `BeginExecuteScalar/EndExecuteScalar`.

To wire up the data returned from the `SqlCommand` into a `System.Data.DataSet` (the storage object for returned results), you need to use an object of type `System.Data.SqlClient.SqlDataAdapter`. Developers frequently use `SqlDataAdapter` objects to map data coming from SQL Server into `DataSet` objects and back, using its `Fill()` and `Update()` methods, respectively.

You may also want to include in your code a try-catch exception-handling block that catches any `SqlException` objects thrown during your code's execution.

To test the many classes we've just mentioned, add the code in Listing 45.1 to the `btnGo_Click()` event handler. To generate the event handler, simply view your form in the Visual Studio designer and then double-click your button.

LISTING 45.1 A Button Event Handler That Illustrates the Use of Several ADO.NET Objects

```
private void btnGo_Click(object sender, EventArgs e)
{
    using (SqlConnection Connection =
        new SqlConnection(ConfigurationManager.AppSettings["SqlConn"]))
    {
        using (SqlCommand Command =
            new SqlCommand(
                @"SELECT TOP 10 * FROM Person.Person"
                , Connection))
        {
            try
            {
                using (SqlDataAdapter Adapter =
                    new SqlDataAdapter(Command))
                {
                    using (DataSet Set = new DataSet())
                    {
                        Connection.Open();
                        Adapter.Fill(Set);
                        GridView.DataSource = Set.Tables[0];
                    }
                }
            }
            catch (SqlException SqlEx)
            {
                foreach (SqlError SqlErr in SqlEx.Errors)
                {
                    MessageBox.Show(
                        "The following SQL Error occurred: " + SqlErr.Message,
                        "SqlError");
                }
            }
        }
    }
}
```

Next, run your Windows Forms application (press F5) and then click `btnGo`. Your form should look something like the one in Figure 45.2.

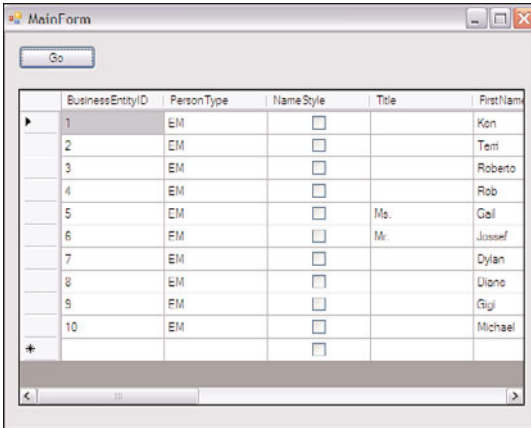

FIGURE 45.2 Using ADO.NET in a simple Windows Forms application.

This code in your form executes as follows: a connection to SQL Server is made via `SqlConnection` and the subsequent call to `Connection.Open()` (which, by the way, is unnecessary because `SqlDataAdapter.Fill()` implicitly opens the closed connection). The `SqlCommand` object `Command` is set to use this connection via its constructor. The constructor also takes a string parameter that contains the text of the query. It can also take the name of a stored procedure, for example. When using a stored procedure name, you change its `CommandType` property from the default of `CommandType.Text` to `CommandType.StoredProcedure`.

Next, you instantiate a `SqlDataAdapter` object that registers the `Command` object as what it will execute on the call to `Fill()`. You also create a `DataSet` object to hold the returned data. In the simplest respect, `DataSet` objects are collections of `DataTable` objects, which map directly to SQL Server query results. Each `DataTable` object, as you may guess, holds an array of `DataRow` objects, each of which in turn holds an array of `DataColumn` values accessible by indexes.

You bind the `DataGridView` object to the filled `DataSet` object's first table (`Tables[0]`), and you can rest assured that the catch block will notify you with a message box about each `SQLException` contained in the `Errors` collection of any raised `SQLException`.

NOTE

One convention used in the code in this chapter is nested using statements with these objects. When you use this C# syntax convention, you don't have to set up a finally block that calls `Dispose()` for every object; using does that implicitly for you.

Many of the database classes provided in ADO.NET have a `Dispose()` method because, under the covers, they utilize unmanaged (COM) resources. The objects you most commonly use for database applications that provide `Dispose()` are `SqlConnection`, `SqlCommand`, `SqlDataAdapter`, `SqlDataReader`, and `DataSet`.

Now that you've had a taste of working with some of the traditional ADO.NET objects, it's time to forge ahead into the new world of LINQ.

Developing with LINQ to SQL

LINQ enables developers to write code in either C# or VB.NET using the same set of syntactic conventions to query object collections (known as *LINQ to Objects*), XML documents (known as *LINQ to XML*), SQL Server data (known as *LINQ to SQL*), and other queryable resources. The focus in the following sections is exclusively on LINQ to SQL.

A LINQ to SQL statement is translated into an in-memory data structure known as an *expression tree*. An expression tree is an abstract representation of executable code. These trees provide a means for translating LINQ expressions into something else—in the case of LINQ to SQL, T-SQL statements. Once translated into T-SQL, the code is executed on SQL Server (not in .NET). This point is important because it highlights the fact that LINQ is independent from its various data providers.

Another important point is that the T-SQL produced by LINQ is not executed until the moment in your .NET code when your LINQ to SQL query is first utilized, not where it is first defined. You may, for example, declare a LINQ to SQL statement near the top of your .NET method but then only actually use it in one branch of an `if-else` block. This provides enormous efficiency.

We should also mention that a certain amount of trust is involved in using LINQ to SQL because it requires you to accept the fact that Microsoft's LINQ team has made most of the right decisions in doing this translation work (and it has). This does not mean that, as a .NET developer, you no longer need to learn T-SQL; on the contrary, there is much more to T-SQL that LINQ simply doesn't do, and you will run into its limitations if you use it a lot. It does mean, however, that you can save an immense amount of time in developing data-driven applications because you no longer have to do the repetitive work of writing T-SQL stored procedures for every simple create, retrieve, update, and delete (CRUD) query.

Getting Started

To start with LINQ to SQL, launch Visual Studio 2008, then right-click your sample project in Solution Explorer, and choose Add New Item. Click on the Data folder on the left side of the ensuing dialog and then select the LINQ to SQL Classes item on the right. Name your new file `AdventureWorks2008` and click OK (illustrated in Figure 45.3).

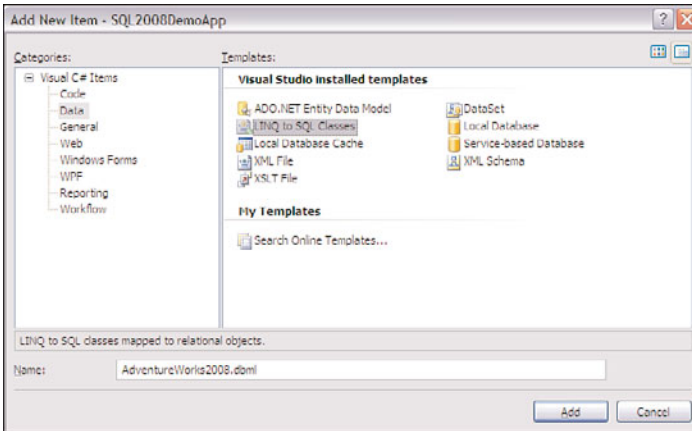

FIGURE 45.3 Adding a LINQ to SQL classes file to your Windows Forms sample application.

After your new `.dbml` file is created in your project, Visual Studio's Object/Relational (O/R) Designer opens up with its blank surface ready. On this surface, you add C# data classes that mirror the tables and relationships in your database. This is the heart of what is known as *object/relational mapping* (ORM): each class represents a database table. Each instance of that class represents a row in that table. Each property on each instance represents either a column and its value, or a collection of related (via ORM) objects. Changes to these object instances (including updates, insertions, and deletions) once committed, are reflected as changes to the underlying rows in your tables. LINQ to SQL operates on these ORM objects, which are defined in the code of your `.dbml` file.

Using Visual Studio's View menu, open Server Explorer. Right-click its root node and select Add Connection. Fill out the form to set up a connection to your `AdventureWorks2008` database. When done, navigate to that new node in Server Explorer (it is named `[ServerName]\[InstanceName].AdventureWorks2008.[SchemaName]`). (This new node should have a tiny image of a plug on its icon.) Expand this node and then expand the Tables node to view the tables in your database.

Shift-click the following table nodes in Server Explorer and then drag them all to your O/R Designer surface and release the mouse button (answer Yes to the ensuing warning dialog):

- ▶ Product (Production)
- ▶ ProductModel (Production)
- ▶ ProductInventory (Production)
- ▶ ProductReview (Production)

Your O/R Designer surface should now look something like the one in Figure 45.4.

The best way to introduce any new technology is with sample code, so let's jump right in and write a LINQ to SQL query.

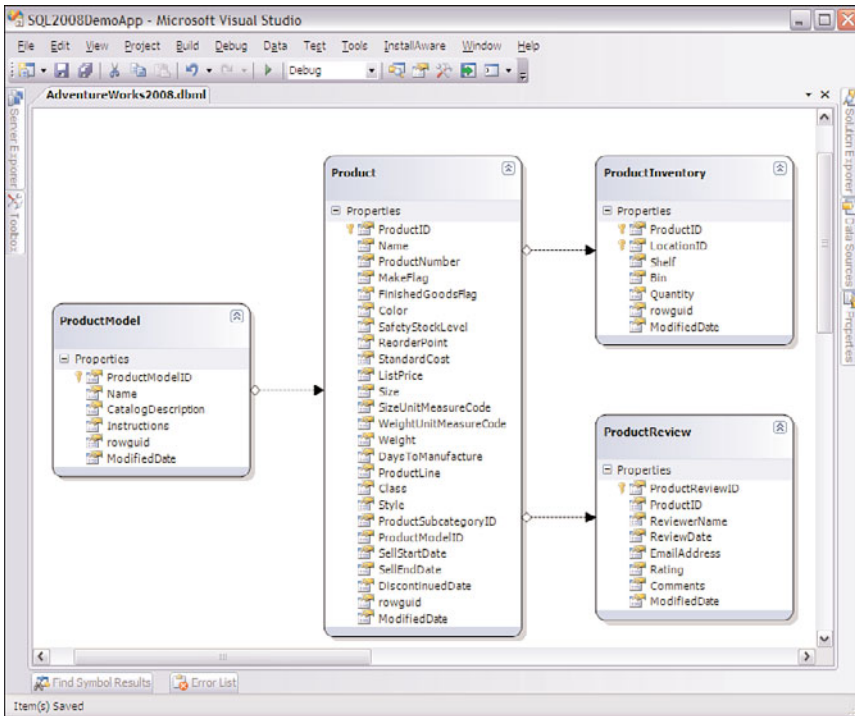

FIGURE 45.4 Viewing Visual Studio's O/R Designer surface for the Windows Forms sample application.

Right-click your Windows Forms project in Solution Explorer and then click Add Class. Name your new class LINQExamples.cs and then add the code from Listing 45.2 into its body.

LISTING 45.2 Your First LINQ to SQL Query

```
public List<Product> GetProductsById(int ProductId)
{
    AdventureWorks2008DataContext Context =
        new AdventureWorks2008DataContext();

    var query =
        from p in Context.Products
        where p.ProductID == ProductId
        select p;

    return query.ToList();
}
```

Going Deeper

LINQ requires an understanding of *generics* (introduced in .NET 2.0), which provide a means of working with classes in a type-independent manner. That is, a generic class provides methods and properties just like any other class; however, it also has a type parameter that enables users of that class to supply a type at runtime that the algorithms in the class will then operate on. In Listing 45.2, for example, the return type of `GetProductsById` uses the generic Framework class `System.Collections.Generic.List<T>`, substituting `Product` as a type parameter for `T`.

When working with LINQ to SQL, you also use the new `var` keyword, which indicates that the named variable is *implicitly typed*. This means that the compiler will infer the type of the statement on the right by walking down the expression at compile time. In many cases, your LINQ statements end up being implicitly typed as `System.Linq.IQueryable<T>`. This generic class stores the abstract expression tree that will be translated (at execution time) to T-SQL, information about the query provider (in this case SQL Server), as well as the enumerable collection itself that provides access to the data the query returns.

`IQueryable<T>` itself derives from `System.Collections.Generic.IEnumerable<T>`. One reason for this is that, under the hood, the compiler converts the query syntax used in Listing 45.2 to actually use generic query operators defined as *extension methods* to `IEnumerable<T>`, including `Select`, `Where`, `OrderBy`, `Distinct`, and so on. (Extension methods provide a means of adding methods to classes that are otherwise *sealed*, that is, noninheritable). This means that the query in Listing 45.2 could also have been written as

```
var query = Context.Products.Where(p => p.ProductID == ProductId);
```

Because of their common return type (`IEnumerable<T>`), LINQ's extension methods may be chained together. For example:

```
var query =
    Context.Products.Where(p => p.ProductID == ProductId).OrderBy(p =>
        p.ProductID).Distinct();
```

The parameter to the `Where` and `OrderBy` methods shown here is built on another new construct called a *lambda expression*, which is an anonymous function that can be cast to a delegate (such as `System.Func<T, TResult>`, the delegate type required by the input parameter to the extension method `Where`). Lambda expressions take the form *input parameters => expression*, where the lambda operator `=>` is read as “goes to.” (For more information, refer to the MSDN article titled “Lambda Expressions.”) Put simply, these expressions provide a compact syntax for writing anonymous functions that you will use more often as you progress deeper in your knowledge of LINQ. For now, let's get back to the code in Listing 45.2.

First, in the method signature, you can see that `GetProductsById` takes an integral `ProductId` as input and returns a generic `List` of `Product` objects. What is a `Product`

object? It's a LINQ to SQL class instance that points (is object/relationally mapped) to a particular row in the `Production.Product` table.

You can think of a `Product` object as an “objectified” SQL Server row, insofar as its primitively typed properties are akin to SQL Server column values. It also has collection-backed properties that point to rows stored in the tables to which it is related. These specialized LINQ collections are of type `System.Data.Linq.EntitySet`. Let's examine the class definition of `Product` to see how this plays out.

Using Solution Explorer, expand the `AdventureWorks2008.dbml` file to reveal `AdventureWorks2008.designer.cs`. This code file contains all the ORM logic needed to use LINQ to SQL with your database. Double-click this file and, using the drop-down at the top left of your code editor window, select `[YourProjectName].Product`.

Above your class's name, notice the `Table` attribute (attributes are .NET classes used to decorate other classes with information queryable at runtime). Its `Name` property reveals that the class it decorates is to be mapped to rows in `Production.Product`. As you scroll down, examine this class a bit more. Notice how its primitive properties map nicely to the columns of your table. Notice also how each property has its own `Column` attribute, signifying the specific SQL Server column to which it is mapped.

As we mentioned earlier, the `Product` class also has collection-backed properties, such as `ProductInventories` and `ProductReviews`. These properties represent the tables related (via primary and foreign keys) to `Product`. By using properties in your .NET code, you can navigate from a parent object in `Product` to a child object in `ProductInventories`, just like you would when writing T-SQL joins. Not surprisingly, each `Association` attribute found on your collection-backed properties denotes the direction of the navigational path from parent to child.

The glue that holds all this together is the `System.Linq.DataContext` class, represented in Listing 45.2 by your `Context` object (which is of type `AdventureWorks2008DataContext`). Put simply, `DataContext` is the ORM bridge or conduit from .NET to SQL Server and back.

At the top of your designer file, you can see that the `DBML` class inherits from `System.Data.Linq.DataContext`. Notice its mapping attribute, `Database`, which indicates that it is mapped to `AdventureWorks2008`. As the SQL Server conduit, you use the `DataContext` instance to select your object-mapped rows. Through it, you commit inserts, updates, and deletes to the underlying tables, by adding, changing properties of, and removing objects from its `System.Data.Linq.Table` collection's properties. These collections represent the tables you added to your O/R Designer's surface. And this is the real power of LINQ to SQL: no longer is it necessary to waste hours writing boilerplate T-SQL to perform simple database operations; you can get it all done with pure .NET code.

Let's look at a slightly more complex LINQ query that leverages the power of key-based relationships to select related database objects. In Listing 45.3, you add a new method to the sample class that gets a `List` of `ProductReview` objects for a given `Product`.

LISTING 45.3 Using Database Relationships to Select Related Objects with LINQ to SQL

```

public List<ProductReview>
    GetProductReviewsByProduct(Product MyProduct)
{
    AdventureWorks2008DataContext Context =
        new AdventureWorks2008DataContext();

    var query =
        from p in Context.Products
        join r in Context.ProductReviews
        on p.ProductID equals r.ProductID
        where p.ProductID == MyProduct.ProductId
        select r;

    return query.ToList();
}

```

Notice the join syntax introduced in this example. As you can see, it's a lot like T-SQL's INNER JOIN, and it performs the same basic function. The where clause in the example is also just like T-SQL's WHERE, except for the fact that you have to use C#'s == operator instead of T-SQL's =). The one big difference to pay attention to is that with LINQ your select statement comes last, and your from clause comes first. Remember that all the tables you want to select from are properties (System.Data.Linq.Table objects) of the DataContext object. Very simple, very powerful.

Uncovering LINQ to SQL with Linqpad

You may be curious about the T-SQL that LINQ is generating for this .NET expression. To reveal this mystery, you can use two tools: SQL Server Profiler and Linqpad. To use Profiler, launch the application from the Windows Start menu, create a new trace using the File menu (select New Trace), and connect to your database of choice. On the ensuing Trace Properties dialog, select the trace template called T-SQL_SPs, start the trace, and then run the LINQ statement found in Listing 45.3. The T-SQL that LINQ generates is revealed in the TextData column.

Alternatively, you can download and use the amazing Linqpad from <http://www.linqpad.net>. Visit the site and download Linqpad.exe. Save it to a folder that you will remember. As of this writing (version 1.35), Linqpad does not have or need an installation program; the download itself is the entire self-contained application.

After you download Linqpad, start it. Click on the Add Connection link at top left of the application's main window; then add a connection to your local server. Next, select the AdventureWorks2008 database using the drop-down at the top left. In the query window,

type the following LINQ statement (Hint: This is the same as shown in Listing 45.3, minus the method signature, input parameter, and Context object):

```
from p in Products
join r in ProductReviews
on p.ProductID equals r.ProductID
select r
```

Click the green arrow button or press F5. Your query results show up in a visually friendly tabular format in the results area below the query window. Notice just above the results area there is a button bar with four buttons: *Results*, Δ ; (lambda expression), *SQL*, and *IL*. You've seen what shows up with the default setting, *Results*. Δ ; reveals the underlying anonymous functions upon which LINQ relies. *IL* shows you the CLR Intermediate Language code that your LINQ expression generates. Finally, *SQL* shows the resultant T-SQL, of main concern to you now. Select *SQL* and press F5 again. Your results should match the code shown in Figure 45.5. You can also use the *Analyze SQL* menu option (above the results area) to jump into SSMS to run your query, or you can even run the T-SQL itself via Linqpad.

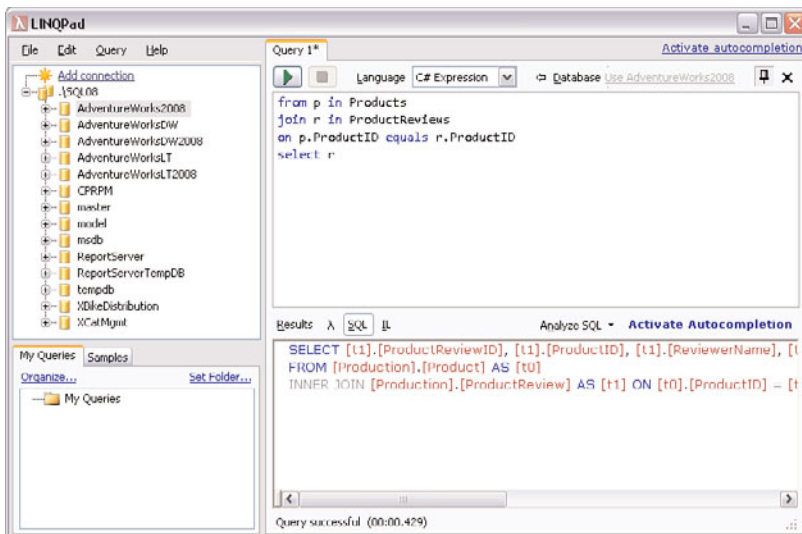

FIGURE 45.5 Viewing the T-SQL Generated by a LINQ Query with Linqpad.

Next, let's examine an insert query using LINQ to SQL, as shown in Listing 45.4.

LISTING 45.4 An Insert Query Using LINQ to SQL

```
public void AddProductReview(
    int ForProductId,
    string Comments,
    string Email,
    int Rating,
    string Reviewer
)
{
    AdventureWorks2008DataContext Context =
        new AdventureWorks2008DataContext();

    ProductReview NewReview =
        new ProductReview()
        {
            Comments = Comments,
            EmailAddress = Email,
            ModifiedDate = DateTime.Now,
            ProductID = ForProductId,
            Rating = Rating,
            ReviewDate = DateTime.Now,
            ReviewerName = Reviewer
        };

    Context.ProductReviews.InsertOnSubmit(NewReview);
    Context.SubmitChanges();

    //Check the new review ID:
    if (NewReview.ProductReviewID > 0)
    {
        Debug.WriteLine(
            string.Format(
                "Success! Added new ProductReview with ID#{0}",
                NewReview.ProductReviewID
            )
        );
    }
}
```

Let's go over this code in detail. First, you can see that the input parameters to the new `AddProductReview` method include a `ProductReviewId` as well as most of the properties that make up a row in `Production.ProductReview`. Next, using C#'s new `new` syntax, you instantiate a `ProductReview` object (`NewReview`) representing a row to be added to

`Production.ProductReview`. To make the insertion happen, you again rely on the `DataContext` object (`Context`). The syntax `Context.ProductReviews` indicates that the target table is `Production.ProductReview`.

When you call `InsertOnSubmit` with your `NewReview` object as its parameter, your new review is added to the table when you call `SubmitChanges` (one line further down in the example). After that call, you can check your object to see if its `ProductReviewID` property was magically populated due to the fact that the row was created in the database (because `ProductReviewID` is bound to the table's primary key, which is an auto-incremental identity column). LINQ is great in this way because it keeps the contents of your objects and data tables in sync.

The next listing, Listing 45.5, illustrates how to perform a delete using LINQ to SQL.

LISTING 45.5 Deleting Rows Using LINQ to SQL

```
public void DeleteProductReview(int ProductReviewId)
{
    AdventureWorks2008DataContext Context =
        new AdventureWorks2008DataContext();

    ProductReview Review
        = (from m in Context.ProductReviews
          where m.ProductReviewID == ProductReviewId
          select m).FirstOrDefault();

    if (Review != null)
    {
        using (TransactionScope Tran = new TransactionScope())
        {
            Context.ProductReviews.DeleteOnSubmit(Review);
            Context.SubmitChanges();
        }
    }
}
```

To run Listing 45.5, you need to add a reference to `System.Transactions` and then add a `using` statement for that namespace. This addition to the code illustrates one way to use transactions with LINQ and also preserves the integrity of your `AdventureWorks2008` data.

Going over the example, the `DeleteProductReview` method takes a `ProductReviewID` value as input. It then looks up that record using a LINQ query, just as you would in T-SQL. If the record was found (that is, if the query returns a non-null value), you then create a new transaction, in which you delete the record by calling `DeleteOnSubmit`. Note that because you do not call the `Complete` method of the `Tran` object, the transaction is implicitly rolled back.

Listing 45.6 rounds out our LINQ examples by showing you how to update a set of rows.

LISTING 45.6 Updating Rows Using LINQ to SQL

```
public void UpdateProductInventories(int Threshold, short NewQty)
{
    AdventureWorks2008DataContext Context =
        new AdventureWorks2008DataContext();

    List<ProductInventory> InventoryItems
        = (from m in Context.ProductInventories
           where m.Quantity < Threshold
           select m).ToList();

    if (InventoryItems.Count > 0)
    {
        using (TransactionScope Tran = new TransactionScope())
        {
            foreach (ProductInventory Item in InventoryItems)
            {
                Item.Quantity = NewQty;
            }

            Context.SubmitChanges();
        }
    }
}
```

In this listing, the query operates on a range of rows, rather than just one. Using LINQ's ORM magic, you select rows from `Production.ProductInventory` as a `List` of `ProductInventory` by matching your `Threshold` criterion against the current `Quantity` value of objects in `DataContext.ProductInventories`. (Notice how LINQ even performs grammatically correct pluralization of table names.) You iterate through each returned object (again, within the scope of a transaction so as to keep `AdventureWorks2008` intact) and then update the `Quantity` for each. Then you submit your changes. Very simple, very powerful, very much a timesaver.

Although this LINQ to SQL primer covers the essentials, we highly recommend you dive deeper into the .NET namespaces you've seen to uncover all the possibilities LINQ to SQL has to offer.

Using ADO.NET Data Services

ADO.NET Data Services (ADODS) is a platform for providing SQL Server data to websites, RIAs (such as Silverlight and Flash applications), and other Internet clients over standard HTTP using modern web development conventions.

Getting Set Up

To start using ADODS, you first need to download and install Visual Studio 2008 Service Pack 1, as well as the .NET Framework 3.5 Service Pack 1. These updates include support for the Microsoft Entity Framework (EF), ADODS core, and ADODS .NET client library. A second configuration step, required for viewing ADODS XML data in the examples that follow, is an Internet Explorer 8 settings change: using the Tools menu, click Internet Options. Click the Content tab and then click the Settings button in the Feeds and Web Slices group. On the Feeds and Web Slices dialog, uncheck the Turn on Feed Reading View check box. Click OK twice.

Essentials

To work with data provided by ADODS services, you make HTTP requests, each of which must include three key parts:

- ▶ A uniform resource identifier (URI), which addresses the data in question
- ▶ An HTTP verb (either GET, POST, MERGE, PUT, or DELETE), which indicates the type of CRUD operation to be performed
- ▶ An HTTP Accept header, which indicates the format of the data being sent or received

As of this writing, ADODS services provide data to clients in one of two formats:

- ▶ **Atom Publishing Protocol (AtomPub)**—An XML format that acts as an application-level protocol for working with web resources. (This is the default ADODS response format. For more information on Atom, visit [http://en.wikipedia.org/wiki/Atom_\(standard\)](http://en.wikipedia.org/wiki/Atom_(standard)).)
- ▶ **JavaScript Object Notation (JSON)**—A text-based format for representing serialized JavaScript objects. Many popular Asynchronous JavaScript and XML (AJAX) client libraries (including JQuery, Prototype, and YUI) include core support for working with JSON.

ADODS services rely on EF to provide an abstract mapping layer between a physical data model and CLR object model. EF is a general-purpose ORM (similar to a LINQ to SQL class) that works with a number of data providers, including SQL Server, Oracle, DB2, and MySQL.

The first step in working with ADODS is to create an EF Entity Data Model (EDM) that includes the objects you want to expose from the AdventureWorks2008 database to the Web.

Let's get started. First, create a new web application project or website using Visual Studio 2008. Next, right-click that project and select Add New Item. On the ensuing Add New Item dialog, click on the Data node under the Categories heading on the left. Under Templates, click ADO.NET Entity Data Model and name your model file AdventureWorks2008.edmx. This is illustrated in Figure 45.6.

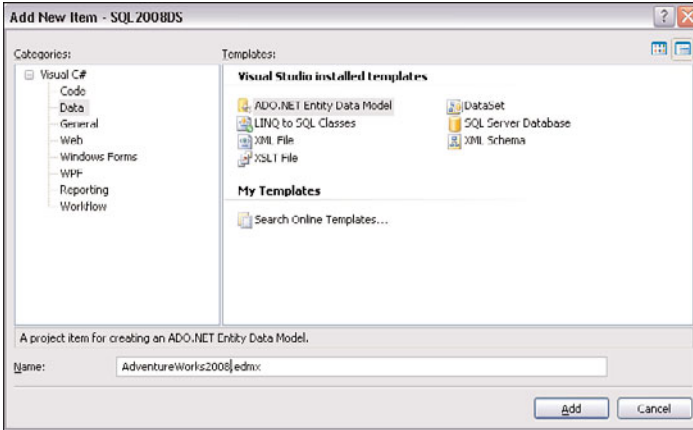

FIGURE 45.6 Creating a new Entity Data Model in Visual Studio 2008.

On the ensuing Entity Data Model Wizard dialog, be sure the Generate from Database option is selected and click Next. On the Choose Your Data Connection screen, select or create a connection to AdventureWorks2008 and then click Next. The result of this step is a new connection string written to your Web.Config file.

NOTE

If you examine this connection string, you will notice that it utilizes the new `System.Data.EntityClient` provider, rather than the traditional `System.Data.SqlClient`. It also uses a new metadata parameter in its connection string itself, which points to Conceptual Schema Definition Language (CSDL) and Storage Metadata Schema (SSDL) XML content found in the AdventureWorks2008.edmx EDM file.

CSDL provides markup for describing content models such as EDMs. SSDL provides markup for describing the underlying data stores used by EDMs. For more information, consult the MSDN articles “Conceptual Schema (CSDL)” and “Storage Metadata Schema (SSDL).”

On the Choose Your Database Objects screen that follows, expand the Tables node and then select the same four tables used previously in the LINQ to SQL examples

(`Production.Product`, `Production.ProductModel`, `Production.ProductInventory`, and `Production.ProductReview`). Take note of the name of your model (`AdventureWorks2008Model1`) and then click **Finish**. The EDM Designer surface opens to reveal your new EDM with your four selected entities, as illustrated in Figure 45.7.

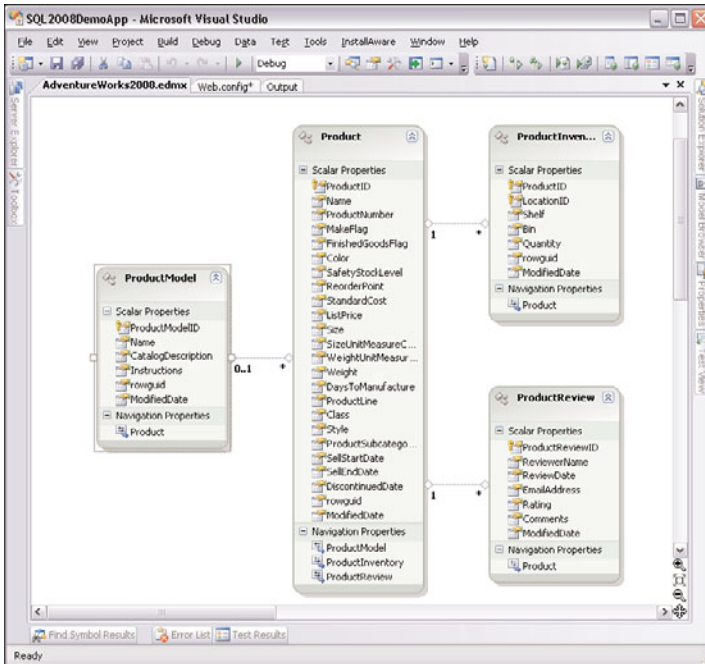

FIGURE 45.7 Visualizing the Entity Data Model with Visual Studio 2008's EDM Designer.

Notice how the new **Model Browser** tool window appears on the right side of Visual Studio. This new window provides access to all the properties of everything in the EDM, including its types, associations, properties, and the underlying data store. Using the **Model Browser**, you could, for example, click on the name of a CLR entity and then change it using the **Visual Studio Properties** window.

The new **Mapping Details** window also appears in Visual Studio. This provides a means of manipulating the mappings from your SQL Server tables and columns to your EDM entities and properties.

Using the **Mapping Details** window, you could, for example, using the drop-down lists found in its **Value/Property** grid column, delete the mapping of a given property by selecting the `<Delete>` option in that mapping's drop-down list. Take a few moments to familiarize yourself with these new tool windows and the EDM Designer surface.

Building Your Data Service

Now that you have your EDM, you can move forward and create your ADODS service. To accomplish this, right-click your web project again in Visual Studio and select Add New Item. Next, click on the Web node under the Categories heading on the left. Under templates, click ADO.NET Data Service and name your service file `AW08Service.svc`. This is illustrated in Figure 45.8.

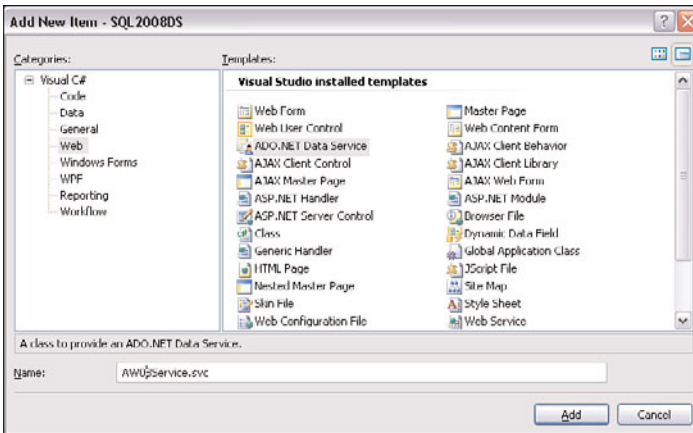

FIGURE 45.8 Creating a new ADO.NET data service in Visual Studio 2008.

The code editor opens in Visual Studio with your new service's code. This code will not compile as is because you need to specify a type argument for the generic base class from which the service derives. ADODS is built on Windows Communication Foundation (WCF), and all ADODS services are specializations of the WCF class `System.Data.Services.DataService<T>`. The `T` in the type argument expects a derivative of `System.Data.Objects.ObjectContext`, which the EDM class `AdventureWorks2008Entities` just happens to be.

Delete the comment in the type argument of the class declaration and then type `AdventureWorks2008Entities`. Believe it or not, your data service is almost ready to start serving data; there is only one more change to make: in the `InitializeService` method, add the following line of code:

```
config.SetEntitySetAccessRule("*", EntitySetRights.All);
```

This `SetEntitySetAccessRule` method on the context `System.Data.Services.IDataServiceConfiguration` controls which entities may be accessed and with which rights. This example enables access to all entities with full access (that is, every entity in the EDM may be selected, updated, or deleted). Here's a second example:

```
config.SetEntitySetAccessRule("Product", EntitySetRights.ReadMultiple);
```

This call enables access only to any set of Product entities as provided by the EDM. (Leave this first example intact and remove the second.) The code in your class should now look like the following:

```
public class AW08Service : DataService<AdventureWorks2008Entities>
{
    public static void InitializeService(IDataServiceConfiguration config)
    {
        config.SetEntitySetAccessRule("*", EntitySetRights.All);
    }
}
```

Now it's time to test your service. In Solution Explorer, right-click the `AW08Service.svc` file and select `Set as Start Page`. Right-click your web project and select `Set as StartUp Project`. Press F5 and view the result in Internet Explorer (illustrated in Figure 45.9).

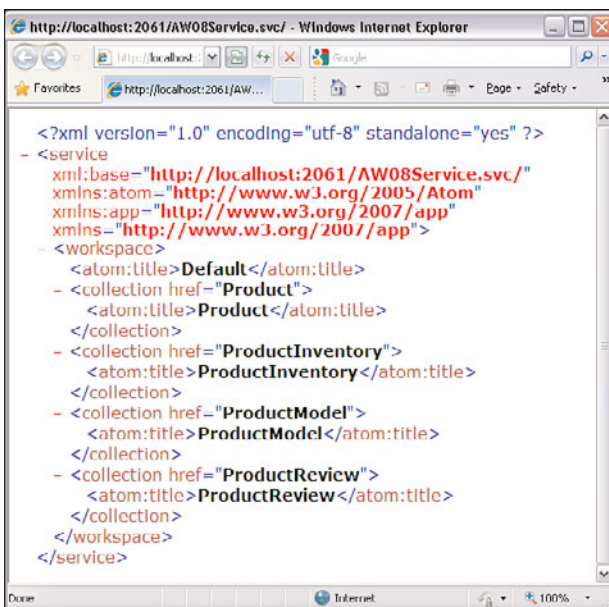

FIGURE 45.9 Atom XML showing the entities exposed by your ADO.NET data service.

The XML displayed (known as the *default service document*) is in Atom format. Notice how each of the entities is represented by a `collection` node. Each `collection` node has an `href` attribute, which indicates the relative navigational path to take to access that entity collection. Let's navigate to the `ProductReview` collection. To do this, type the following URI in Internet Explorer's address box:

```
http://server:port/AW08Service.svc/ProductReview
```

The XML response to the HTTP GET request is quite long; it contains every record in the ProductReview table. The reason is that the request is translated by ADODS to the following T-SQL query:

```
SELECT * FROM AdventureWorks2008.Production.ProductReview
```

Most of the time, your applications won't (or shouldn't) be doing queries like this. To narrow the query to a ProductReview row having a specific key value, supply that key value in parentheses after the entity name, like this:

```
http://server:port/AW08Service.svc/ProductReview(1)
```

The result is illustrated in Figure 45.10.

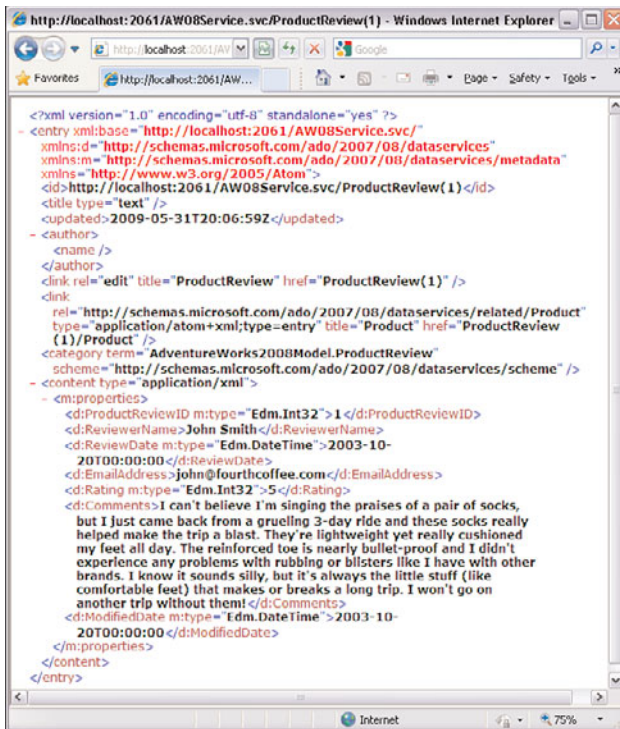

FIGURE 45.10 Atom XML document showing a single **ProductReview** entity.

The URI syntax for your requests may be broadly defined as

```
http[s]://server:port/ServiceName.svc/[EntitySetName[(KeyValu)]
[/EntitySetName[(KeyValu)]]...[?QueryString]
```

The power of this addressing syntax is that it enables you to write URIs that traverse an entity model in depth. For example:

```
http://server:port/AW08Service.svc/Product(1)/ProductReview(5)/Comments
```

The preceding request asks your service for value of the `Comments` property of `ProductReview #5` by way of `Product` entity #1.

Next, let's ask for the top two `ProductReview` entities for `Product #937`, in descending order, where the `ProductReviewID` is greater than or equal to 2:

```
http://server:port/AW08Service.svc/Product(937)/ProductReview?$top=2&$filter=
ProductReviewID ge
  2&$orderby=ProductReviewID desc
```

The query string in this example makes use of three different query options (denoted with `$`). Table 45.1 lists them all.

TABLE 45.1 Query Options for ADO.NET Data Service URI Query Strings

Option	Purpose
<code>\$top</code>	Like T-SQL's <code>TOP</code> operator; limits results
<code>\$skip</code>	Use with <code>\$top</code> when paging; skips <i>n</i> number of rows
<code>\$orderby</code>	Like T-SQL's <code>ORDER BY</code> clause; includes support for ascending (<code>asc</code>) and descending (<code>desc</code>) sorting
<code>\$filter</code>	Like T-SQL's <code>WHERE</code> clause; has its own set of operators, listed in Table 45.2
<code>\$expand</code>	Instead of pointing to related objects via a URI (see Atom's <code>link</code> element), includes them inline in the response

As mentioned in Table 45.1, the `$filter` option has its own set of operators for filtering values. Table 45.2 contains an abbreviated list of these operators.

TABLE 45.2 Operators for the ADO.NET Data Service URI **\$filter** Query Option

Operator(s)	Usage
<code>eq, gt, lt, ge, le</code>	<code>=, >, <, >=, <=</code>
<code>and, or, not</code>	Logical AND, logical OR, logical NOT
<code>()</code>	Grouping precedence
<code>add, sub, mul, div, mod, round, floor, ceiling, and so on</code>	Math functions
<code>length, indexof, startswith, endswith, substring, trim, concat, insert, remove, replace, toupper, tolower, and so on</code>	String functions
<code>day, hour, minute, second, day, month, year, and so on</code>	Date functions
<code>IsOf, Cast</code>	Type functions

Now that you know how to work with ADODS URIs, let's examine the salient parts of the Atom XML response.

First, notice its root entry node. This contains the base address for the service (in its `xml:base` attribute value), as well as three namespace declarations:

- ▶ <http://www.w3.org/2005/Atom>—Atom Syndication Format namespace, the default
- ▶ <http://schemas.microsoft.com/ado/2007/08/dataservices>—Namespace for entity content
- ▶ <http://schemas.microsoft.com/ado/2007/08/dataservices/metadata>—Namespace for entity metadata

Moving down the response document shown in Figure 45.10, the `id` node indicates the URI of the entity you've just requested, the `updated` node indicates the date and time of your request, the `author` node is blank (it's required by Atom), followed by the `link` elements.

Each `link` element includes a `title` attribute, indicating the name of the current or a related entity that you can address in future requests, and an `href` attribute, indicating the relative URI of that entity (also known as a *navigational property*). The first `link` element also contains a `rel` attribute with the value `edit`, indicating that the entity in question may be updated by a subsequent request (using a `PUT` or `MERGE` request, covered in the next section). The second and final `link` element tells you, via its `href`, which URI to use to traverse the EDM to find related `ProductReview` entities.

Below the `link` elements is the `content` element, which contains the result of your request: the entity `ProductReview(1)` and all its properties.

NOTE

To change the response format from Atom to JSON, you must change the value of your request's `HTTP Accept` header to `application/json`. To accomplish this in a test environment, we recommend using the freeware HTTP testing application known as Fiddler, available at <http://www.fiddler2.com>. Use Fiddler's Request Builder feature to modify a prior request and then examine the response with its Session Inspector.

Note that requests sent with an `Accept` header value of either `*/*`, `application/xml`, `text/xml`, `text/*`, or `application/atom+xml` all result in an Atom-based response.

Listing 45.7 contains the JSON-formatted version of the response generated by this request. The outer object is simply called `d`. It has a child object called `__metadata` that contains properties describing the `uri` and entity type. The properties that follow are those of the selected entity, including a navigational property object leading to related

Product entities (`__deferred`). JSON responses like this one should integrate seamlessly with your AJAX-enabled Web applications.

LISTING 45.7 JSON-Formatted Response from the ADODS Service

```
{
  "d": {
    "__metadata": {
      "uri": "http://localhost:2061/AW08Service.svc/ProductReview(1)",
      "type": "AdventureWorks2008Model.ProductReview"
    },
    "ProductReviewID": 1,
    "ReviewerName": "John Smith",
    "ReviewDate": "\/Date(1066608000000)\/",
    "EmailAddress": "john@fourthcoffee.com",
    "Rating": 5,
    "Comments": "I can't believe I'm singing...",
    "ModifiedDate": "\/Date(1066608000000)\/",
    "Product": {
      "__deferred": {
        "uri":
"http://localhost:2061/AW08Service.svc/ProductReview(1)/Product"
      }
    }
  }
}
```

CRUD Operations

In keeping with the principles of Representational State Transfer (REST), ADODS provides a mechanism for selecting, inserting, updating, and deleting data via HTTP requests to particular URIs. To put this into practice, a client application must be able to formulate its requests using specific HTTP verbs, as shown in Table 45.3.

TABLE 45.3 HTTP Verbs Corresponding to CRUD Operations for ADO.NET Data Services

HTTP Verb	Operation
GET	Select
MERGE	Update the specified properties
PUT	Update all properties (replace-style update)
POST	Insert
DELETE	Delete

To simplify the proper creation of these potentially complex HTTP requests, rather than hand-crafting them, you can use the new .NET client library, `System.Data.Services.Client`, which comes with ADO DS.

Create a new website or web application project using Visual Studio 2008. Add a reference to `System.Data.Services.Client` by right-clicking your new project and then clicking Add Reference, as you have done previously. Next, right-click the project again and select Add Service Reference. Type the URI to the service in the Address box; then, at the bottom of the dialog, type `AW08Service` in the Namespace box (as illustrated in Figure 45.11). (Note: You can also use the new command-line tool `dataserviceutil.exe`, located in `c:\Windows\Microsoft .NET\Framework\3.5`, to generate the same service reference classes as necessary.)

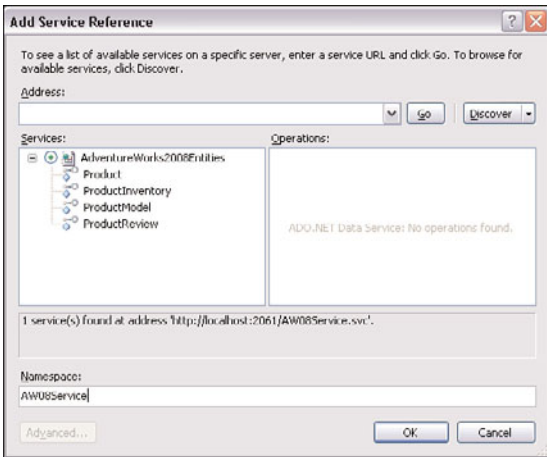

FIGURE 45.11 Adding a service reference to the data service with Visual Studio 2008.

Let's write some quick code to exemplify each of the CRUD operations. First, add a new class called `ServiceClient.cs` to your sample project. Completely empty the file and then add all the code in Listing 45.8 (substitute `ProjectName`, located in the fifth using statement, with the name of your web project).

LISTING 45.8 .NET Class Leveraging the ADO.NET Data Services Client Library

```
using System;
using System.Data.Services.Client;
using System.Diagnostics;
using System.Linq;
using ProjectName.AW08Service;
```

```

public class ServiceClient
{
    Uri _svcUri = new Uri("http://localhost:2061/AW08Service.svc/");
    DataServiceContext _ctx = null;

    public ServiceClient ()
    {
        _ctx = new DataServiceContext(_svcUri);
    }

    public Product GetProduct(int ProductId)
    {
        string Query = string.Format("Product({0})", ProductId);
        Uri RelativeUri = new Uri(Query, UriKind.Relative);
        Product P = _ctx.Execute<Product>(RelativeUri).FirstOrDefault();

        if (P != null)
        {
            Debug.WriteLine(string.Format("Success! Found Product {0}", P.Name));
        }

        return P;
    }
}

```

The class shown in Listing 45.8 requests data from an ADODS service. Its variable declarations introduce the `DataServiceContext` class (`_ctx`), which facilitates communication between client applications and ADODS services. Notice its URI-based initialization in the constructor. Further down, examine the `GetProduct` method. (As with LINQ to SQL, its object selection code is built on `IEnumerable<T>` and its extension methods.) To call the service, you construct a relative URI (`RelativeUri`) containing the path and query options to the entity or entities you want to retrieve. You then pass this relative URI to the `Execute<T>` method of the context, supplying `Product` for its type parameter. Finally, you call `FirstOrDefault` against the query result, which in turn returns either the first selected entity returned or `null`. Because this is merely a retrieval, an HTTP GET request is issued to retrieve the `Product`.

Let's add an update query to the client class, as shown in Listing 45.9. Under the hood, this query uses the HTTP MERGE verb to update a particular `ProductReview` entity.

LISTING 45.9 An Update Query Using the ADO.NET Data Services Client Library

```

public ProductReview UpdateProductReview(int ProductReviewId, string NewComments)
{
    AdventureWorks2008Entities NewContext =

```

```

        new AdventureWorks2008Entities(_svcUri);

ProductReview P =
    NewContext.ProductReview.Where
    (
        p => p.ProductReviewID == ProductReviewId
    ).FirstOrDefault();

if (P != null)
{
    string OldComments = P.Comments;
    P.Comments = NewComments;
    NewContext.UpdateObject(P);
    NewContext.SaveChanges();

    Debug.WriteLine(string.Format("Success! Updated comments to {0}"
, P.Comments));

    //put old comments back:
    P.Comments = OldComments;
    NewContext.UpdateObject(P);
    NewContext.SaveChanges();
}

return P;
}

```

Notice the use of the `NewContext` object. It is of type `AdventureWorks2008Entities`, a `DataServiceContext` derivative that was generated when you added your service reference. You *must* use this class, rather than the original `_ctx` object, to perform any CRUD query other than a retrieval.

Walking through the code in Listing 45.9, you first select your desired `ProductReview` entity and then update its `Comments` property. Then you call `UpdateObject` and `SaveChanges` to commit your changes to the database through your service.

Next up, Listing 45.10 illustrates how to perform an insert of a new `ProductReview` (related to an existing `Product`) using ADODS. Under the hood, it uses the HTTP POST verb to accomplish its goal. In this example, you first fetch your `Product` (to which you associate your new `ProductReview`), then set the properties of your `ProductReview`, add that new object (PR) to the current list (via `NewContext.AddToProductReview`), set the `Product` property on PR, and then call `SetLink` to tell your context that you have made this association. Finally, you call `SaveChanges` to commit your work.

LISTING 45.10 An Insert Query Using the ADO.NET Data Services Client Library

```

public ProductReview AddProductReview(int ToProductId, string Comments)
{
    AdventureWorks2008Entities NewContext =
        new AdventureWorks2008Entities(_svcUri);

    Product P =
        (
            from p in NewContext.Product
            where p.ProductID == ToProductId
            select p
        ).FirstOrDefault();

    ProductReview PR = null;

    if (P != null)
    {
        PR = new ProductReview()
            {
                Comments = Comments,
                EmailAddress = "alex@unifieddigital.com",
                Rating = 4,
                ReviewDate = DateTime.Now,
                ModifiedDate = DateTime.Now,
                ReviewerName = "Alex T. Silverstein"
            };

        NewContext.AddToProductReview(PR);
        PR.Product = P;
        NewContext.SetLink(PR, "Product", P);
        NewContext.SaveChanges();

        Debug.WriteLine(string.Format("Success! Added new review {0}",
PR.ProductReviewID));
    }

    return PR;
}

```

To round things out, in this final example, Listing 45.11 illustrates how to perform a delete using ADODS. Its syntax is straightforward and simple. All that is needed is to fetch the object to be deleted and then call `DeleteObject` on your context and then

SaveChanges. Note that in this final example, the URI for your deletion is `http://server:port/AW08Service.svc/ProductReview(11)`, no payload is sent to the server, and your HTTP verb is DELETE.

LISTING 45.11 A Delete Query Using the ADO.NET Data Services Client Library

```
public void DeleteProductReview(int ProductReviewId)
{
    AdventureWorks2008Entities NewContext =
        new AdventureWorks2008Entities(_svcUri);

    ProductReview PR =
        (
            from p in NewContext.ProductReview
            where p.ProductReviewID == ProductReviewId
            select p
        ).FirstOrDefault();

    if (PR != null)
    {
        NewContext.DeleteObject(PR);
        NewContext.SaveChanges();
    }
}
```

Although you've learned quite a bit about ADODS in this short space, we encourage you to continue exploring this exciting new framework on your own, using Fiddler to examine the HTTP traffic in detail. For now, it's time to switch gears to a new topic.

Leveraging the Microsoft Sync Framework

Microsoft Sync Framework (MSF) is a complete platform enabling synchronization of data, files, feeds, or other critical information between clients, peers, and servers over common transport protocols and across networks. It provides the necessary interfaces, assemblies, code-generation tools, script wizards, and other components that make it easy for developers to begin using it.

The main use case for MSF we cover in this chapter is that of the Occasionally Connected Application (OCA). *OCA* is a descriptive term for a program that relies on data on a regular basis, yet which is not permanently connected to the Internet. If your target users are stuck with a slow, unreliable, or occasionally unavailable network provider, they are the perfect targets candidate for building an OCA.

OCA's include phone, PDA, tablet, or other portable device applications, such as those needed by a mobile salesperson, floor manager, insurance adjuster, physician, or any other professional who is on the go. People in these positions cannot be expected to always

have access to a high-speed wireless network, and MSF enables you to build programs that accommodate them.

Getting Started with MSF and Sync Services for ADO.NET

As is the trend with many new Microsoft technologies, much of the work of configuring and preparing your application is done by wizards and other code-generation mechanisms. In the sections that follow, we examine how to use the MSF-related tools and templates provided with SQL Server 2008 and Visual Studio 2008 to accomplish our goal of building an OCA-style Windows Forms application.

To begin, you must first have MSF installed on your local machine. To accomplish this, you have two options: install the feature using the SQL Server installer (illustrated in Figure 45.12) or download MSF using the links found at MSF's home page at <http://www.msdn.com/sync>.

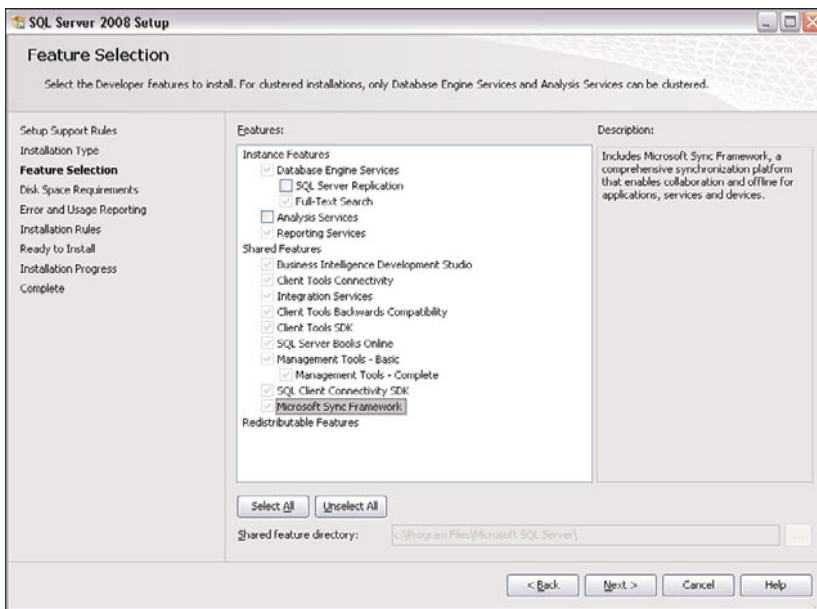

FIGURE 45.12 Installing MSF via the SQL Server 2008 installer.

You also need to install Sync Services for ADO.NET (SSADO) if your system does not have it already. SSADO provides assemblies in the `Microsoft.Synchronization.Data*` namespaces that enable data synchronization for ADO.NET applications. To see whether you have these assemblies, open Windows Explorer and navigate to `%PROGRAMFILES%\Microsoft Synchronization Services\ADO.NET`. If they aren't installed, visit the MSF home page and look for the Sync Services for ADO.NET links; then download and install.

The general architectural model for MSF with SSADO is made up of the following:

- ▶ Synchronization providers, both client and server side, which abstract the details of and provide access to the data stores on each side of the synchronization
- ▶ A synchronization agent, which acts as the runtime that communicates with each synchronization provider
- ▶ Databases, which store the desired content as well as synchronization metadata and supporting T-SQL code

The main idea behind these components is that they enable your application to read and write to a local database; then, when synchronization time comes, any changes that happened on the local side get pushed up to the server database. In turn, any changes that happened on the server since the last synchronization get pushed down to the local database. Any conflicts that occur are resolved by the conflict resolution logic built in to the synchronization components (which, of course, you can tweak as necessary). In this way, when synchronization completes, your local database always has the latest and greatest, and you can continue to work offline until the next synchronization.

In the sample OCA, you build a simple WinForms application that synchronizes with the AdventureWorks2008 database on your local server.

Building Our Example OCA

To begin, start Visual Studio and create a new Windows Forms application (this example is in C#). Next, right-click your application name in Solution Explorer and click Add New Item. Click the Data node under the Categories heading on the left. Under Templates, click Local Database Cache, and name this new file AW08LocalCache.sync (as illustrated in Figure 45.13). Local database caches (LDCs) provide you with the code area in your project where you can control how data synchronization works.

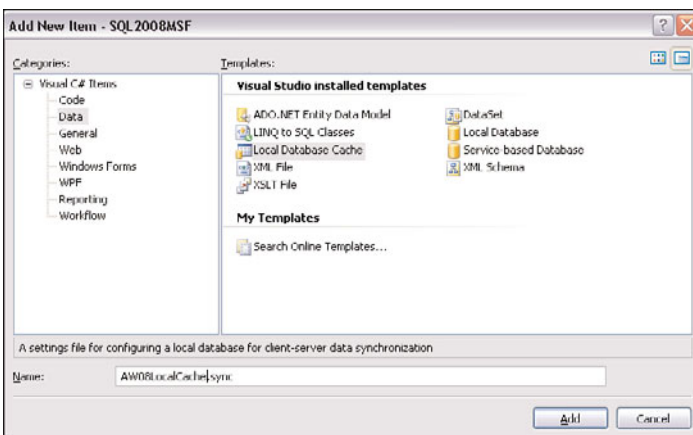

FIGURE 45.13 Adding a local database cache file to the sample application.

After your LDC has been added, the new Configure Data Synchronization (CDS) dialog opens (you can also view this dialog anytime by double-clicking your LDC). This is a critical dialog to understand because it is responsible for generating all the C#, T-SQL, and configuration code needed for using synchronization in your program.

When you use SSADO with SQL Server 2008 databases, two options exist for performing the change tracking at its core:

- ▶ Using SQL Server Change Tracking, a new feature in SQL Server 2008 that natively tracks row changes and stores them as metadata, accessible via a new set of functions (covered in detail in Chapter 42, “What’s New for Transact-SQL in SQL Server 2008”)
- ▶ Using the default tracking mechanism, which relies on T-SQL triggers to compare **datetime** values stored in columns added to the server tables

Returning to the CDS dialog, under the Database Connections group box, select the connection to your local AdventureWorks2008 database under Server Connection. Under Client Connection, leave the default AdventureWorks2008.sdf (New) selection. This option creates a new SQL Server Compact (SQLCE) 3.5 database in your application that acts as your OCA’s local data store (illustrated in Figure 45.14).

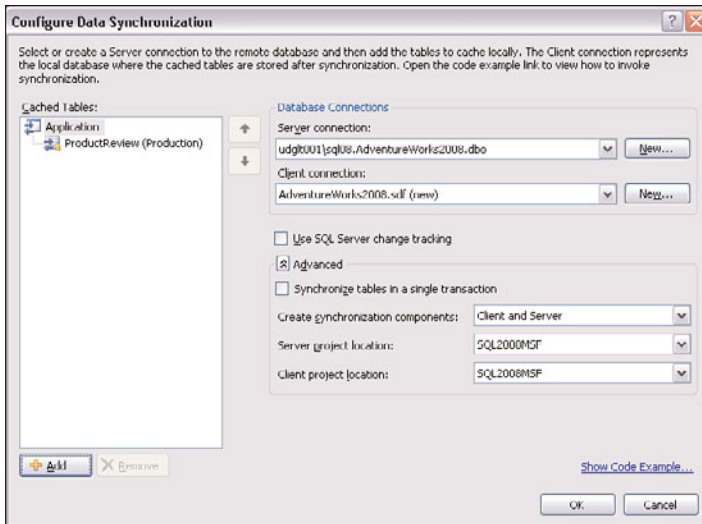

FIGURE 45.14 Using the Configure Data Synchronization dialog to configure MSF with ADO.NET.

On the left side of the dialog, under Cached Tables, is a tree structure (the top of the tree represents the Application itself). Using the Add and Remove buttons below the tree, you can configure which tables you want to synchronize between the local SQLCE database and the remote database. Those you select are created and/or populated before your first synchronization with the server.

Click the Add button, and, using the ensuing Configure Tables for Offline Use dialog, scroll down under Tables and put a check mark next to ProductReview (Production) (illustrated in Figure 45.15). As you can see on the right side, there are a number of options for which data to download (all or incremental), which columns will be used to compare records (either by using existing columns or adding new ones to the server table), and where deleted records' keys will be stored on the server (*TableName_Tombstone* is the default naming convention). The wizard adds the *CreationDate* and *ModifiedDate* columns to *ProductReview* in both the local and server databases. The wizard creates the *ProductReview_Tombstone* table on the server. It also generates two handy T-SQL DDL scripts in your Visual Studio project to accomplish and undo these changes.

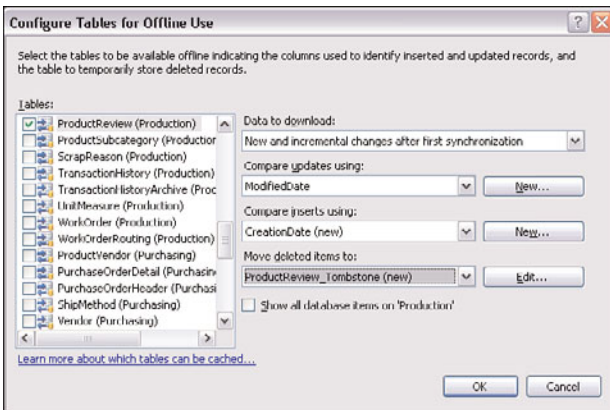

FIGURE 45.15 Using the Configure Tables for Offline Use dialog to select tables to be synchronized.

When your Configure Tables for Offline Use dialog matches the one in Figure 45.15, click OK to return to the main CDS dialog. Next, uncheck the Use SQL Server Change Tracking check box, found under the Database Connections group box. Next, click the Advanced button. This group box contains options that allow you to generate the server and client provider code in either the same or two different Visual Studio projects.

If you click the Show Code Example link button on the bottom of the CDS dialog, you are presented with a handy dialog that provides you with a block of prewritten synchronization code and a Copy button that puts that code on the Clipboard. Click the Copy button and then click Close. When your CDS dialog matches the one in Figure 45.14, click OK. To make things even easier for development, the next dialog that appears (Data Source Configuration Wizard) will generate a strongly typed dataset (called *AdventureWorks2008DataSet*) that encapsulates your selected tables (illustrated in Figure 45.16). Be sure to put a check mark in the root Tables node; then click Finish. (If you get a warning about MSF needing to upload or synchronize changes, accept the default state of the dialog and click OK.)

Using Solution Explorer, examine all the files created throughout this process. Notice your new *App.Config* and corresponding *Settings.Settings* files, with their connection strings

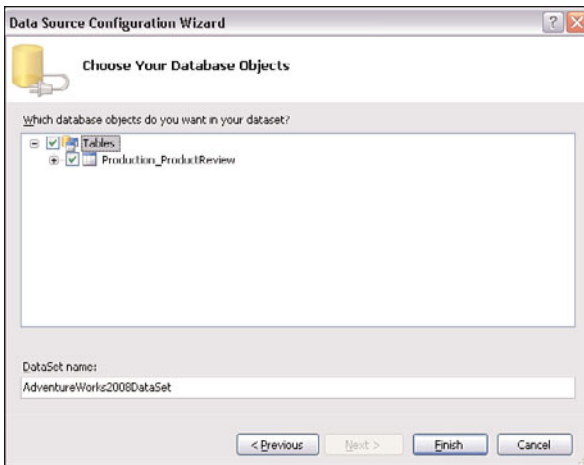

FIGURE 45.16 Using the Data Source Configuration Wizard to generate a strongly typed dataset.

to the local and server databases. Then look at the T-SQL DLL script that creates the triggers, columns, and tombstone table which facilitate change tracking. Examine your new SQLCE database (using SSMS if you like), strongly typed dataset, LDC, and other code files.

Believe it or not, the only things left to do to set up the OCA for synchronization are to add a DataGridView to the application's main form, associate it with the strongly typed dataset, add the block of code that you copied to your Clipboard (earlier, from the CDS dialog) to an event handler, and change your agent to perform bidirectional synchronization (it does unidirectional download-only by default).

Perform the following steps to complete your application:

- ▶ To set the synchronization mode, open your LDC's designer file (AW08LocalCache.designer.cs), locate the synchronization agent class (AW08LocalCacheSyncAgent), and replace its partial method declaration for OnInitialize to the following:

```
private void OnInitialized()
{
    Production_ProductReview.SyncDirection =
        Microsoft.Synchronization.Data.SyncDirection.Bidirectional;
}
```

- ▶ Next, open your project's main form in the forms designer. Reveal the Data Source tool window by pressing Shift+Alt+D. Drag the Production_ProductReview node from the Data Source tool window onto your form. This provides your form with an instance of your strongly typed dataset (AdventureWorks2008DataSet) as well as a DataGridView (production_ProductReviewDataGridView) with standard buttons, table adapter (production_ProductReviewTableAdapter) and associated manager

(tableAdapterManager), and data navigator (production_ProductReviewBindingNavigator) for moving through the data using the toolbar.

- ▶ Set the Dock property of your DataGridView to Fill. The final result should look something like the form shown in Figure 45.17.

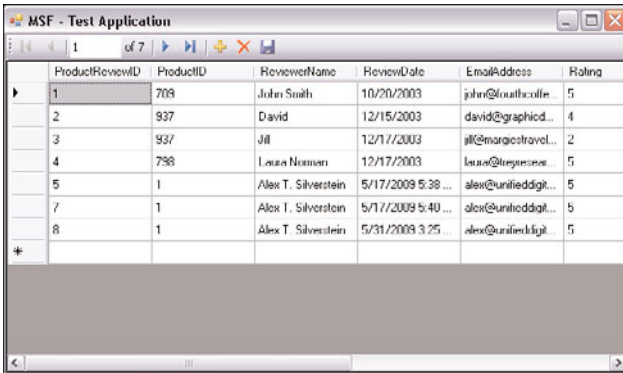

FIGURE 45.17 Windows Forms application UI showing synchronization data.

- ▶ Double-click the title area of your form. In the OnLoad event handler that opens in the text editor, replace the code in the body with the following synchronization code:

```
private void Form_Load(object sender, EventArgs e)
{
    //Sync the data when the application starts
    try
    {
        new AW08LocalCacheSyncAgent().Synchronize();
    }
    catch (Exception)
    {
        MessageBox.Show("Unable to synchronize at this time.");
    }
    finally
    {
        production_ProductReviewTableAdapter.Fill(
            adventureWorks2008DataSet.Production_ProductReview);
    }
}
```

- ▶ Run your application in debug mode. Edit and save any record using your `DataGridView`; then, using SQL Server Management Studio, edit and save a different record in the `Production.Product` review table. Examine the results of bidirectional synchronization by restarting your application. Validate the changes by querying the server data by writing a new `SELECT` query and executing it in SSMS.

If you are interested in learning all the implementation details of MSF, feel free to walk through your synchronization code in debug mode to familiarize yourself with all the components at work, including the providers, agent, adapters, and T-SQL triggers.

Although this tutorial provided an MSF jump-start, you should be sure to visit the MSF Developer Center at <http://www.msdn.com/sync> for full coverage on all aspects of MSF and SSADO.

Summary

In this chapter, you saw how to develop data-driven applications using several new and updated frameworks including ADO.NET 3.5, LINQ to SQL, ADO.NET Data Services, and the Microsoft Sync Framework.

Chapter 46, "SQLCLR: Developing SQL Server Objects in .NET," shows how to write stored procedures, functions, triggers, aggregates, and custom data types in C# or VB.NET.

This page intentionally left blank

CHAPTER 46

SQLCLR: Developing SQL Server Objects in .NET

IN THIS CHAPTER

- ▶ What's New for SQLCLR in SQL Server 2008
- ▶ Developing Custom Managed Database Objects

This chapter examines the deep integration of the .NET Framework with SQL Server 2008. It delves into SQL Server 2008's support for the creation of custom managed database objects, otherwise known as *SQLCLR*.

What's New for SQLCLR in SQL Server 2008

Although there are only a few changes to SQLCLR in SQL Server 2008, including support for multiparameter aggregates, support for large-value data types (such as `nvarchar(MAX)`) and support for the new SQL Server 2008 data types (such as `date` and `time`), SQLCLR itself introduces a wealth of new possibilities for developing with .NET and SQL Server that you should consider leveraging in your data-driven applications.

In the following sections, we give you all the tools you need to write your own stored procedures, functions, triggers, data types, and aggregate functions in C# or VB .NET.

Developing Custom Managed Database Objects

SQL Server 2008 hosts the common language runtime (CLR), implementing what's known as the Hosting API. The Hosting API gives SQL Server 2008 full control over the execution of .NET code in a carefully managed environment that honors the shared resource usage of both SQL Server and the CLR. The CLR provides an execution context for

safer than that of code you might formerly have run in an extended stored procedure or COM object under SQL Server 2000 and previous editions.

In the sections that follow, you will create one of each of the managed versions of database routines and types. You work with both the SQL Server project type in Visual Studio 2008 as well as the T-SQL Data Definition Language (DDL) syntax for managed objects.

Finally, you'll learn about advanced topics such as transaction control in mixed (T-SQL and managed) environments.

An Introduction to Custom Managed Database Objects

The capability to run managed code presents a world of possibilities, yet these features must be leveraged appropriately. The meaning of *appropriate* will ultimately be the result of ongoing dialogs between database administrators and the developers who want to use the .NET Framework in SQL Server.

Just like SQL Server's capability to host web services (covered in Chapter 48, "SQL Server Web Services"), this feature set begins to blur the line between SQL Server as a database server and SQL Server as a lightweight application server.

.NET assemblies are built using Visual Studio or the command-line compilers and then literally uploaded into the database and loaded into memory on the same physical server as the SQL Server instance. CLR objects may therefore consume valuable server and network resources.

This scenario presents a challenging new management paradigm that database administrators, managers, and developers have to negotiate. Administrators are just beginning to consider strategies for what kinds of .NET code they should allow to run and in which contexts. Following are a few general rules to consider regarding when managed objects should and should not be used:

- ▶ Data selection and modification should always be performed using T-SQL because that's what it's optimized to do. You should not create a T-SQL wrapper in your .NET code.
- ▶ You should use managed code when you need to overcome the procedural limitations of T-SQL, such as avoiding the use of nested cursors that connect to multiple databases and other awkward constructs. (SQL was never developed to be a procedural language, only a set-based query language.)
- ▶ You should use managed code when you want to extend the per-row or per-set effects of routines to leverage managed resources, such as XML parsers, web services, and custom code libraries.

The software development staff still must decide what to do, but we can be thankful that SQL Server has some rules of its own for what kinds of operations can be called and under which permission sets, as discussed in the following section.

Managed Object Permissions

The first thing to know about managed object permissions is that SQL Server has only blessed a certain group of assemblies usable under each of the three SQL Server permission sets.

Figure 46.1 shows the Add References dialog for a SQL Server project in Visual Studio 2008, listing these .NET Framework assemblies. They are the only assemblies (aside from user-created assemblies) that can be referenced in SQL Server projects. Note that this list doesn't change in Visual Studio, regardless of the permission set used. Note also that SQL Server and/or Visual Studio walks down the reference chain to see whether any referenced assemblies reference anything that is not blessed. Therefore, you shouldn't bother trying to get around this list; there isn't even a Browse button on the dialog box as there is with the other project types.

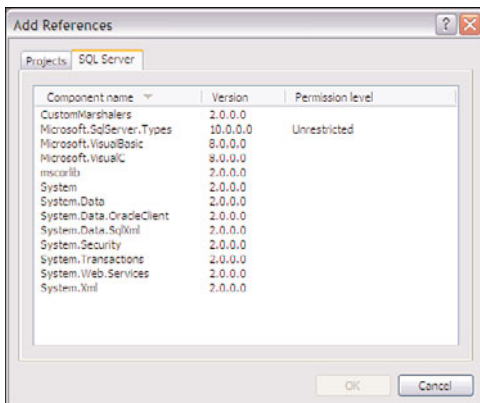

FIGURE 46.1 Blessed assemblies in the Add References dialog in Visual Studio 2008.

The Three Permission Sets

SQL Server has three built-in .NET Code Access Security (CAS) permission sets that define which kinds of operations can be executed at runtime. Using the CAS layer is a huge improvement over running extended stored procedures under default login credentials because it allows for fine-grained permission granting and revocation.

These are the permission sets, in increasing order of freedom:

- ▶ SAFE
- ▶ EXTERNAL_ACCESS
- ▶ UNSAFE

These keywords are used in the DDL syntax for assemblies.

Assuming that you have built an assembly targeted for SQL Server use (which you do in the next section), you can use the following syntax for loading that assembly into your database of choice:

```
CREATE ASSEMBLY AssemblyName [AUTHORIZATION LoginName]
FROM StringPathToAssemblyDll | BinaryDataValue
[WITH PERMISSION_SET (SAFE | EXTERNAL_ACCESS | UNSAFE) ]
```

This syntax is reasonably self-explanatory: you tell SQL Server the name of the assembly and the path (using a UNC if needed) to it. If you're loading an assembly from a varbinary column, you supply the actual data that makes up the compiled code of the assembly instead of the path to it (Visual Studio does this).

NOTE

CREATE ASSEMBLY and ALTER ASSEMBLY are commands used by Visual Studio's Deploy feature, which does the managed code DDL work for you.

The WITH PERMISSION SET clause is optional, and it defaults to SAFE. Marking an assembly with the SAFE permission set indicates that no external resources (for example, the Registry, web services, file I/O) are going to be accessed. The DDL will fail if assemblies such as `System.IO` are referenced, and anything causing a permission demand for executing similar operations will result in an exception being thrown at runtime. Marking an assembly with the EXTERNAL_ACCESS permission set tells SQL Server that it will be using resources such as networking, files, and so forth. Assemblies such as `System.Web.Services` (but not `System.Web`) may be referenced with this set.

Marking an assembly with the UNSAFE permission set tells SQL Server that not only might external resources be used, but unmanaged code may even be invoked from managed code.

Some assemblies in the .NET Framework go so far as to tell the processes that ultimately host them (such as SQL Server or Internet Explorer) about their relative safety, using a specific .NET attribute: `HostProtectionAttribute` (HPA).

The enumeration flags of the HPA's parameter indicate to the host what kinds of operations the classes decorated with it may attempt. Because documentation of the HPA with regards to SQL Server is scant, it's unclear whether SQL Server ultimately relies on the HPA to determine what may be loaded. (It seems to do so at runtime, but the blessed list is likely to be hard coded.)

Following are some of the operations you cannot perform with .NET code running under SQL Server's SAFE and EXTERNAL_ACCESS options (but possibly under UNSAFE):

- ▶ Thread synchronization
- ▶ External process management
- ▶ Framework security changes
- ▶ Use of non-read-only static fields

Only those in the `sysadmin` role can upload `UNSAFE` assemblies to SQL Server. (Just don't tell your DBA we told you how to do it.)

The `EXTERNAL_ACCESS` permission on master is required for uploading `EXTERNAL_ACCESS` assemblies. And anyone in the `db_owner` role may load `SAFE` assemblies.

Developing Managed Objects with Visual Studio 2008

When SQL Server 2008 is installed, it includes `Microsoft.SqlServer.Server`, the assembly that contains the attributes and other classes needed for SQLCLR (the common acronym for managed code running in SQL Server) programming.

The first step in working with SQLCLR is to enable the feature in SQL Server.

Setting Up the Server for Managed Code Execution

Before you can work with managed database objects, you need to execute the following T-SQL commands in the context of the `master` database:

```
sp_configure 'clr enabled', 1
RECONFIGURE
go
```

This step is necessary because SQL Server comes with managed code execution turned off by default.

At this point, you're ready to create your first SQLCLR project using Visual Studio 2008 (VS). Start VS and create a new C#-based SQL Server project with a name of your choosing (the example is named `SQL2008SQLCLR`). Figure 46.2 shows the Add New Project dialog.

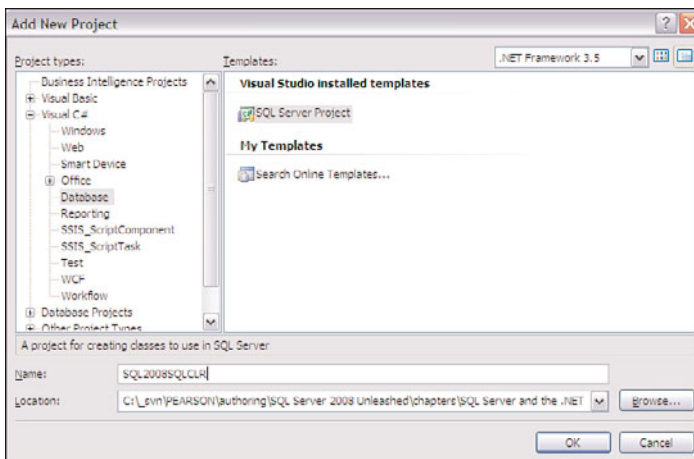

FIGURE 46.2 Using the Add New Project dialog in Visual Studio 2008 to create a SQLCLR project.

Next, VS asks you to create or add a reference to a database to which you will deploy your new assembly. During deployment, your assembly (and with it, all its SQLCLR types and routines) is uploaded directly into SQL Server's system tables. Select AdventureWorks2008 so you can work with the examples that follow.

Next, you create your first managed SQL Server object, a stored procedure written in C#.

Developing Managed Stored Procedures

Stored procedures are a great starting point for getting into SQLCLR because they are easy to implement. To do so, right-click your new project in VS's Solution Explorer and then select Add, Stored Procedure. Name your new class StoredProcedures.cs. A partial class of that name opens in the VS code window. Note that VS automatically adds the required reference to Microsoft.SqlServer.Server and its associated using statement.

Microsoft.SqlServer.Server contains the SqlParameter attribute required for turning ordinary methods into SQLCLR stored procedures.

Change your autogenerated method name from StoredProcedures to GetProductReviews. Next, if you're not working in VS, you need to decorate this method with the SqlParameter attribute.

Attributes and the Implementation Contract

If you've never used attributes, you can think of them as metadata that tells callers, usually through reflection, that the decorated element (known as the *target*) meets some criterion. All the managed objects you create in this chapter require certain attributes to be applied; otherwise, they cannot be used in a SQL Server context.

The classes you build must also implement particular methods and/or method signatures to be built and deployed successfully to SQL Server. This is known as *fulfilling the implementation contract*. For stored procedures, fulfilling this contract requires that your method be marked static. Its return type must be one of the following: void, Int32, Nullable<Int32>, or SqlInt32. Its input parameters and their types are up to you, but keep in mind that these must be convertible from a T-SQL context to a .NET context. These are the only contract requirements to be filled for stored procedures.

NOTE

It makes sense that these methods must be marked static because they are called by the CLR host via the class's type object, rather than via an object instance (that is, `AssemblyName.ClassName.StaticMethodName(Parameters)`).

Object-oriented (OO) purists might suggest that this way of creating managed SQL Server objects could have been done in a more OO-friendly way if the contract to be filled required overriding the methods of an abstract class or implementing interfaces. The static requirement, however, currently makes this impossible because static members are not inherited and cannot be used to implement interface members.

The constructor for the `SqlParameter` attribute is overloaded to either take zero parameters or take one parameter that is actually a list of named parameters. (Having a list of named parameters in the attribute signature is common to most of the attributes used in this chapter, although the choice of named parameter pairs varies from attribute to attribute.)

For the `SqlParameter`, only one named parameter exists: `Name`. You use `Name` when you want to name the method one thing but have the name it generates for use in a T-SQL context to be another name.

The code in Listing 46.1 illustrates the use of a named parameter in this attribute and contains a simple example of how to generate a set of rows using `SQLCLR`.

LISTING 46.1 A Managed Stored Procedure That Generates a Set of Rows

```
[SqlParameter(Name = "clr_GetProductManuals")]
public static void GetProductManuals()
{
    using (SqlConnection ContextConnection =
        new SqlConnection("context connection=true"))
    {
        SqlDataRecord record =
            new SqlDataRecord(
                new SqlMetaData[]
                {
                    new SqlMetaData("ProductModelId",
                        SqlDbType.Int),
                    new SqlMetaData("Manual",
                        SqlDbType.Xml)
                }
            );

        SqlContext.Pipe.SendResultsStart(record);

        using (SqlCommand Command = new SqlCommand())
        {
            Command.CommandText =
                @"SELECT TOP 10 ProductModelId, Instructions
                FROM Production.ProductModel
                WHERE Instructions IS NOT NULL";

            Command.Connection = ContextConnection;
            ContextConnection.Open();

            using (SqlDataReader reader = Command.ExecuteReader())
            {
                while (reader.Read())
                {
```

```

        int ProductModelId = reader.GetInt32(0);
        SqlXml ManualXml = reader.GetSqlXml(1);

        record.SetInt32(0, ProductModelId);
        record.SetSqlXml(1, ManualXml);
        SqlContext.Pipe.SendResultsRow(record);
    }
}

SqlContext.Pipe.SendResultsEnd();
}
}
}
}

```

Although this example does not require it, if your SQLCLR code needs to access server resources (such as files), it would be necessary to change your assembly's permission set from the default of `SAFE` to `EXTERNAL_ACCESS`. To do this in VS, right-click your project in Solution Explorer and select Properties. Then, on the left side of the window, select the Database tab. (Note that the Database tab is the place where VS stores a connection string matching your database reference. You can change that here as well.) Under the Permission Level drop-down, change the value from Safe to External and save the project. You can also type in the name of the SQL Server login (under Assembly Owner), which will be specified for the `AUTHORIZATION` parameter of `CREATE ASSEMBLY` during deployment by VS.

The idea behind the code in Listing 46.1 is that, given a set of rows from `Production.ProductModel`, the procedure generates a result set of only those products that have a reference manual. Let's examine the new objects in this code.

The Context Connection

In our managed procedure, we use a special ADO.NET connection string ("`context connection=true`"), known as the context connection string, to connect to the session of SQL Server under which our managed stored procedure is currently executing (that is, once the assembly has been deployed and is running in a T-SQL context).

Objects in `Microsoft.SqlServer.Server`

Our managed procedure also uses some specialized objects to send data to SQL Server through the active connection:

- ▶ **SqlContext**—This represents the server execution context for the managed routine. You can think of it as the line of communication between the .NET and SQL Server environments.
- ▶ **SqlContext.Pipe**—**SqlContext** holds the crucial `Pipe` property, used to send `SqlDataRecord` objects or text messages to the method's caller, which, by the way, may be either another managed routine (via ADO.NET) or any T-SQL user code.

- ▶ **SqlDataRecord**—This is an abstraction that represents a record in any given table. The schema of columns for a `SqlDataRecord` object is created by using `SqlMetaData` objects, as shown in Listing 46.1.
- ▶ **SqlMetaData**—An array of `SqlMetaData` objects is passed to the constructor of each `SqlDataRecord`. Each `SqlMetaData` object defines the name, type, precision, scale, and so forth for its target column via its overloaded constructors.

Returning to the code in Listing 46.1, before looping through our `SqlDataReader` object (reader), we call `Pipe.SendResultsStart`, passing a `SqlDataRecord` object whose structure matches our desired output. This tells SQL Server that our procedure is about to send rows (to the caller) having a specific structure.

Looping through the reader (using `while (reader.Read())`), we select the values to be returned. To do this, we use the `Set[DataTypeName]` methods on our `SqlDataRecord` object called `record`. When our values are all set, we call `SqlContext.Pipe.SendResultsRow(record)` to return these data.

After the code has finished sending data to the client, it cleans up by calling `Pipe.SendResultsEnd`. Note that the `Pipe` object also has an `ExecuteAndSend` method that takes a `SqlCommand` parameter, executes it, and sends all the results back to the caller in one fell swoop. In addition, you can query the status of the `Pipe` object by checking its `IsSendingResults` Boolean property. You can even send an informational text message (similar to T-SQL's `print` function) to the caller, using `Pipe.Send("Text")`. `Send()` is overloaded to accept a `SqlDataRecord` object or a `SqlDataReader` object that contains the data to be returned.

Building and Deploying the Assembly

At this point, you can build the VS project and then choose the new `Deploy` command from VS's `Build` menu. In this step, VS generates the T-SQL DDL scripts needed to upload our assembly to SQL Server and then add our managed stored procedure to the `AdventureWorks2008` database.

You've already seen the `CREATE ASSEMBLY` DDL that VS uses. For now, let's assume that you've already uploaded the assembly once. In this scenario, you need to execute the following T-SQL to replace that assembly with a newly compiled version of the same:

```
ALTER ASSEMBLY AssemblyName
[AUTHORIZATION LoginName]
FROM StringPathToAssemblyDll | BinaryDataValue
[PERMISSION_SET = (SAFE | EXTERNAL_ACCESS | UNSAFE) ]
```

You can also use `ALTER ASSEMBLY` to upload your C# class files so that when you're debugging any exceptions you get source code line numbers in the stack dump (seamlessly reported by SQL Server's built-in error reporting mechanism). Here's an example:

```
ALTER ASSEMBLY AssemblyName ADD FILE FROM FilePath
```

TIP

The use of any managed user-defined types in your database (covered later in this chapter) prevents an assembly from being dropped or altered until any type already in use is dropped (because it is a dependency).

After you load your assembly to SQL Server, you can execute the following DDL to add your managed stored procedure to AdventureWorks2008:

```
CREATE PROCEDURE [dbo].[clr_GetProductManuals]
WITH EXECUTE AS CALLER
AS
EXTERNAL NAME
[ProjectName].[StoredProcedures].[GetProductManuals]
```

The new `WITH EXECUTE AS CALLER` clause tells SQL Server that the permissions for executing the procedure should be those of its caller. (See the “EXECUTE AS” Books Online topic for more information.)

The new `EXTERNAL NAME` keywords tell SQL Server that the routines or types being created belong to a specific class in a loaded assembly. The dot-notation for the string parameter of `EXTERNAL NAME` is as follows:

```
AssemblyName.ClassName.RoutineOrTypeName
```

You’ll see this parameter again in the DDL of the other managed objects we’ll soon create.

To view the objects created during script execution or VS deployment, open the Object Explorer in SQL Server Management Studio (SSMS), expand the AdventureWorks2008 database node, and then expand the Programmability node. There you can find the Assemblies node. (The managed objects in the assembly are kept in their respective folders.) If you right-click an assembly and view its properties, another window appears where you can view or change the assembly’s permissions.

Debugging Managed Code

Now open a new query window in SSMS and test your new managed stored procedure, just as you would any other. Try the following:

```
EXEC clr_GetProductManuals
Go
ProductModelId    Manual
-----
7                 <root xmlns="http://schemas.microsoft.com/sqlserver/2004/07/...
10                <root xmlns="http://schemas.microsoft.com/sqlserver/2004/07/...
...
(10 rows(s) affected.)
```

Let's try debugging with VS. By default, every SQL Server project is created with a Test Scripts folder and a file called `Test.sql`. `Test.sql` (or any other `.sql` file in a SQL Server project) is kind of like a hybrid of a code file and a query window. In this file you can execute a batch of arbitrary database commands, and you can also set breakpoints on each code line. The output of the commands appears in the Database Output section of VS's Output window.

Enter the same T-SQL in `Test.sql` that you just did in SSMS. Then set a breakpoint on any line. Press F5 or click the Run button, and you can now execute and step through your managed stored procedure in a single environment.

You may first need to acknowledge a dialog window that asks whether it's okay to enable SQLCLR debugging on the server. Answer in the affirmative, unless you're in a nontesting environment. (One caveat: As with remote debugging in general, this setup may not work in all environments.)

Developing Managed User-Defined Functions (UDFs)

Using SQL Server 2008 and the .NET Framework, you can write both *scalar* (single-valued) and table-valued user-defined functions in managed code. Scalar functions are the easier of the two, so we look at those first.

Scalar UDFs

In VS, right-click your SQLCLR project in the Solution Explorer and select Add, Add New Function. Next, name this new class `XSLT`, and, when it opens in the code editor, rename its default method to `XSLTransform` because that's what it is going to do—transform the content of an `xml`-typed variable using XSLT, using a stylesheet also stored in an `xml` column.

The `xml` data type lets you take advantage of server-side storage of XML, and why not leverage that same technology to store XSLT stylesheets? You'll have the assurance that before you save your XSLTs to your table, they are guaranteed to be well formed.

You need to add `using` statements to the newly created `XSLT.cs` file for the namespaces `System.IO`, `System.Xml`, and `System.Xml.Xsl`. You need `System.IO` to use the streams it offers (but not to write files), and you need the `XslCompiledTransform` object to perform the transformation.

Listing 46.2 shows the code of our new scalar function (note that we removed the namespace statement from `XSLT.cs`).

LISTING 46.2 A Managed Scalar UDF for Transforming XML

```
using System.Data.SqlTypes;
using Microsoft.SqlServer.Server;
```

```

using System.IO;
using System.Xml;
using System.Xml.Xsl;

public class XSLT
{
    [SqlFunction(
        DataAccess = DataAccessKind.None,
        IsDeterministic=false,
        IsPrecise=true,
        Name="clr_XSLTransform",
        SystemDataAccess=SystemDataAccessKind.None
    )]
    public static SqlXml XSLTransform(SqlXml InputXml, SqlXml XSLT)
    {
        MemoryStream ms = new MemoryStream();
        XslCompiledTransform xslcomp = new XslCompiledTransform(false);
        xslcomp.Load(XSLT.CreateReader());
        xslcomp.Transform(InputXml.CreateReader(), null, ms);
        ms.Seek(0, SeekOrigin.Begin);
        XmlTextReader xreader = new XmlTextReader(ms);
        return new SqlXml(xreader);
    }
};

```

Notice the use of the new `SqlFunction` attribute and its named parameter list. The implementation contract for managed scalar functions is just the same as for stored procedures: mark it as static and decorate it with the appropriate attribute.

The following named parameters are available for scalar UDFs:

- ▶ **DataAccess**—Tells SQL Server whether the function will access user table data on the server in its body. If you provide the enum value `DataAccessKind.None`, some optimizations may be made.
- ▶ **SystemDataAccess**—Tells SQL Server whether the function will access system table data on the server in its body. Again, if you provide the enum value `SystemDataAccessKind.None`, some optimizations may be made.
- ▶ **IsDeterministic**—Tells SQL Server whether the function will always return the same values, given the same input parameters.

A common example of a nondeterministic function is `GETDATE()`, which always returns something different. A function is also said to be nondeterministic if any of the functions that it calls are nondeterministic. `ISNUMERIC()` is a good example of a deterministic function.

- ▶ **IsPrecise**—Tells SQL Server whether the function does floating-point arithmetic (in which case, you provide the value `false`). Precise functions can be indexed; nonprecise functions cannot.
- ▶ **Name**—Tells the deployment routine what to call the function when it is created in the database.

What's neat about the code in Listing 46.2 is that it performs the entire XML transformation without using file I/O (except for the I/O required for SQL Server's paging functionality). You should build and deploy the code in this listing to your instance of SQL Server.

To test this example, create the following table in `AdventureWorks2008`, which will hold XSLTs pertaining to the tables in the `HumanResources` schema:

```
CREATE TABLE HumanResources.XmlResources
(
    XmlResourceId int IDENTITY(1,1) PRIMARY KEY CLUSTERED,
    XmlResourceType int NOT NULL DEFAULT(1),
    XmlResourceName varchar(50) NOT NULL,
    XmlResource xml
)
```

You also need a stylesheet to test it. Listing 46.3 inserts into this table an XSLT that searches the XML in the `Resume xml` column of `JobCandidate` and pulls out the name and address information into a more simplified XML structure.

LISTING 46.3 Inserting the XSLT Used by Our Managed Scalar UDF

```
INSERT HumanResources.XmlResources
SELECT
    1,
    'ResumeAddressTransformer',
    '<?xml version="1.0" ?>
<xsl:stylesheet
    xmlns:xsl="http://www.w3.org/1999/XSL/Transform"
    xmlns:ns="http://schemas.microsoft.com/sqlserver/2004/07/adventure-works/Resume"
    version="1.0">
    <xsl:template match="ns:Resume">
        <NameAndAddress>
            <xsl:apply-templates/>
        </NameAndAddress>
    </xsl:template>

    <xsl:template match="ns:Name">
```

```

    <Name>
      <xsl:value-of select="ns:Name.First" />
      <xsl:text disable-output-escaping="yes">&#160;</xsl:text>
      <xsl:value-of select="ns:Name.Last" />
    </Name>
  </xsl:template>

  <xsl:template match="ns:Address[ns:Addr.Type='Home']">
    <HomeAddress>
      <HomeStreet>
        <xsl:value-of select="ns:Addr.Street" />
      </HomeStreet>
      <HomeCity>
        <xsl:value-of
select="ns:Addr.Location/ns:Location/ns:Loc.City" />
      </HomeCity>
      <HomeState>
        <xsl:value-of
select="ns:Addr.Location/ns:Location/ns:Loc.State" />
      </HomeState>
      <HomeZip>
        <xsl:value-of select="ns:Addr.PostalCode" />
      </HomeZip>
    </HomeAddress>
  </xsl:template>
  <xsl:template match="node()" />
</xsl:stylesheet>
'

```

Now that you have your new resource saved, you need to test it on some data. Copy the code from Listing 46.3 into a new SSMS query window and execute it. Deploy your assembly using VS. Then copy the code in Listing 46.4 into another SSMS query window and execute it, preferably using the results-to-text (Ctrl+T) option.

You should use results-to-text here because the code in the listing executes the UDF and then, using `query()`, performs an XQuery against the results of the transformation (itself an instance of the `xml` data type) to reformat the content as textual output for use by a mail merge program.

LISTING 46.4 Running the XSLT UDF and Transforming the Output

```

DECLARE @inputXML xml, @XSLT xml

SELECT @inputXML = Resume
FROM HumanResources.JobCandidate

```

```

WHERE Resume.exist('
    declare namespace
        ns="http://schemas.microsoft.com/sqlserver/2004/07/adventure-works/Resume";
    /ns:Resume/ns:Name[ns:Name.First="Shai"]
') = 1

SELECT @XSLT = XmlResource
FROM HumanResources.XmlResources
WHERE XmlResourceName = 'ResumeAddressTransformer'

SELECT dbo.clr_XSLTransform(@inputXML, @XSLT).query('
    declare namespace
        ns="http://schemas.microsoft.com/sqlserver/2004/07/adventure-works/Resume";

    text {(/NameAndAddress/Name/text())[1]},
    text {"&#10;"},
    text {(/NameAndAddress/HomeAddress/HomeStreet/text())[1]},
    text {"&#10;"},
    text {(/NameAndAddress/HomeAddress/HomeCity/text())[1]},
    text {"", "},
    text {(/NameAndAddress/HomeAddress/HomeState/text())[1]},
    text {(/NameAndAddress/HomeAddress/HomeZip/text())[1]}
') AS StreetAddress
go

```

Table-Valued UDFs (TVFs)

Like scalar UDFs, table-valued UDFs (TVFs) use the `SqlFunction` attribute, except that for TVFs, two additional named parameters are available:

- ▶ **TableDefinition**—Because you'll be returning a table, you need to tell the compiler what the schema of that table will be. `TableDefinition` takes a string that corresponds to the column definition list used in the `CREATE TABLE` statement (that is, `ColumnName ColumnDataType Constraints (etc)`).
- ▶ **FillRowMethodName**—At execution time, each row in the returned table is represented in the class as an array of object (for example, in C#, `Object[]`). SQL Server needs to call a particular method of the TVF's class on a per-row basis that takes an empty array of object and fills each value of the array with an appropriate column value for the current row.

As you may have already surmised, SQL Server relies quite a bit on the .NET interfaces `IEnumerable` and `IEnumerator` to build a table of rows.

The main method of any TVF must be decorated with the `SqlFunction` attribute and also must implement `IEnumerable`. This simply means it must provide a parameterless method called `GetEnumerator()` that returns an instance of an object that implements `IEnumerator`.

The object that implements `IEnumerator` in turn implements the `MoveNext()` and `Reset()` methods and the `Current` property. If you have used and implemented .NET Framework collections, this approach should seem straightforward.

It may be useful to think of SQL Server as the “user” that calls the implemented methods of the code. The reason is that the actual runtime caller only needs to specify the name of the `SqlFunction` object; the caller doesn’t need to know (or care) how things actually get called under the covers at runtime.

One thing on everyone’s wish list for T-SQL has always been the use of regular expressions because the `LIKE` operator just isn’t powerful enough for many matches. The code in Listing 46.5 contains a set of classes for a TVF that acts as a regular expression evaluator. It’s unique from many examples out there in a few respects:

- ▶ It takes an input string, a user-defined type (covered later in this chapter) that represents a regular expression pattern (the `RegexPattern` UDF provides built-in pattern validation and storage), and an `Int32` that represents the .NET Framework `System.Text.RegularExpressions.RegexOptions` enum.
- ▶ It returns a two-column table of results, one row per match:
 - ▶ The first column is an incremental ID for the match.
 - ▶ The second column is an instance of the `xml` data type that contains the text of the match, the groups matched, and their respective captures.

The neat thing is that you can use this class just as you would the `Regex.Match()` method, options and all, and get a complete report of the matches on a per-match (think *per-row*) basis.

TIP

You need to add the C# `RegexPattern` struct to your assembly (covered in the next section on UDTs, in Listing 46.6) before you can deploy the code in Listing 46.5 to SQL Server using VS.

LISTING 46.5 A Table-Valued UDF for Pattern Matching

```
using System;
using System.Data;
using System.Data.Sql;
```

```

using System.Data.SqlTypes;
using Microsoft.SqlServer.Server;

//added
using System.Text.RegularExpressions;
using System.Collections;
using System.Xml;
using System.IO;
using System.Data.SqlClient;

public class RegexLibrary
{
    [Microsoft.SqlServer.Server.SqlFunction

else
{
    return false;
}
}

public Object Current
{
    get {
        return _current;
    }
}
}
}

```

When `MatchAll()` is invoked, it returns an instance of the `RegexReader` class. In its constructor, `RegexReader` sets the passed-in regular expression, input string, and options to its data members. Then, at initialization time, SQL Server invokes `RegexReader`'s `GetEnumerator()` instance method, which returns an instance of `RegexEnumerator`, which does all the real work, utilizing the members of the `RegexReader` object that is passed into its constructor and set to its private `_reader` object.

`Reset()` is called in `RegexEnumerator`'s constructor so that it can initialize its members in the following way:

- ▶ `RegexEnumerator` uses a private `Regex` object (`_rex`) for performing the match and stores the resulting array of `Match` (`Match[]`) in a private `Regex.Match` object (`_match`).
- ▶ The ordinal number of the match is kept in `_matchIndex` and initialized to 0 (in case there are no matches).
- ▶ When `Reset()` is complete, it is up to SQL Server to iterate through the matches by calling `MoveNext()`.

`MoveNext()` does the work of re-creating the row (represented as a private array of object called `_current`) for every successful match stored in `_match`:

- ▶ `_match[0]` is set to the value of `_matchIndex` (incremented on a per-match basis) and corresponds to the output table column (defined in the `TableDefinition` named parameter) `MatchIndex`.
- ▶ `_match[1]` is set to the value of an XML document that is built for every match and contains subnodes for each group and group capture. This value corresponds to the output table column `GroupList`.

When SQL Server uses the `RegexEnumerator`, it first calls `MoveNext()` and then uses the `Current` property.

Next, execution passes to the method specified in `FillRowMethodName` (`FillMatchAll()`).

Finally, the CLR passes the latest value of `_current` to `FillMatchAll()` as the row parameter. Each out parameter of `FillMatchAll()` is set to the value for the columns in the output row.

NOTE

If this implementation seems daunting, the best way to overcome that is to walk through the function line by line in debug mode, using VS.

Developing Managed User-Defined Types (UDTs)

In the preceding section, you used a managed user-defined type (UDT) called `RegexPattern` to store the regular expression pattern. In this section, you explore how custom UDTs are built and used in SQL Server.

The first thing to note is that although the name *UDT* is the same as the extended data types built using SQL Server 2000, they are by no means the same in SQL Server 2008.

SQL Server 2000's UDTs were actually retro-named "alias data types" in SQL Server 2005. SQL Server 2008 UDTs are *structs* (value types) built using the .NET Framework.

To create a UDT of your own, you right-click your Visual Studio project and then select Add, User-Defined Type. Next, you should name both the class and its autogenerated method `RegexPattern`. Notice the attribute used to decorate the `RegexPattern` struct: `SqlUserDefinedType`. Its constructor has the following parameters:

- ▶ **Format**—Tells SQL Server how serialization (and its complement, deserialization) of the struct should be done. You specify `Format.Native` to let SQL Server handle serialization for you. You specify `Format.UserDefined` to do your own serialization.

When `Format.UserDefined` is specified, the struct must implement the `IBinarySerialize` interface to explicitly take the values from `string` (or `int`, or whatever the value passed into the constructor of the type is) back to `binary` and vice versa.

- ▶ **A named parameter list**—This list contains the following:
 - ▶ **IsFixedLength**—Tells SQL Server that the byte count of the struct is the same for all its instances.
 - ▶ **IsByteOrdered**—Tells SQL Server that the bytes of the struct are ordered so that it may be used in binary comparisons, as with `ORDER BY`, `GROUP BY`, or `PARTITION BY` clauses, in indexing, and when the UDT is a primary or foreign key.
 - ▶ **MaxByteSize**—Tells SQL Server not to allow more than the specified number of bytes to be held in an instance of the UDT. The overall limit is 8KB. You must specify this when using `Format.UserDefined`.
 - ▶ **Name**—Tells the deployment routine what to call the UDT when it is created in the database.
 - ▶ **ValidationMethodName**—Tells SQL Server which method of the struct to use to validate it when it has been deserialized (in certain cases).

The implementation contract for any UDT is as follows:

- ▶ It must provide a static method called `Parse()`, used by SQL Server for conversion to the struct from a `string`.
- ▶ It must provide an instance method that overrides the default `ToString()` method for converting from the struct to a `string`.
- ▶ It must implement the `INullable` interface, providing a `Boolean` instance method called `IsNull`, used by SQL Server to determine whether an instance is `null`.
- ▶ It must have a static property called `Null` of the type of the struct. This property returns an instance of the struct whose value is `null` (that is, where `IsNull` is true for that instance). (This concept seems to be derived from the "null object" design pattern.)

Also, you need to be aware that UDTs can have only read-only static fields, they cannot use inheritance, and they cannot have overloaded methods (except the constructor, whose overloads are mainly used when ADO.NET is the calling context).

Given these fairly stringent requirements, Listing 46.6 provides an implementation of a UDT representing a regular expression pattern.

LISTING 46.6 A UDT Representing a Regular Expression Pattern

```
using System;
using System.Data;
using System.Data.Sql;
using System.Data.SqlTypes;
using Microsoft.SqlServer.Server;
//added
using System.Text.RegularExpressions;

[Serializable]
[Microsoft.SqlServer.Server.SqlUserDefinedType(
    Format.UserDefined, // requires IBinarySerialize
    IsFixedLength=false,
    IsByteOrdered=true,
    MaxByteSize=250,
    ValidationMethodName = "RegexPatternValidator"
)]
public struct RegexPattern : INullable, IBinarySerialize
{
    //instance data fields
    private Regex _reg;
    private bool _null;

    //constructor
    public RegexPattern(String Pattern)
    {
        _reg = new Regex(Pattern);
        _null = (Pattern == String.Empty);
    }

    //instance method
    public override string ToString()
    {
        return _reg.ToString();
    }

    //instance property
    public bool IsNull
```

```
{
    get
    {
        if (_reg == null || _reg.ToString() == string.Empty)
        {
            return true;
        }
        else
            return false;
    }
}

//static method
public static RegexPattern Null
{
    get
    {
        RegexPattern NullInstance = new RegexPattern();
        NullInstance._null = true;
        return NullInstance;
    }
}

//static method
public static RegexPattern Parse(SqlString Pattern)
{
    if (Pattern.IsNull)
        return Null;
    else
    {
        RegexPattern u = new RegexPattern((String)Pattern);
        return u;
    }
}

//private instance method
private bool RegexPatternValidator()
{
    return (_reg.ToString() != string.Empty);
}

//instance method
public Int32 Match(String Input)
{
    Match m = _reg.Match(Regex.Escape(Input.ToString()));
    if (m != null)
```

```

        return Convert.ToInt32(m.Success);
    else
        return 0;
}

//instance property
public bool IsFullStringMatch
{
    get
    {
        Match m = Regex.Match(_reg.ToString(), @"^\^+\$");
        if (m != null)
            return m.Success;
        else
            return false;
    }
}

//instance method
[SqlMethod(
    DataAccess = DataAccessKind.None,
    IsMutator = false,
    IsPrecise = true,
    OnNullCall = false,
    SystemDataAccess = SystemDataAccessKind.None
)]
public Int32 MatchingGroupCount(SqlString Input)
{
    Match m = _reg.Match(Regex.Escape(Input.ToString()));
    if (m != null)
        return m.Groups.Count;
    else
        return 0;
}

//static method
[SqlMethod(
    DataAccess = DataAccessKind.None,
    IsMutator = false,
    IsPrecise = true,
    OnNullCall = false,
    SystemDataAccess = SystemDataAccessKind.None
)]
public static bool UsesLookaheads(RegexPattern p)
// must be static to be called with :: syntax
{

```

```

Match m = Regex.Match(p.ToString(), @
if (m != null)
    return m.Success;
else
    return false;
}

#region IBinarySerialize Members

public void Read(System.IO.BinaryReader r)
{
    _reg = new Regex(r.ReadString());
}

public void Write(System.IO.BinaryWriter w)
{
    w.Write(_reg.ToString());
}

#endregion
}

```

As you can see by scanning this code, it meets the required implementation contract. In addition, it declares static and instance methods, as well as instance properties. Both static and instance methods can optionally be decorated with the `SqlMethod` attribute. By default, methods of UDTs are declared to be nondeterministic and nonmutator, meaning that they do not change the value of the instance.

You use the named parameters of the constructor for `SqlMethod` to override this and other behaviors. These are its named parameters:

- ▶ **DataAccess**—Tells SQL Server whether the method will access user table data on the server in its body. If you provide the enum value `DataAccessKind.None`, some optimizations may be made.
- ▶ **SystemDataAccess**—Tells SQL Server whether the method will access system table data on the server in its body. Again, if you provide the enum value `SystemDataAccessKind.None`, some optimizations may be made.
- ▶ **IsDeterministic**—Tells SQL Server whether the method always returns the same values, given the same input parameters.
- ▶ **IsMutator**—Must be set to true if the method changes the state of the instance.
- ▶ **Name**—Tells the deployment routine what to call the UDT when it is created in the database.
- ▶ **OnNullCall**—Returns null if any arguments to the method are null.

- **InvokeIfReceiverIsNull**—Indicates whether to invoke the method if the instance of the struct itself is null.

To create this type in SQL Server without using Visual Studio, you use the CREATE TYPE DDL syntax, as follows:

```
CREATE TYPE RegexPattern EXTERNAL NAME SQLCLR.RegexPattern
```

Note that DROP TYPE *TypeName* is also available, but there is no ALTER TYPE statement.

Let us add a few words on the code in Listing 46.6. The constructor to RegexPattern validates the expression passed to it via the constructor of System.Text.RegularExpressions.Regex.

If you pass an invalid regex to the T-SQL SET statement (when declaring a variable of type RegexPattern) or when the UDT is used as a table column data type and a value is modified, the Regex class does its usual pattern validation, as it does in the .NET world.

Let's look at some of the ways you can use your UDT. The following example shows how to call all the public members (both static and instance) of RegexPattern:

```
DECLARE @rp RegexPattern
SET @rp = '(\w+)\s+(?!bar) '

SELECT
    @rp.ToString() AS ToString,
    @rp.IsFullStringMatch AS FullStringMatch,
    @rp.Match('uncle freddie') AS Match,
    @rp.MatchGroupCount('loves elken') AS GroupCount,
    RegexPattern::UsesLookaheads(@rp) AS UsesLH
go
ToString          FullStringMatch Match GroupCt  UsesLH
-----
(\w+)\s+(?!bar)  0              1      2         1
(1 row(s) affected)
```

Note that static members can be called (without an instance, that is) by using the following new syntax:

```
TypeName::MemberName(OptionalParameters)
```

To try this, you can create a table and populate it as shown here:

```
CREATE TABLE dbo.RegexTest
(
    PatternId int IDENTITY(1,1),
    Pattern RegexPattern
)
GO
```

```

INSERT RegexTest SELECT '\d+'
INSERT RegexTest SELECT 'foo(?:bar)'
INSERT RegexTest SELECT '(\s+)'
Msg 6522, Level 16, State 2, Line 215
A .NET Framework error occurred during execution of user defined
routine or aggregate
'RegexPattern':
System.ArgumentException: parsing "(\s+)" - Not enough ')s'.
System.ArgumentException:
  at System.Text.RegularExpressions.RegexParser.ScanRegex()
  at System.Text.RegularExpressions.RegexParser.Parse(String re,
RegexOptions op)
  at System.Text.RegularExpressions.Regex..ctor(String pattern,
RegexOptions options,
Boolean useCache)
  at System.Text.RegularExpressions.Regex..ctor(String pattern)
  at RegexPattern..ctor(String Pattern)
  at RegexPattern.Parse(SqlString Pattern)

```

Do you see what happens when you try to insert an invalid regex pattern into the Pattern column (the third insert statement)? The parenthesis count is off, and the CLR tells you so in the query window's output.

Because the UDT has the `IsByteOrdered` named parameter set to `true`, you can index this column (based on the struct's serialized value) and use it in `ORDER BY` statements. Here's an example:

```

CREATE NONCLUSTERED INDEX PatternIndex ON dbo.RegexTest(Pattern)
GO
SELECT
    Pattern.ToString(),
    RegexPattern::UsesLookaheads(Pattern)
FROM RegexTest
ORDER BY Pattern
go
PatString    UsesLookaheads
-----
\d+          0
foo(?:bar)  1
(2 row(s) affected)

```

Back using ADO.NET, you can access the UDT by using the new `SqlDbType.Udt` enum value. To try this, you can add a new C# Windows application to your sample solution. You can add a project reference to your sample project ("SQLCLR") and then add a `using` statement for `System.Data.SqlClient`. Then you should add a list box called `lbRegexes` to the form. Finally, you should add a button called `btnCallUDT` to the form, double-click it, and add the code in Listing 46.7 to the body of its `OnClick` event handler.

LISTING 46.7 Using a UDT from ADO.NET in a Client Application

```
private void btnCallUDT_Click(object sender, EventArgs e)
{
    using (SqlConnection c =
        new SqlConnection(ConfigurationManager.AppSettings["connstring"]))
    {
        using (SqlCommand s = new SqlCommand("SELECT Pattern FROM dbo.RegexTest", c))
        {
            c.Open();
            SqlDataReader r = s.ExecuteReader(CommandBehavior.CloseConnection);
            {
                while (r.Read())
                {
                    RegexPattern p = (RegexPattern)r.GetValue(0);
                    lbRegexes.Items.Add(p.ToString());
                }
            }
            r.Close();
        }
    }
}
}
```

In this example, you selected all the rows from the sample table `dbo.RegexText` and then cast the `Pattern` column values into `RegexPattern` structs. Finally, you called the `ToString()` method of each struct, adding the text of the regex as a new item in the list box.

You can also create `SqlParameter` objects to be mapped to UDT columns by using code such as the following:

```
SqlParameter p = new SqlParameter("@Pattern", SqlDbType.Udt);
p.UdtTypeName = "RegexPattern";
p.Value = new RegexPattern(@"d+\s+d+");
command.Parameters.Add(p);
```

Finally, keep in mind that FOR XML does not implicitly serialize UDTs. You have to do that yourself, as in the following example:

```
SELECT Pattern.ToString() AS '@Regex'
FROM dbo.RegexTest
FOR XML PATH('Pattern'), ROOT('Patterns'), TYPE
go
<Patterns>
  <Pattern Regex="\d+" />
  <Pattern Regex="foo (?bar)" />
</Patterns>
```

Developing Managed User-Defined Aggregates (UDAs)

A highly specialized feature of SQL Server 2008, managed user-defined aggregates (UDAs) provide the capability to aggregate column data based on user-defined criteria built in to .NET code. You can now extend the (somewhat small) list of aggregate functions usable inside SQL Server to include those you custom-define.

NOTE

If you've been following the examples in this chapter sequentially, at this point, you need to drop the sample table `dbo.RegexTest` to redeploy the assembly after creating the UDA example.

The implementation contract for a UDA requires the following:

- ▶ A static method called `Init()`, used to initialize any data fields in the struct, particularly the field that contains the aggregated value.
- ▶ A static method called `Terminate()`, used to return the aggregated value to the UDA's caller.
- ▶ A static method called `Aggregate()`, used to add the value in the current row to the growing value.
- ▶ A static method called `Merge()`, used when SQL Server breaks an aggregation task into multiple threads of execution (SQL Server actually uses a thread abstraction called a *task*), each of which needs to merge the value stored in its instance of the UDA with the growing value.

UDAs cannot do any data access, nor can they have any side-effects—meaning they cannot change the state of the database. They take only a single input parameter, of any type. You can also add public methods or properties other than those required by the contract (such as the `IsPrime()` method used in the following example).

Like UDTs, UDAs are structs. They are decorated with the `SqlUserDefinedAggregate` attribute, which has the following parameters for its constructor:

- ▶ **Format**—Tells SQL Server how serialization (and its complement, deserialization) of the struct should be done. This has the same possible values and meaning as described earlier for `SqlUserDefinedType`.
- ▶ **A named parameter list**—This list contains the following:
 - ▶ **IsInvariantToDuplicates**—Tells SQL Server whether the UDA behaves differently with respect to duplicate values passed in from multiple rows.
 - ▶ **IsInvariantToNulls**—Tells SQL Server whether the UDA behaves differently when null values are passed to it.
 - ▶ **IsInvariantToOrder**—Tells SQL Server whether the UDA cares about the order in which column values are fed to it.

- ▶ **IsNullIfEmpty**—Tells SQL Server that the UDA will return null if its aggregated value is empty (that is, if its value is 0, or the empty string "", and so on).
- ▶ **Name**—Tells the deployment routine what to call the UDA when it is created in the database.
- ▶ **MaxByteSize**—Tells SQL Server not to allow more than the specified number of bytes to be held in an instance of the UDA. You must specify this when using `Format.UserDefined`.

For this example, you implement a very simple UDA that sums values in an integer column, but only if they are prime. Listing 46.8 shows the code to do this.

LISTING 46.8 A UDA That Sums Prime Numbers

```
using System;
using System.Data;
using System.Data.Sql;
using System.Data.SqlTypes;
using Microsoft.SqlServer.Server;

[Serializable]
[Microsoft.SqlServer.Server.SqlUserDefinedAggregate(
    Format.Native,
    IsInvariantToDuplicates=false,
    IsInvariantToNulls=true,
    IsInvariantToOrder=true,
    IsNullIfEmpty=true
)]
public struct SumPrime
{
    SqlInt64 Sum;

    private bool IsPrime(SqlInt64 Number)
    {
        for (int i = 2; i < Number; i++)
        {
            if (Number % i == 0)
            {
                return false;
            }
        }
        return true;
    }

    public void Init()
    {
        Sum = 0;
    }
}
```

```

}

public void Accumulate(SqlInt64 Value)
{
    if (!Value.IsNull && IsPrime(Value) && Value > 1)
        Sum += Value;
}

public void Merge(SumPrime Prime)
{
    Sum += Prime.Sum;
}

public SqlInt64 Terminate()
{
    return Sum;
}
}

```

In this code, SQL Server first calls `Init()`, initializing the private `Sum` data field to 0.

For each column value passed to the aggregate, the `Accumulate()` method is called, wherein `Sum` is increased by the value of the column, if it is prime.

When multiple threads converge, `Merge()` is called, adding the values stored in each instance (as the `Prime` parameter) to `Sum`.

When the rowset has been completely parsed, SQL Server calls `Terminate()`, wherein the accumulated value `Sum` is returned.

Following are the results of testing `SumPrime` on `Production.Product` (an existing `AdventureWorks2008` table):

```

SELECT TOP 10 dbo.SumPrime(p.ProductId) AS PrimeSum, p.Name
FROM Production.Product p
JOIN Production.WorkOrder o ON
o.ProductId = p.ProductId
WHERE Name LIKE '%Frame%'
GROUP BY p.ProductId, p.Name
ORDER BY PrimeSum DESC
go
PrimeSum  Name
-----
360355    HL Mountain Frame - Black, 42
338462    HL Mountain Frame - Silver, 42
266030    HL Road Frame - Red, 48
214784    HL Road Frame - Black, 48

```

```

133937    HL Touring Frame - Yellow, 46
68338    LL Road Frame - Red, 52
54221    LL Mountain Frame - Silver, 48
15393    ML Road Frame - Red, 52
0        HL Mountain Frame - Black, 38
0        HL Road Frame - Black, 44
(10 row(s) affected.)

```

Following is the DDL syntax for this UDA:

```

CREATE AGGREGATE SumPrime(@Number bigint)
RETURNS bigint
EXTERNAL NAME SQLCLR.SumPrime

```

As with UDTs, with UDAs there is no ALTER AGGREGATE, but you can use DROP AGGREGATE to drop them.

Developing Managed Triggers

Managed triggers are static methods of a .NET class decorated with the `SqlTrigger` attribute. `SqlTrigger` has three named parameters:

- ▶ **Event**—A required string-valued parameter that tells SQL Server which type of trigger you're defining, as is done when defining T-SQL triggers.
- ▶ **Target**—A required string-valued parameter that tells SQL Server which schema and table you're attaching the trigger to.
- ▶ **Name**—An optional string parameter that tells the deployment routine what to call the trigger when it is created in the database.

The implementation contract for a managed trigger is only that it be a static method that returns void.

Inside the method body of a managed trigger, you need to get a reference to the execution context of the trigger so you can find out what Data Manipulation Language (DML) statement the trigger is responding to and which columns have been updated. You do this by using the `SqlContext.TriggerContext` object of type `SqlTriggerContext`. (Note that this object is null when used in nontrigger contexts.) It has the following members:

- ▶ **ColumnCount**—An integer property that indicates how many columns were affected by the operation.
- ▶ **IsUpdatedColumn**—A Boolean method that indicates whether the column at a specific position was updated during the operation.
- ▶ **TriggerAction**—An enum that indicates which operation caused the trigger to fire. For DML triggers, this is either `TriggerAction.Insert`, `TriggerAction.Update`, or `TriggerAction.Delete`. For DDL triggers, the list is quite a bit longer. Refer to MSDN to see all the possible values of the `TriggerAction` enumeration.

- **EventData**—In the case of a DDL trigger, an object of type `SqlXml` that contains an XML document whose content explains the DDL that just fired. (The XML content model for this object is the same as that returned by the `EVENTDATA()` built-in function.)

Have you ever wanted to be notified by email that some important column value in your tables has been created or updated? There are many ways to do this, including using Query Notifications. You can also accomplish this by writing a managed trigger that calls a web service, which in turn sends an email.

Up until now, you haven't had to decrease the runtime safety of your assembly. But because certain aspects of web services use the `Synchronized` attribute (which means they do thread synchronization), we have to change our SQLCLR assembly's permission set to `UNSAFE`.

CAUTION

Only the `sysadmin` role can upload an `UNSAFE` assembly to SQL Server. You should allow this uploading only when you know the code being uploaded doesn't do anything that might compromise the integrity of the data, the server, or your job.

First, you need to create a simple web service routine that sends your email. To do this using Visual Studio 2008, you create a new local IIS website called `photoserve` and add to it a new web service called `PhotoService.asmx`. Then you replace the entire body of `PhotoService.cs` with the following C# code:

```
using System;
using System.Web.Services;
using System.Net.Mail;
using System.Configuration;

[WebService(Namespace = "urn:www-sampublishing-com:examples:sqlclr:triggers")]
[WebServiceBinding(ConformsTo = WsiProfiles.BasicProfile1_1)]
public class PhotoService : System.Web.Services.WebService
{
    [WebMethod]
    public void PhotoUpdateNotify(int ProductPhotoId)
    {
        MailMessage m = new MailMessage();
        m.Subject = "New Photo: " + ProductPhotoId.ToString();
        m.From = new MailAddress("ProductPhotoService@localservername");
        m.Body = "http://localhost:1347/photoserve/getphoto.aspx?ppid=" +
ProductPhotoId.ToString();
        m.To.Add(new MailAddress("PhotoAdmin@ localservername "));
        SmtpClient s = new SmtpClient("localservername", 25);
        s.Send(m);
    }
}
```

Of course, you need to have SMTP and IIS correctly configured on your server for this example to work completely. You also need to replace `localhost` and `localhostservername` and the email account names shown in the code with values that work for you.

Next, you should add a new web form called `getphoto.aspx` to the site. You replace the entire contents of `getphoto.aspx.cs` with the code in Listing 46.9.

LISTING 46.9 A Web Form That Retrieves Photos from SQL Server

```
using System;
using System.Data;
using System.Configuration;
using System.Web;
using System.Data.SqlClient;
using System.IO;

public partial class getphoto : System.Web.UI.Page
{
    protected void Page_Load(object sender, EventArgs e)
    {
        if (Request.QueryString["ppid"] != null)
        {
            string ppid = Request.QueryString["ppid"].ToString();
            string FileName = "photos/" + ppid + ".jpeg";
            string MappedFileName = Server.MapPath(FileName);
            using (SqlConnection c =
                new SqlConnection(
                    "Data Source=(local);Initial Catalog=AdventureWorks2008;
Integrated Security=True"
                )
            )
            {
                using (SqlCommand s = new SqlCommand(
                    @"SELECT LargePhoto
                    FROM Production.ProductPhoto
                    WHERE ProductPhotoId = " + ppid, c)
                )
                {
                    c.Open();
                    using (SqlDataAdapter a = new SqlDataAdapter(s))
                    {
                        using (DataSet d = new DataSet())
                        {
                            a.Fill(d);
                            if (d.Tables.Count == 1 && d.Tables[0].Rows.Count == 1)
                            {

```

```

byte[] BigImg = (byte[])d.Tables[0].Rows[0]["LargePhoto"];
FileStream f =
    new FileStream(
        MappedFileName,
        FileMode.Create,
        FileAccess.Write);
f.Write(BigImg, 0, BigImg.GetUpperBound(0));
f.Close();
Response.Redirect(FileName, false);
}
else
{
    Response.Write("<H2>Sorry, ProductPhotoId " + ppid
        + " was not found.</H2>");
}
}
}
}
}
else
{
    Response.Write("<H2>A querystring value for ppid is required.</H2>");
}
}
}
}
}

```

Next, you add a subfolder to the site called photos. This is the place where the web form will save product photos as JPEG files and redirect the email recipient. The main body of the code in Listing 46.9 illustrates how to save LOB values to file in a succinct manner, so it may prove useful for your other applications.

You either need to give your ASP.NET user file I/O permissions on photos or have the web application impersonate a user who has those permissions.

To recap, the website code so far consists of the following: a web service (PhotoService.asmx) that generates notification emails containing URLs. These URLs in turn point to a web form (getphoto.aspx) that saves the varbinary value of `Production.ProductPhoto.LargePhoto` (given a particular `ProductPhotoId`) to the photos folder as `[ProductPhotoId].jpeg`.

The last item you need is the reason you're writing this code in the first place: a managed trigger that invokes the web service to kick off the whole process. To add this, you right-click the SQLCLR project and then select Add, Trigger. Name this new trigger class `Triggers.cs` (the default). Then replace the entire content of `Triggers.cs` with the code in Listing 46.10.

LISTING 46.10 A Managed Trigger That Invokes a Web Service

```

using System;
using System.Data;
using Microsoft.SqlServer.Server;
using System.Data.SqlClient;
using SQLCLR.photoserve;

public partial class Triggers
{
    [Microsoft.SqlServer.Server.SqlTrigger(
        Event = "FOR UPDATE",
        Name = "Production.PhotoUpdateTrigger",
        Target = "Production.ProductPhoto"
    )]
    public static void PhotoUpdateTrigger()
    {
        SqlTriggerContext stc = SqlContext.TriggerContext;
        if (stc.TriggerAction == TriggerAction.Update)
        {
            if (stc.IsUpdatedColumn(3)) //The LargePhoto varbinary(max) column
            {
                using (SqlCommand s = new SqlCommand(
                    "SELECT DISTINCT ProductPhotoId FROM INSERTED",
                    new SqlConnection("context connection=true")))
                {
                    s.Connection.Open();
                    using (SqlDataReader r =
                        s.ExecuteReader(CommandBehavior.CloseConnection))
                    {
                        PhotoService p = new PhotoService();
                        while (r.Read())
                        {
                            SqlContext.Pipe.Send(
                                "Notifying Web Service of Update for PPID: " +
                                r.GetInt32(0).ToString());
                            p.PhotoUpdateNotify(r.GetInt32(0));
                        }
                    }
                }
            }
        }
    }
}

```

Now that all the code is in place, all that's left is an explanation of the code of `PhotoUpdateTrigger()` and a test case.

In the code in Listing 46.10, you check to see whether the current `TriggerAction` is `TriggerAction.Update`, meaning that the trigger is firing due to an update. You declare this to be true by using the `Event` named parameter of the `SqlTrigger` attribute.

Next, you select the `ProductPhotoId` of the updated row from the `INSERTED` table and connect to the database by using the context connection.

You execute the command and get your `SqlDataReader (r)`; then you instantiate the `PhotoService` web service. Using the overloaded method of the `Pipe` object, you send a string literal informational message (equivalent to T-SQL's `print` function), which tells any clients what is about to happen. You call the `PhotoUpdateNotify` method of the web service and pass in the `ProductPhotoId`, which in turn sends the email containing the link back to `getphoto.aspx`, which generates the photo JPEG for that `ProductPhotoId`.

To make the test case work, you need to make your local machine's Network Service user a SQL Server login and a user in `AdventureWorks2008` with at least `db_datareader` access. In addition, you might need to use the Visual Studio `sgen.exe` tool to create a serialization assembly for `SQL2008SQLCLR.d11` (which `sgen.exe` would, by default, name `SQL2008SQLCLR.XmlSerializers.d11`).

You need to load this serialization assembly into `AdventureWorks2008` before loading the main assembly (using `CREATE ASSEMBLY`). (At the time of this writing, it was necessary to also load `System.Web.d11` and its dependencies into `AdventureWorks2008` before loading the application assemblies.)

To test the trigger, you simply update a value of `Production.ProductPhoto.LargePhoto`:

```
UPDATE Production.ProductPhoto
SET LargePhoto = LargePhoto
WHERE ProductPhotoId = 69
go
Notifying Web Service of Update for PPID: 69
(1 row(s) affected.)
```

If you get an email in your test inbox, you've done everything right. If not, don't fret; this is a challenging example developed mainly to show the power of managed code.

Using Transactions

When you are writing managed objects, just as with T-SQL, it's important to be aware of the current transaction context under which your code may be running.

Managed database objects have the option of making use of the classes in the new `System.Transactions` namespace to control transactions. Following are the main objects you use to do this:

- **Transaction.Current**—This is a static object of type `Transaction` that represents the current transaction. You use this object to explicitly roll back the current transaction

(using `Rollback()`). It contains an `IsolationLevel` property that indicates the current transaction isolation level, as well as a `TransactionCompleted` event that your objects may subscribe to and a `TransactionInformation` property that indicates `TransactionStatus` and other attributes of the transaction. You can also use this object to manually enlist additional objects in the current transaction.

- ▶ **TransactionScope**—This object represents a transactional scope that is used to wrap managed code. Note that transactions automatically roll back unless they are explicitly committed using this object's `Complete()` method. It is enough to merely instantiate this object at the beginning of the managed code: If a current transaction is active, the instantiated object assumes that transaction; if not, a new transaction is initiated.

Note that it is not necessary to explicitly declare or even use transactions: if your managed code is already running in the scope of a transaction, it automatically participates in that transaction. (To turn off this behavior, you append `"enlist=false"` to your connection string.) In fact, even if your code opens additional connections on additional servers, the transaction context is not only preserved but is automatically promoted to a distributed transaction that enlists all the connections involved. (The MSDTC service must be running for distributed transactions to work.)

One thing you cannot do with managed transactions that you can with T-SQL is begin a new transaction and then just leave it open.

The code example in Listing 46.11 illustrates the use of the `System.Transactions` objects in a managed stored procedure. You need to add a new managed stored procedure to the SQLCLR project and call it `SpTrans`. Then you need to add the using statement using `System.Transactions`; and replace the autogenerated method with the code from Listing 46.11.

LISTING 46.11 Using Transactions in a Managed Stored Procedure

```
[SqlProcedure]
public static void SpTrans()
{
    TransactionScope ts = null;
    try
    {
        SqlContext.Pipe.Send("Proc Started");
        if (Transaction.Current != null)
        {
            SqlContext.Pipe.Send("A) Current tran is not null.");
            SqlContext.Pipe.Send("A) About to rollback current tran...");
            Transaction.Current.Rollback(
                new ApplicationException("I wanted to do this."));
            SqlContext.Pipe.Send("A) Rollback Complete.");
        }
    }
    else
```

```

{
    SqlContext.Pipe.Send("A) Current tran is null.");
}

ts = new System.Transactions.TransactionScope();
SqlContext.Pipe.Send("New Tran Started");
if (Transaction.Current != null)
    SqlContext.Pipe.Send("B) Current tran is not null.");
else
    SqlContext.Pipe.Send("B) Current tran is null.");

if (ts != null)
    ts.Complete();
    SqlContext.Pipe.Send("B) Complete() is Complete.");
}
finally
{
    if (ts != null)
        ts.Dispose();
    SqlContext.Pipe.Send("Proc Complete");
}
}

```

To test this code, you simply run the stored procedure from a query window (or use `sqlcmd.exe`) inside and outside a transactional scope and watch the results. Here's an example:

```

BEGIN TRAN
EXEC dbo.SpTrans
ROLLBACK TRAN
EXEC dbo.SPTrans

```

Using the Related System Catalogs

As with other database objects, SQL Server provides catalog views that enable you to view loaded managed assemblies, routines, and types. The base view for finding these objects is `sys.assemblies`.

To see which assemblies have been loaded (including the one you created in this chapter), you use the following query:

```

SELECT TOP 5
    name,
    assembly_id,
    permission_set_desc as permission_set
FROM sys.assemblies

```

```
ORDER BY assembly_id desc
go
name                                assembly_id  permission_set
-----
SQLCLR                              65719       UNSAFE_ACCESS
System.Configuration.Install        65705       UNSAFE_ACCESS
System.ServiceProcess               65704       UNSAFE_ACCESS
System.Web.RegularExpressions                 65703       UNSAFE_ACCESS
System.Drawing.Design               65702       UNSAFE_ACCESS
```

Now that you have the `assembly_id` for your SQLCLR project (yours will not be the same value as shown here), you can look up its routines and classes in `sys.assembly_modules`:

```
SELECT TOP 5
    name,
    assembly_class as class,
    assembly_method as method
FROM sys.assembly_modules am
JOIN sys.assemblies a
ON am.assembly_id = a.assembly_id
WHERE a.assembly_id = 65719
GO
name      class                method
-----
SQLCLR    StoredProcedures      GetSetIllustrationWebLinks
SQLCLR    StoredProcedures      SpTrans
SQLCLR    RegexLibrary          MatchAll
SQLCLR    XSLT                  XSLTransform
SQLCLR    SumPrime              NULL
```

Notice that the class holding your UDA (`SumPrime`) is listed, but your UDA itself is not listed. In addition, your UDT (`RegexPattern`) is not listed. To see everything, you right-click SQLCLR in the `Assemblies` node of the Object Browser and then select `View Dependencies`.

Summary

This chapter covered the development of SQLCLR code using user-defined managed database objects in conjunction with ADO.NET. We also reviewed advanced topics, such as transaction control and system catalog viewing.

If you attempted the examples from start to finish, you have upgraded your SQL Server and .NET programming arsenal and opened the doorway to a new world of data-integrated software.

In Chapter 47, “Using XML in SQL Server 2008,” we cover SQL Server’s extensive support for XML.

CHAPTER 47

Using XML in SQL Server 2008

SQL Server first planted its Extensible Markup Language (XML) roots with the introduction of the `FOR XML` and `OPENXML` keywords in SQL Server 2000, right around the time XML was growing in popularity as a markup format with seemingly unlimited uses.

With the release of SQL Server 2008, the bar has clearly been raised for XML support in relational databases.

What's New in Using XML in SQL Server 2008

XML and relational data may exist side by side and are more interchangeable than ever, thanks to SQL Server's XML-centric features, such as the `xml` data type, extensions to `FOR XML`, schema storage, content validation, indexing, XQuery support, and more.

With the release of SQL Server 2008, the SQL Server team added support for the few XML features that were unavailable in SQL Server 2005, including

- ▶ Support for lax validation in XML schemas
- ▶ Improved support for union and list types in XML schemas
- ▶ Addition of the `let` clause in XQuery
- ▶ Enhancements to XML Data Modification Language (DML) expressions

The introduction of these features is both vital and timely because XML has become the standard for everything from

IN THIS CHAPTER

- ▶ Understanding XML
- ▶ Relational Data as XML: The **FOR XML** Modes
- ▶ XML as Relational Data: Using **OPENXML**
- ▶ Using the **xml** Data Type
- ▶ Indexing and Full-Text Indexing of **xml** Columns

traditional markup for publications to business-to-business data exchange, web services, application programming (with XAML), graphics display (with SVG), news syndication (with RSS), and the list goes on.

But before digging into the world of SQL Server XML, let's briefly look at what XML is.

Understanding XML

XML was first created as a solution to the complexity inherent in the Standard Generalized Markup Language (SGML), the granddaddy of all structured markup languages. What you may not know is that SGML actually contains the rules that define how to produce other markup languages, such as HTML. XML is just a subset or restriction of those rules, providing the specifications for producing markup for all kinds of content based on a few simple conventions.

XML documents are either *well formed*, meaning they contain a single root element that contains every other element (or none), or *valid*, meaning they are well formed and all their elements adhere to all the constraints set forth in their associated Document Type Definition (DTD) or XML Schema Definition (XSD).

An XML document that adheres to the constraints of a particular DTD or schema is known as an *instance* of that DTD or schema. In some cases, an XML document is referred to as a *fragment*, meaning it contains more than one root element and/or text-only nodes.

XML documents are generally made up of elements (also called *tags*), attributes, instructions to the applications that use the document (known as *processing instructions*), comments, and text. Despite their variation in kind, all these structures are commonly known as *nodes*.

Keep in mind that there is no set list of predefined XML tags: they can be anything the XML specialist chooses. And just as HTML is considered to be an instance of SGML, the XML content model is also itself an instance of XML.

XML's only job is to provide the specification for how a document may be structured (or *marked up*). It contains no inherent information pertaining to data display or layout, content usage, or anything else.

The pages that follow provide many examples of XML, both simple and complex. We tour the many ways SQL Server can produce, store, load, and transform XML.

Relational Data As XML: The FOR XML Modes

One of the most important uses of XML is to provide a way of describing and encapsulating relational data. Doing so requires a mapping between two basic kinds of data structures: sets and trees. The techniques shown in this section thus have a single goal: converting the columns and rows that make up the sets derived from any SELECT statement into XML trees.

Note that before XML came along, selected result sets would most likely be exported to delimited text files for consumption by disparate systems. Today, most data interchange favors the use of XML. In response, developers have come to rely on XSL for Transformations (XSLT) as a companion skill for translating XML into HTML, PDF, RTE, or any other type of document.

Let's look at how the `SELECT...FOR XML` syntax can automatically mark up relational data in a variety of ways. The simplest approach uses `FOR XML RAW`.

RAW Mode

When specified at the end of a `SELECT` statement, the keywords `FOR XML RAW` tell SQL Server to generate a one-XML-element-per-row structure. The `FOR XML` statement has a few options that change its output from the default of document fragments to well-formed documents with a slightly (compared to a few other `FOR XML` options) reshaped structure. This is its syntax:

```
FOR XML RAW [ ('ElementName') ]
[
[ , BINARY BASE64 ]
[ , TYPE ]
[ , ROOT [ ('RootName') ]
]
[ , { XMLDATA | XMLSCHEMA [ ('TargetNameSpaceURI') ] } ]
[ , ELEMENTS [ XSINIL | ABSENT ] ]
```

Listing 47.1 illustrates the XML generated by the no-option version of `FOR XML RAW`. (Note that all the code in this chapter relies on the AdventureWorks2008 sample database.)

LISTING 47.1 A **SELECT** Statement That Uses **FOR XML RAW** with No Additional Modifiers

```
SELECT Name, ListPrice, Color
FROM Production.Product [Product]
WHERE Name LIKE '%Chain%'
ORDER BY Name
FOR XML RAW
go
<row Name="Chain" ListPrice="20.2400" Color="Silver" />
<row Name="Chain Stays" ListPrice="0.0000" />
<row Name="Chainring" ListPrice="0.0000" Color="Black" />
<row Name="Chainring Bolts" ListPrice="0.0000" Color="Silver" />
<row Name="Chainring Nut" ListPrice="0.0000" Color="Silver" />
```

This kind of XML shape is known as *attribute-centric* XML because each column in the result set is mapped to an attribute rather than an element. Each row is mapped to an element named `row`, which holds these attributes.

Listing 47.2 illustrates how the resultant XML can be changed into an *element-centric* shape, where each selected column is converted to an XML element simply through the addition of the `ELEMENTS` keyword to `FOR XML RAW`.

LISTING 47.2 A **SELECT** Statement That Uses **FOR XML RAW, ELEMENTS**

```

SELECT Name, ListPrice, Color
FROM Production.Product [Product]
WHERE Name LIKE '%Chain%'
ORDER BY Name
FOR XML RAW, ELEMENTS
go
<row>
  <Name>Chain</Name>
  <ListPrice>20.2400</ListPrice>
  <Color>Silver</Color>
</row>
<row>
  <Name>Chain Stays</Name>
  <ListPrice>0.0000</ListPrice>
</row>
<row>
  <Name>Chainring</Name>
  <ListPrice>0.0000</ListPrice>
  <Color>Black</Color>
</row>
<row>
  <Name>Chainring Bolts</Name>
  <ListPrice>0.0000</ListPrice>
  <Color>Silver</Color>
</row>
<row>
  <Name>Chainring Nut</Name>
  <ListPrice>0.0000</ListPrice>
  <Color>Silver</Color>
</row>

```

If the tag name `row` is undesirable, you can change the element name by simply adding a string-valued parameter, in parentheses, to the `RAW` keyword.

Note that in contrast to `FOR XML AUTO` (discussed later in this chapter), in this case, aliasing the `Production.Product` table has no effect on the output. Here's an example:

```

SELECT Name, ListPrice, Color
FROM Production.Product [Product]
WHERE Name LIKE '%Chain%'

```

```
ORDER BY Name
FOR XML RAW('ChainElement'), ELEMENTS
```

SQL Server 2008 also enables you to return NULL column values in generated XML. Previously, when a NULL column value was returned in the result set when using FOR XML, the null value was simply omitted from the XML: no attribute or element was generated at all. In SQL Server 2008, by specifying the keyword XSINIL after ELEMENTS, you can ensure that all null values are represented in the XML.

Note how the `xsi:nil="true"` attribute is produced for elements representing null column values. In addition, SQL Server automatically adds the XML schema namespace declaration to each node of the resulting fragment. This is required under the rules of XML because this fragment uses a Boolean attribute called `nil`, which is declared in the XML schema located at the specified URL. This, as well as the effect of the ELEMENTS keyword, is illustrated in Listing 47.3.

LISTING 47.3 A **SELECT** Statement That Uses **FOR XML RAW, ELEMENTS XSINIL**

```
SELECT TOP 1 Name, ListPrice, Color, Weight
FROM Production.Product [Product]
WHERE Name LIKE '%Chain%'
ORDER BY Name
FOR XML RAW('ChainElement'), ELEMENTS XSINIL
go
<ChainElement xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance">
  <Name>Chain</Name>
  <ListPrice>20.2400</ListPrice>
  <Color>Silver</Color>
  <Weight xsi:nil="true" />
</ChainElement>
```

Note that the XML results in Listing 47.3 happen to produce a well-formed XML document only because a single row was selected: this one row acts as both the root of the document and its entire content. All other XML results (including all the previous listings) encapsulating two or more rows are actually just fragments.

To easily change these XML fragments to well-formed documents, you can apply the ROOT keyword to add a root node to the output, as shown in Listing 47.4.

LISTING 47.4 A **SELECT** Statement That Uses **FOR XML RAW** and the **ROOT** Keyword

```
SELECT Name, ListPrice, Color, Weight
FROM Production.Product [Product]
WHERE Name LIKE '%Chain%'
ORDER BY Name
FOR XML RAW('ChainElement'), ELEMENTS XSINIL, ROOT('ChainDoc')
go
```

```

<ChainDoc xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance">
  <ChainElement>
    <Name>Chain</Name>
    <ListPrice>20.2400</ListPrice>
    <Color>Silver</Color>
    <Weight xsi:nil="true" />
  </ChainElement>
  <ChainElement>
    <Name>Chain Stays</Name>
    <ListPrice>0.0000</ListPrice>
    <Color xsi:nil="true" />
    <Weight xsi:nil="true" />
  </ChainElement>
  <ChainElement>
    <Name>Chainring</Name>
    <ListPrice>0.0000</ListPrice>
    <Color>Black</Color>
    <Weight xsi:nil="true" />
  </ChainElement>
  <ChainElement>
    <Name>Chainring Bolts</Name>
    <ListPrice>0.0000</ListPrice>
    <Color>Silver</Color>
    <Weight xsi:nil="true" />
  </ChainElement>
  <ChainElement>
    <Name>Chainring Nut</Name>
    <ListPrice>0.0000</ListPrice>
    <Color>Silver</Color>
    <Weight xsi:nil="true" />
  </ChainElement>
</ChainDoc>

```

Users (or applications) on the receiving side of RAW-produced XML may also require an inline XML schema (XSD) or an inline XML-Data Reduced (XDR) schema. Note that inline XDR schemas are considered to be deprecated in this release.

To produce these schemas, you add the XMLSCHEMA or XMLDATA keyword to the clause. The results are too long to be listed here, but to see how these schema types differ, compare the output of this:

```

SELECT Name, ListPrice, Color, Weight
FROM Production.Product [Product]
WHERE Name LIKE '%Chain%'
ORDER BY Name
FOR XML RAW, ELEMENTS XSINIL, XMLDATA

```

to the output of this:

```
SELECT Name, ListPrice, Color, Weight
FROM Production.Product [Product]
WHERE Name LIKE '%Chain%'
ORDER BY Name
FOR XML RAW('ChainElement'),
    ELEMENTS XSINIL,
    ROOT('ChainDoc'),
    XMLSCHEMA ('urn:www-sampublishing-com:examples')
```

XML schemas are discussed in further detail later in this chapter, in the section “Using XML Schema Collections.”

NOTE

The XMLDATA keyword is not permitted when ROOT is specified or when a tag name parameter has been passed to RAW (for example, RAW('ChainElement')).

Note also that XMLSCHEMA takes an optional string-valued parameter, allowing you to specify a value for the target namespace of the produced XML (for example, XMLSCHEMA ('urn:www-sampublishing-com:examples')).

Working with Binary Columns

Even though XML is purely a text-based markup language, FOR XML still has the capability to generate XML that contains data selected from binary–data-typed columns, such as image, binary, and varbinary. To do this, SQL Server base-64 encodes the data, resulting in a long character string.

To implement this in a query, you add joins from the table Production.Product to Production.ProductProductPhoto and then to Production.ProductPhoto, which contains the varbinary(max)–data-typed ThumbnailPhoto column. Then you add the keywords BINARY BASE64 to the FOR XML clause. Listing 47.5 illustrates this and also shows the schema generated by the XMLSCHEMA keyword. (Note that the base-64 character data is truncated in the listing for brevity with the character string {...}.)

LISTING 47.5 A **SELECT** Statement That Uses **FOR XML RAW** and the **BINARY BASE64** Option

```
SELECT TOP 1 Name, ListPrice, Color, Weight, ThumbnailPhoto
FROM Production.Product [Product]
JOIN Production.ProductProductPhoto PhotoJunction ON
    [Product].ProductId = PhotoJunction.ProductId
JOIN Production.ProductPhoto Photo
ON Photo.ProductPhotoId = PhotoJunction.ProductPhotoId
WHERE Name LIKE '%Chain%'
ORDER BY Name
FOR XML RAW('ChainElement'),
```

```

ELEMENTS XSINIL,
ROOT('ChainDoc'),
XMLSCHEMA('urn:www.sampublishing-com:examples'),
BINARY BASE64
go

    <ThumbNailPhoto>R01G0D1hUAAxAPcAAKeamoyLj {...}</ThumbNailPhoto>
</ChainElement>
</ChainDoc>

```

AUTO Mode

When RAW mode is not enough, FOR XML AUTO provides a few more ways to shape your XML output. Its usefulness derives from its capability to produce nested XML elements from rows derived by joining multiple tables, in contrast to the flat structure of RAW mode.

The ROOT keyword introduced earlier also applies with AUTO mode, and it is good practice to continue to use it in your queries. Like RAW mode, AUTO mode produces attribute-centric XML by default, but you can change this by using the ELEMENTS keyword. XSINIL and XMLSCHEMA are also applicable here, having the same effect as with RAW mode. Listing 47.6 illustrates these points.

LISTING 47.6 A SELECT Statement That Uses FOR XML AUTO, ELEMENTS XSINIL, ROOT

```

SELECT
    Color,
    Offer.SpecialOfferId Id,
    Product.ProductId Id,
    Name,
    Description [Desc],
    Size
FROM Sales.SpecialOffer Offer
JOIN Sales.SpecialOfferProduct OP ON
    OP.SpecialOfferId = Offer.SpecialOfferId
JOIN Production.Product Product ON
    Product.ProductId = OP.ProductId
WHERE Name LIKE 'Mountain Bike%'
FOR XML AUTO, ELEMENTS XSINIL, ROOT('MountainBikeSpecials')
go

```

```

<MountainBikeSpecials xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance">
  <Product>
    <Color>White</Color>
    <Id>710</Id>
    <Name>Mountain Bike Socks, L</Name>
    <Size>L</Size>
    <Offer>
      <Id>1</Id>
      <Desc>No Discount</Desc>
    </Offer>
  </Product>
  <Product>
    <Color>White</Color>
    <Id>709</Id>
    <Name>Mountain Bike Socks, M</Name>
    <Size>M</Size>
    <Offer>
      <Id>1</Id>
      <Desc>No Discount</Desc>
    </Offer>
    <Offer>
      <Id>2</Id>
      <Desc>Volume Discount 11 to 14</Desc>
    </Offer>
    <Offer>
      <Id>3</Id>
      <Desc>Volume Discount 15 to 24</Desc>
    </Offer>
    <Offer>
      <Id>4</Id>
      <Desc>Volume Discount 25 to 40</Desc>
    </Offer>
  </Product>
</MountainBikeSpecials>

```

With AUTO mode, the keywords `BINARY BASE64` have the same effect as with `RAW` mode, with one major difference: `RAW` mode generates an error if binary data is selected and `BINARY BASE64` is not specified; therefore, it is required. With `AUTO` mode, binary data may be selected without specifying `BINARY BASE64`, although SQL Server requires that the primary key of the table containing the binary data be selected. This is so that SQL Server can generate a path to the binary field, using the primary key to address the row (in place of the encoded data), of the following form:

```
'dbobject/SchemaName.TableName[@PrimaryKeyName="PrimaryKeyValue"]/@ColumnName'
```

This special XPath-like output is unique to AUTO mode and is useful for applications that incorporate SQLXML's URL-based querying to return the desired binary data. Listing 47.7 illustrates this XML production.

LISTING 47.7 Addressing Binary Data That Uses **FOR XML AUTO**

```

SELECT Top 1
    Photo.ProductPhotoId, ThumbnailPhoto, Color, Offer.SpecialOfferId Id,
    Product.ProductId Id, Name, Description [Desc], Size
FROM Sales.SpecialOffer Offer
JOIN Sales.SpecialOfferProduct OP ON
    OP.SpecialOfferId = Offer.SpecialOfferId
JOIN Production.Product Product ON
    Product.ProductId = OP.ProductId
JOIN Production.ProductProductPhoto PhotoJunction ON
    Product.ProductId = PhotoJunction.ProductId
JOIN Production.ProductPhoto Photo ON
    Photo.ProductPhotoId = PhotoJunction.ProductPhotoId
WHERE Name LIKE 'Mountain Bike%'
FOR XML AUTO, ELEMENTS XSINIL, ROOT('MountainBikeSpecials')
go
<MountainBikeSpecials xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance">
  <Photo>
    <ProductPhotoId>1</ProductPhotoId>
    <ThumbnailPhoto>
      dboobject/Production.ProductPhoto[@ProductPhotoID='1']/@ThumbnailPhoto
    </ThumbnailPhoto>
    <Product>
      <Color>White</Color>
      <Id>710</Id>
      <Name>Mountain Bike Socks, L</Name>
      <Size>L</Size>
      <Offer>
        <Id>1</Id>
        <Desc>No Discount</Desc>
      </Offer>
    </Product>
  </Photo>
</MountainBikeSpecials>

```

Notice how you can generate an additional level of nesting (with the Photo element) in the XML hierarchy simply by selecting a value from an additional table.

SQL Server has a set of rules it uses for nesting elements in AUTO mode. As rows are streamed to output, the XML engine studiously compares the values in adjacent columns

to check for differences from the first row on down to the last. When one or more primary keys have been selected in the query, only the primary key values are used in the column comparison. When no primary keys have been selected, all column values are used in the comparison, except for columns of type ntext, text, image, or xml, whose values are always assumed to be different.

The following example includes primary keys in the SELECT statement:

```
SELECT Offer.SpecialOfferId, Product.ProductId, Name
FROM Sales.SpecialOffer Offer
JOIN Sales.SpecialOfferProduct OP ON
OP.SpecialOfferId = Offer.SpecialOfferId
JOIN Production.Product Product ON
Product.ProductId = OP.ProductId
WHERE Name LIKE 'Mountain Bike%'
go
SpecialOfferId    ProductId    Name
-----
1                710         Mountain Bike Socks, L
1                709         Mountain Bike Socks, M
2                709         Mountain Bike Socks, M
3                709         Mountain Bike Socks, M
4                709         Mountain Bike Socks, M
(5 row(s) affected)
```

As the XML engine works down this result set, it sees that SpecialOfferId has the same value in the first and second rows, but ProductId differs in the same rows. It therefore creates one Offer element and nests the two different Product values in Product subelements.

Column selection order is also a determining factor in AUTO mode XML composition. Notice that even though in Rows 2–5, the ProductId remains 709, the XML engine still nests Product under Offer because Offer.SpecialOfferId is specified first in the list of selected columns. When FOR XML AUTO is added to the preceding query, it results in the following:

```
<MountainBikeSpecials>
  <Offer SpecialOfferId="1">
    <Product ProductId="710" Name="Mountain Bike Socks, L" />
    <Product ProductId="709" Name="Mountain Bike Socks, M" />
  </Offer>
  <Offer SpecialOfferId="2">
    <Product ProductId="709" Name="Mountain Bike Socks, M" />
  </Offer>
  <Offer SpecialOfferId="3">
    <Product ProductId="709" Name="Mountain Bike Socks, M" />
  </Offer>
```

```

<Offer SpecialOfferId="4">
  <Product ProductId="709" Name="Mountain Bike Socks, M" />
</Offer>
</MountainBikeSpecials>

```

To tell the XML engine that you prefer to nest Offer under Product, you simply change the column order in the SELECT statement:

```

SELECT Product.ProductId, Offer.SpecialOfferId, Name
FROM Sales.SpecialOffer Offer
JOIN Sales.SpecialOfferProduct OP ON
OP.SpecialOfferId = Offer.SpecialOfferId
JOIN Production.Product Product ON
Product.ProductId = OP.ProductId
WHERE Name LIKE 'Mountain Bike%'
FOR XML AUTO, ROOT('MountainBikeSpecials')
go
<MountainBikeSpecials>
  <Product ProductId="710" Name="Mountain Bike Socks, L">
    <Offer SpecialOfferId="1" />
  </Product>
  <Product ProductId="709" Name="Mountain Bike Socks, M">
    <Offer SpecialOfferId="1" />
    <Offer SpecialOfferId="2" />
    <Offer SpecialOfferId="3" />
    <Offer SpecialOfferId="4" />
  </Product>
</MountainBikeSpecials>

```

EXPLICIT Mode

FOR XML EXPLICIT is a powerful, oft-maligned, somewhat daunting mode of SQL Server XML production. It allows for the shaping of row data in any desirable XML structure, but the SQL required to produce it can easily end up being hundreds (or, in some cases, thousands) of lines long, leading to a potential maintenance headache.

With EXPLICIT mode, the query author is responsible for making sure the XML is well formed and that the rowset generated behind the scenes corresponds to a very particular format.

The FOR XML PATH statement renders FOR XML EXPLICIT obsolete except when you need to output column values as CDATA. This section therefore briefly covers the required query structure for and provides an example of this particular case.

NOTE

It's not an easy task to understand EXPLICIT mode just by reading. Practice is essential. After you've succeeded in using it a few times, it will begin to feel like an intuitive, albeit complex, way of doing things.

Microsoft calls the relational structure behind EXPLICIT mode queries the *universal table*. The universal table has a hierarchical structure sometimes known as the *adjacency list model*. Put simply, this means that the first column in the table is the primary key, and the second column is a foreign key referencing it, creating a parent–child relationship between rows in the same table. XML similarly models this relationship through the nesting of elements because nodes contained inside other nodes also hold a parent–child relationship.

Each level of hierarchical depth in the universal table is created by a separate SELECT statement, and each SELECT is unioned to the next, producing the complete rowset. Some details on the table structure help make this clearer:

- ▶ The first column in the universal table (think of it as the primary key) must be named Tag and hold an integer value. The value of Tag can be thought of as representing the depth of the node that will be produced.
- ▶ The second column must be named Parent and must refer to a valid value of Tag, or null, in the case of the first branch.
- ▶ The rest of the selected columns in the query are mapped either to attributes, subelements, or CDATA nodes, or they may be selected but not produced in the resultant XML.

Listing 47.8 shows a query that returns a universal table. Later, you can change it so that it returns XML by adding FOR XML EXPLICIT.

LISTING 47.8 A Query That Generates the Universal Table Rowset Format

```
SELECT
    1 as Tag,
    NULL as Parent,
    Reason.ScrapReasonId 'ScrapReason!1!ScrapReasonId!element',
    Name 'ScrapReason!1!!cdata',
    WorkOrderId 'WorkOrder!2!WorkOrderId',
    NULL 'WorkOrder!2!ScrappedQuantity'
FROM Production.ScrapReason Reason
JOIN Production.WorkOrder WorkOrder
ON Reason.ScrapReasonId = WorkOrder.ScrapReasonID
WHERE Reason.ScrapReasonId = 12

UNION ALL
```

```

SELECT
    2 as Tag,
    1 as Parent,
    Reason.ScrapReasonId,
    NULL,
    WorkOrderId,
    ScrappedQty
FROM Production.ScrapReason Reason
JOIN Production.WorkOrder WorkOrder
ON Reason.ScrapReasonId = WorkOrder.ScrapReasonID
WHERE Reason.ScrapReasonId = 12

```

The first SELECT statement in the union must use a special column alias syntax that tells the XML generator how to shape each column. This is the syntax:

```
element_name!corresponding_Tag_value!attribute_or_subelement_name[!directive]
```

The following list explains each part of the preceding syntax:

- ▶ **element_name**—The name of the generated element associated with each row.
- ▶ **corresponding_Tag_value**—The value of Tag for the context rowset.
- ▶ **attribute_or_subelement_name**—The name of the attribute or subelement associated with the column in the context row.
- ▶ **directive**—An optional directive to the XML generator. The possible values are
 - ▶ **element**—When specified, tells the XML generator to produce the column associated with *attribute_or_subelement_name* as a subelement. (An attribute is produced by default.)
 - ▶ **hide**—Tells the XML generator not to show the associated column data at all in the produced XML. This may be needed if there is some side effect desired from selecting the column but the data does not need to be shown.
 - ▶ **cdata**—Tells the XML generator to output the associated column data as a CDATA section.
 - ▶ **xml**—Disables entitization of text data. This can lead to non-well-formed XML because the XML special characters (&, ', ", <, >) are output directly.

In all subsequent SELECT statements, the columns corresponding to the rowsets identified by Tag are selected according to the layout specified in the first SELECT.

Notice how in Listing 47.8, NULL is selected for WorkOrder!2!ScrappedQuantity. This is done because the value for that column will be filled in by the SELECT statement having a Tag value of 2, as specified in *corresponding_Tag_value*. Likewise, ScrappedQty is selected only in the second SELECT statement (where NULL is supplied for ScrapReason!1!!cdata) because Name is selected in this column in the first SELECT. The primary key

(ScrapReasonId) that is the common thread joining both sets of rows must be specified in both SELECT statements for this query to work.

Now that you have an understanding of the universal table structure that must be built, the only thing left to do is add FOR XML EXPLICIT to the query in Listing 47.8 and then order the output according to the desired element hierarchy. Listing 47.9 illustrates the final query and its result.

LISTING 47.9 Using FOR XML EXPLICIT

```

SELECT
    1 as Tag,
    NULL as Parent,
    Reason.ScrapReasonId 'ScrapReason!1!ScrapReasonId!element',
    Name 'ScrapReason!1!!cdata',
    WorkOrderId 'WorkOrder!2!WorkOrderId',
    NULL 'WorkOrder!2!ScrappedQuantity'
FROM Production.ScrapReason Reason
JOIN Production.WorkOrder WorkOrder
ON Reason.ScrapReasonId = WorkOrder.ScrapReasonID
WHERE Reason.ScrapReasonId = 12
UNION ALL
SELECT
    2 as Tag,
    1 as Parent,
    Reason.ScrapReasonId,
    NULL,
    WorkOrderId,
    ScrappedQty
FROM Production.ScrapReason Reason
JOIN Production.WorkOrder WorkOrder
ON Reason.ScrapReasonId = WorkOrder.ScrapReasonID
WHERE Reason.ScrapReasonId = 12
ORDER BY 'ScrapReason!1!ScrapReasonId!element', 'WorkOrder!2!WorkOrderId'
FOR XML EXPLICIT, ROOT('ScrappedWorkOrders')
go
<ScrappedWorkOrders>
  <ScrapReason>
    <ScrapReasonId>12</ScrapReasonId>
    <![CDATA[Thermoform temperature too high]]>
    <WorkOrder WorkOrderId="2573" ScrappedQuantity="14" />
  </ScrapReason>
  <ScrapReason>
    <ScrapReasonId>12</ScrapReasonId>
    <![CDATA[Thermoform temperature too high]]>
    <WorkOrder WorkOrderId="4972" ScrappedQuantity="1" />

```

```

</ScrapReason>
<ScrapReason>
  <ScrapReasonId>12</ScrapReasonId>
  <![CDATA[Thermoform temperature too high]]>
  <WorkOrder WorkOrderId="7771" ScrappedQuantity="6" />
</ScrapReason>
<ScrapReason>
  <ScrapReasonId>12</ScrapReasonId>
  <![CDATA[Thermoform temperature too high]]>
  <WorkOrder WorkOrderId="9071" ScrappedQuantity="1" />
</ScrapReason>
<ScrapReason>
  <ScrapReasonId>12</ScrapReasonId>
  <![CDATA[Thermoform temperature too high]]>
  <WorkOrder WorkOrderId="10274" ScrappedQuantity="1" />
</ScrapReason>
{...}
</ScrappedWorkOrders>

```

In the ORDER BY clause, you tell the XML generator to first produce ScrapReason elements and then nest the WorkOrder elements underneath them.

Like the other modes, FOR XML EXPLICIT supports the BINARY BASE64 keywords, although base-64 encoding is performed automatically by the parser, even if not specified.

The ROOT keyword can also be used, although not when specifying XMLDATA. XMLSCHEMA is not supported as of this writing. ELEMENTS and XSINIL are also not supported, probably because you can get along without them, thanks to the many shaping options available.

PATH Mode

PATH mode is the latest and best addition to the FOR XML syntax. It provides a straightforward way of using a limited XPath syntax to specify the shaping of query-produced XML. It is also a very compact syntax in comparison with some of the other modes, especially EXPLICIT.

Let's look at how PATH mode works by re-creating the XML produced in Listing 47.9, this time using PATH mode. Listing 47.10 illustrates this mode.

LISTING 47.10 Using **FOR XML PATH** to Simplify an **EXPLICIT** Query

```

SELECT
  Reason.ScrapReasonId,
  Name 'text()',
  WorkOrderId 'WorkOrder/@WorkOrderId',
  ScrappedQty 'WorkOrder/@ScrappedQuantity'
FROM Production.ScrapReason Reason

```

```

JOIN Production.WorkOrder WorkOrder
ON Reason.ScrapReasonId = WorkOrder.ScrapReasonID
WHERE Reason.ScrapReasonId = 12
FOR XML PATH('ScrapReason'), ROOT('ScrappedWorkOrders')
go
<ScrappedWorkOrders>
  <ScrapReason>
    <ScrapReasonId>12</ScrapReasonId>
    Thermoform temperature too high
    <WorkOrder WorkOrderId="2573" ScrappedQuantity="14" />
  </ScrapReason>
  <ScrapReason>
    <ScrapReasonId>12</ScrapReasonId>
    Thermoform temperature too high
    <WorkOrder WorkOrderId="4972" ScrappedQuantity="1" />
  </ScrapReason>
  <ScrapReason>
    <ScrapReasonId>12</ScrapReasonId>
    Thermoform temperature too high
    <WorkOrder WorkOrderId="7771" ScrappedQuantity="6" />
  </ScrapReason>
  <ScrapReason>
    <ScrapReasonId>12</ScrapReasonId>
    Thermoform temperature too high
    <WorkOrder WorkOrderId="9071" ScrappedQuantity="1" />
  </ScrapReason>
{...}
</ScrappedWorkOrders>

```

The only difference between Listing 47.10 and Listing 47.9 is that here you aren't outputting a CDATA section—just a text node for the ScrapReason.Name column. Which FOR XML query would you rather maintain?

As the query in Listing 47.10 illustrates, the PATH keyword works like RAW in that all columns values are wrapped in a default element. Like RAW, PATH takes a parameter to specify the name of this default element. If a name is not specified, row is used, just as it is with RAW.

Unlike RAW, PATH mode is element-centric. When a column is not specified to be generated as an attribute (for example, using an XPath column alias, such as WorkOrderId '@Id'), it is produced as a subelement of the default tag.

You can also specify the ROOT keyword and the ELEMENTS XSINIL keywords in the same manner as RAW, although using ELEMENTS is somewhat redundant because PATH mode defaults to element-centric XML. Using ELEMENTS XSINIL is still the only way to produce null values in the XML.

You are not allowed to specify XMLSCHEMA and XMLDATA. BINARY BASE64 may be specified, but it is not required because base-64 encoded data is automatically generated.

To build the XML, the engine first works down the column list to figure out the desired XML shape to be output. XML is then generated for each row, based on the shape specified by the column names or aliases. Columns can be aliased using the literal string XPath format, or they may have no alias at all.

In the example in Listing 47.10, the following structure is specified by the column selections:

- ▶ For Reason.ScrapReasonId, output a subelement of ScrapReason (specified by PATH('ScrapReason')) called ScrapReasonId. When no alias is specified, the default shape is element-centric.
- ▶ For Name, output the value as a text-only child node of ScrapReason.
- ▶ For WorkOrderId, output a child node of ScrapReason called WorkOrder and add an attribute called WorkOrderId to it.
- ▶ For ScrappedQty, output an attribute of WorkOrder called ScrappedQuantity.

Usually, when you set out to shape XML, you intuitively know where you want your values to be, so it's more a matter of practice and application than memorization. When you know the basics, the syntax is intuitive enough to create whatever XML you desire.

FOR XML PATH has a few other neat features, which Listing 47.11 illustrates in one fell swoop.

LISTING 47.11 Demonstrating Several Features of **FOR XML PATH** in a Single Query

```
SELECT
    Reason.ScrapReasonId '*',
    'Comment: Name = ' + Name 'comment()',
    ModifiedDate 'processing-instruction(ModDatePI)',
    (
        SELECT WorkOrderId 'data()'
        FROM Production.WorkOrder WorkOrder
        JOIN Production.ScrapReason Reason
        ON Reason.ScrapReasonId = WorkOrder.ScrapReasonID
        WHERE Reason.ScrapReasonId = 12
        ORDER BY WorkOrderId desc
        FOR XML PATH('')
    ) 'WorkOrders/@WorkOrderIds'
FROM Production.ScrapReason Reason
WHERE Reason.ScrapReasonId = 12
FOR XML PATH('ScrappedWorkOrder'), ROOT('ScrappedWorkOrders')
go
<ScrappedWorkOrders>
```

```

<ScrapReason>12
  <!--Comment: Name = Thermoform temperature too high-->
  <?ModDatePI 1998-06-01T00:00:00?>
  <WorkOrders WorkOrderIds="72370 72273 70875 69474 69173 68573 65970 60472
56975 56875 55275 53771 50370 47670 45773 42071 41975 39372 36673
36671 32872 32775 32770 31073 29370 27771 24174 22673 22670 17674
16073 13073 10274 9071 7771 4972 2573" />
  </ScrapReason>
</ScrappedWorkOrders>

```

Let's review the selected columns in Listing 47.11: the first is aliased with the asterisk (*) character. This character tells SQL Server to inline-generate the data for that column (as text). (Using the text() node test would do the same in this case.)

Next, the comment() node test is specified for Name, telling the XML generator to output its value in a comment. For clarity's sake, we added a little syntactic sugar in this statement by prepending the text 'Comment: Name = ' to the value produced inside the comment.

Next, the processing-instruction() node test is specified to output each value of ModifiedDate to a new processing instruction called ModDatePI.

Finally, the fourth column is produced as a list of WorkOrderId values, using the magical data() keyword in a nested FOR XML PATH statement. data() tells SQL Server to generate a space-delimited list of atomic column values, one value for each row in the result set.

Note that the nested query is merely used to generate a list of WorkOrderId values. The empty string is given for the PATH keyword, telling the XML engine not to generate a default element at all, so no XML is generated whatsoever! You can extract and test the statement to see this in action.

The nested query applies the same WHERE clause as its parent to filter WorkOrderId values where the value of ScrapReasonId is 12. This ensures the relevancy of the nested data to the outer query.

The resulting list of values is grafted to the XML of the outer statement, using the column alias 'WorkOrders/@WorkOrderIds'.

FOR XML and the xml Data Type

By default, the results of any FOR XML query (using all four modes) is streamed to output as a one-column/one-row dataset with a column named XML_F52E2B61-18A1-11d1-B105-00805F49916B of type nvarchar(max). (In SQL Server 2000, this was a stream of XML split into multiple varchar(8000) rows.)

One of the biggest limitations of SQL Server 2000's XML production was the inability to save the results of a FOR XML query to a variable or store it in a column directly without using some middleware code to first save the XML as a string and then insert it back into an ntext or nvarchar column and then select it out again.

Today, SQL Server 2008 natively supports column storage of XML, using the `xml` data type. Be sure to read the section “Using the `xml` Data Type,” later in this chapter, for a complete overview.

You can easily convert FOR XML results to instances of `xml` by using the `TYPE` directive with all four modes (RAW, AUTO, EXPLICIT, and PATH). Listing 47.12 demonstrates the use of FOR XML PATH with the `TYPE` directive.

LISTING 47.12 Using **FOR XML PATH, TYPE** to Create an Instance of the **xml** Data Type

```
SELECT *
FROM Production.WorkOrder WorkOrder
WHERE ScrapReasonId = 12
AND WorkOrderId = 72370
FOR XML RAW('WorkOrder'), ELEMENTS XSINIL, ROOT('WorkOrders'), TYPE
go
<WorkOrders xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance">
  <WorkOrder>
    <WorkOrderID>72370</WorkOrderID>
    <ProductID>329</ProductID>
    <OrderQty>48</OrderQty>
    <StockedQty>47</StockedQty>
    <ScrappedQty>1</ScrappedQty>
    <StartDate>2008-07-01T00:00:00</StartDate>
    <EndDate>2008-07-11T00:00:00</EndDate>
    <DueDate>2008-07-12T00:00:00</DueDate>
    <ScrapReasonID>12</ScrapReasonID>
    <ModifiedDate>2008-07-11T00:00:00</ModifiedDate>
  </WorkOrder>
</WorkOrders>
```

Notice that in contrast to the preceding FOR XML examples, in this example, the query window in SQL Server Management Studio (SSMS) no longer displays the lengthy XML column UUID in the results frame, nor on the window tab. The results have been cast to a single instance of the `xml` data type, ready for use in variables of type `xml`, in subsequent queries, inserted into `xml` columns, or returned to the client.

The five `xml` data type methods—`value()`, `exist()`, `nodes()`, `query()`, and `modify()`, discussed later in this chapter, in the section “The Built-in `xml` Data Type Methods”—can be intermixed with relational queries by using all FOR XML modes. This makes it even easier to shape your XML exactly the way you want.

Listing 47.13 demonstrates how you can nest XQuery queries inside regular FOR XML T-SQL to produce XML documents built from both relational and XML sources.

LISTING 47.13 Bridging the Gap Between Relational and XML Data by Using FOR XML PATH and the xml Data Type

```

SELECT
    FirstName,
    LastName,
    E.JobTitle,
    Resume.query(
        'declare namespace ns="http://schemas.microsoft.com/sqlserver/2004/07/
adventure-works/Resume";
        //ns:Education
        '
    ) '*'
FROM HumanResources.Employee E
JOIN Person.Person C on E.BusinessEntityID = C. BusinessEntityID
JOIN HumanResources.JobCandidate J on J. BusinessEntityID = E. BusinessEntityID
WHERE J.JobCandidateId = 8
FOR XML PATH('AWorthyJobCandidate'), TYPE
go
<AWorthyJobCandidate>
  <FirstName>Peng</FirstName>
  <LastName>Wu</LastName>
  <Title>Quality Assurance Supervisor</Title>
  <ns:Education xmlns:ns="http://schemas.microsoft.com/sqlserver/2004/07/adventure-
works/Resume">
    <ns:Edu.Level> </ns:Edu.Level>
    <ns:Edu.StartDate>1986-09-15Z</ns:Edu.StartDate>
    <ns:Edu.EndDate>1990-05-15Z</ns:Edu.EndDate>
    <ns:Edu.Degree>Bachelor of Science</ns:Edu.Degree>
    <ns:Edu.Major> </ns:Edu.Major>
    <ns:Edu.Minor />
    <ns:Edu.GPA>3.3</ns:Edu.GPA>
    <ns:Edu.GPAScale>4</ns:Edu.GPAScale>
    <ns:Edu.School>Western University</ns:Edu.School>
    <ns:Edu.Location>
      <ns:Location>
        <ns:Loc.CountryRegion>US </ns:Loc.CountryRegion>
        <ns:Loc.State>WA </ns:Loc.State>
        <ns:Loc.City>Seattle</ns:Loc.City>
      </ns:Location>
    </ns:Edu.Location>
  </ns:Education>
</AWorthyJobCandidate>

```

In this example, the asterisk (*) is used as a column alias for the results of the nested query (on `HumanResources.JobCandidate.Resume`), telling SQL Server to simply output the XML inline with the other nodes.

XML As Relational Data: Using OPENXML

This section covers what might be called the inverse of FOR XML: OPENXML. You use OPENXML in T-SQL queries to read XML data and *shred* (or decompose) it into relational result sets. OPENXML is part of the SELECT statement, and you use it to generate a table from an XML source.

The first step required in this process is a call to the system stored procedure `sp_xml_preparedocument`. `sp_xml_preparedocument` creates an in-memory representation of any XML document tree for use in querying. It takes the following parameters:

- ▶ An integer output parameter for storing a handle to the document tree
- ▶ The XML input data
- ▶ An optional XML namespace declaration, used in subsequent OPENXML queries

`sp_xml_preparedocument` is able to convert the following data types into internal XML objects: text, ntext, varchar, nvarchar, single-quoted literal strings, and untyped XML (data from an `xml` column having no associated schema collection). This is its syntax:

```
sp_xml_preparedocument integer_variable OUTPUT[, xmltext ][, xpath_namespaces ]
```

And here is an example of OPENXML in use:

```
DECLARE @XmlDoc XML, @iXml int
SET @XmlDoc = '
    <ex:ExampleDoc xmlns:ex="urn:www-sampublishing-com:examples">
      <ex:foo>hello</ex:foo>
      <ex:bar>sql!</ex:bar>
    </ex:ExampleDoc>'
EXEC sp_xml_preparedocument
    @iXml OUTPUT,
    @XmlDoc,
    '<ExampleDoc xmlns:ex="urn:www-sampublishing-com:examples"/>'
SELECT id, parentid, nodetype, localname, prefix
FROM OPENXML(@iXml, '/ex:ExampleDoc/ex:foo')
--WITH (foo varchar(10) '/ex:ExampleDoc/ex:foo')
EXEC sp_xml_removedocument @iXml
go
```

id	parentid	nodetype	localname	prefix
3	0	1	foo	ex
5	3	3	#text	NULL

Notice in the example that the `WITH` predicate has been commented out. This is to illustrate in the query results what is known as an *edge table*: the XML document in its relational form. *Edge* is a term taken from graph theory. It refers to what you might visualize as a depth line between two nodes.

If the edge table looks familiar, the reason is probably that it bears a resemblance to the *universal table* that must be created for `EXPLICIT` mode. As with the universal table, the edge table follows the adjacency list model for its hierarchical relationships. The node types of the input XML are marked in the `nodetype` column (1 = element, 2 = attribute, 3 = text). Namespaces are stored in `namespaceuri`, and the data of each node is stored in the `text` column.

If you uncomment the `WITH` predicate and change the query from `SELECT *` to `SELECT foo`, you get back a one-row/one-column table with a column called `foo` that has the `varchar(10)` value `he1lo`. This shows that the `WITH` predicate instructs `OPENXML` how to decompose the nodes to columns by using XPath syntax.

The syntax for `OPENXML` (including the `WITH` predicate) is as follows:

```
OPENXML(integer_document_handle_variable int, rowpattern nvarchar, [flags byte])
    [WITH (SchemaDeclaration | TableName) ]
```

Let's match this syntax with the values in the example:

- ▶ The first parameter is the local variable `@iXml`, which acts as a handle to the internal XML representation.
- ▶ The next parameter is a row pattern in XPath syntax that tells `OPENXML` how to select nodes into rows. `OPENXML` generates one row in the result set for each node that matches this row pattern. This is similar to the .NET `XmlDocument` object's `SelectNodes()` method, insofar as every matching node in `rowpattern` returns a row in the rowset.
- ▶ The result set's columns are then defined, using matching nodes as the context and the XPath in the column definitions of the `WITH` predicate to find the values relative to the node.
- ▶ The `flags` parameter is a combinable byte value that controls how the selected XML nodes are to be decomposed. The following values are possible:
 - ▶ **0**—Uses attribute-centric decomposition. In this case, each attribute in the source XML is decomposed into a column. This is the default.
 - ▶ **1**—Uses attribute-centric decomposition. May be combined with flag **2** (that is, the value **3** may be specified). Combining flags **1** and **2** tells the rowset generator how to deal with the values in the XML not yet accounted for in the down-

ward parse of the XML document from nodes into rows. In other words, attribute-centric decomposition takes place before element-centric decomposition. This point is important because without the combinability of the flags, only one or the other decomposition will happen, and (lacking a WITH predicate that captures all the nodes) some nodes would not make it into the rowset.

- ▶ **2**—Uses element-centric decomposition. Combinable with flag **1** (that is, specify **3**).
- ▶ **8**—Tells the rowset generator how to deal with text data in the metaproperties (not covered in this chapter). Can be combined with flags **1**, **2**, or both.

Note that the column generation determined by the flags **0**, **1**, and **2** can all be overridden by the XPath expressions expressed in the lines of the WITH predicate. For example, if the **1** flag is specified to map a particular attribute to a column, but in the line of the WITH predicate for that same column, the XPath maps the value from an XML element, the WITH predicate takes precedence. It's truly best to just set the value of *flags to 3* in most cases, unless you care to ignore attributes or elements for some reason.

The syntax of the WITH predicate tells the rowset generator which column names and data types to use when mapping the XML to rows. If the structure of the input XML matches the schema of a particular table in your database, the name of that table may be specified. An example of this case occurs when the input XML has been produced from an existing table, using FOR XML. The values in the FOR XML-produced document have been updated, and the new values need to make it back into the table. The following code example illustrates this common scenario:

```
DECLARE @JobCandidateXmlDoc XML, @iXml int
SET @JobCandidateXmlDoc = '
  <JobCandidateUpdate>
    <ModifiedDate>
      10/5/2008 12:34PM
    </ModifiedDate>
  </JobCandidateUpdate>'
EXEC sp_xml_preparedocument
  @iXml OUTPUT,
  @JobCandidateXmlDoc,
  '<JobCandidateUpdate
  xmlns:ns="http://schemas.microsoft.com/sqlserver/2004/07/adventure-
works/Resume"/>';
UPDATE HumanResources.JobCandidate
SET ModifiedDate = OXML.ModifiedDate
FROM
(
  SELECT *
  FROM OPENXML(@iXml, '/JobCandidateUpdate', 2)
  WITH HumanResources.JobCandidate
) AS OXML
```

```
WHERE JobCandidateId = 8
EXEC sp_xml_removedocument @iXml
go
(1 row(s) affected)
```

If a table name is not specified, you need to specify a comma-separated list of lines, using the following syntax:

```
column_name datatype 'XPath'
```

The following list explains each part of the preceding syntax:

- ▶ ***column_name***—Provides a relational name for the XML-produced column.
- ▶ ***datatype***—Provides a T-SQL data type for the XML-produced column.
- ▶ ***'XPath'***—Specifies a row pattern that matches the nodes in the XML whose values are to be mapped to the XML-produced column.

When you're done reading out the XML, it's important to free the memory used to hold the internal XML document. You accomplish this by calling the system stored procedure `sp_xml_removedocument`, as in the following example:

```
EXEC sp_xml_removedocument @iXml
```

Using the `xml` Data Type

The `xml` data type is a real problem solver for those who use both XML and SQL Server on a daily basis. Relational columns and XML data can be stored side by side in the same table, in an implementation that plays to the strengths of both. With SQL Server's powerful XML storage, validation, querying, and indexing capabilities, it's bound to cause quite a stir in the field of XML content management and beyond.

Some of the benefits of storing XML on the database tier can be realized immediately. Building middleware using the .NET Framework to manage XML stored in columns, rather than on the filesystem, is a far more robust solution than depending on the filesystem; plus, it's a lot easier to access the content from anywhere.

SQL Server inherently provides to stored XML the traditional DBMS benefits of backup and restoration, replication and failover, query optimization, granular locking, indexing, and content validation. The `xml` data type can be used with local variable declarations, as the output of user-defined functions, as input parameters to stored procedures and functions, and much more. XML instances containing up to 128 levels of nesting can be stored in `xml` columns; deeper instances cannot be inserted, nor may existing instances be made to increase beyond this depth via the `modify()` data type method.

`xml` columns can also be used to store code files such as XSLT, XSD, XHTML, and any other well-formed content. These files can then be retrieved by user-defined functions written in managed code hosted by SQL Server. (See Chapter 53, "SQL Server 2008 Reporting Services," for a full review of SQL Server-managed hosting.)

NOTE

In some cases, it's still a perfectly valid scenario to store XML on the filesystem or in [n]varchar(max), [n]text, or [n]varbinary(max) columns. In a few cases this usage is actually recommended. The following summary details some possible XML usage scenarios and makes suggestions for each.

XML data is stored in an internal binary format and can be up to 2GB in size.

Before we dig into the many uses of the xml data type, it's worthwhile to consider some of the different ways you can leverage your institution's XML with SQL Server:

- ▶ XML can be used solely as a temporary output format produced from relational data, using FOR XML. This applies in scenarios in which the relational tables hold the real-time data and XML is produced only for read-only application uses, as in the display of dynamic web pages. In this scenario, the XML really just provides a DBMS-independent, easy-to-transform view of the data.
- ▶ XML can be stored in relational (nvarchar and so on) columns, as done previously. This might be the best option when your XML is sometimes not well formed or when the learning curve to XQuery is too high for an application-delivery time frame. This is also a valuable option when the byte-for-byte exactness of the XML must be preserved.

Note that the latter is a necessary option in some institutions because *typed XML* (that is, xml data type columns associated with a schema collection) storage disregards extra whitespace characters, namespace prefixes, attribute order, and the XML declaration to make way for query optimizations. This scenario also leverages fast data retrieval because, as far as SQL Server is concerned, XML is never brought into the mix (it's all relational). The data can still be converted to the xml data type, using the methods described earlier, and applications can use OPENXML to read it as well. To read XML into SQL Server from server-side accessible files, you call the T-SQL OPENROWSET function.

- ▶ The XML can be stored as untyped XML—that is, XML stored in an xml data type column lacking an associated schema collection. This provides the benefits of querying the XML using the data type methods (discussed later in the section “The Built-in xml Data Type Methods”) and provides server-side checks for well-formed XML. This scenario also allows for the possibility that XML adhering to any (or no) schemas may reside in the column. A schema collection could be added later to provide validation on the existing data (although a few intermediate editing steps may be necessary if any documents fail to validate).

Safely armed with an understanding of some of the different options and uses, let's plunge into our discussion of xml.

Defining and Using xml Columns

You can add columns of type `xml` to any table by using a familiar Data Definition Language (DDL) syntax, with a few new twists. Much like their relational counterparts, `xml` columns, parameters, and variables may contain null or non-null values.

The following snippet shows the DDL used to create the table `HumanResources.JobCandidate` from `AdventureWorks2008`. The column you are concerned with is `Resume`:

```
CREATE TABLE [HumanResources].[JobCandidate](
    [JobCandidateID] [int] IDENTITY(1,1) NOT NULL,
    [EmployeeID] [int] NULL,
    [Resume] [xml](CONTENT [HumanResources].[HRRResumeSchemaCollection]) NULL,
    [ModifiedDate] [datetime] NOT NULL
    CONSTRAINT [DF_JobCandidate_ModifiedDate] DEFAULT (getdate()),
    CONSTRAINT [PK_JobCandidate_JobCandidateID] PRIMARY KEY CLUSTERED
)
[JobCandidateID] ASC
) ON [PRIMARY]
) ON [PRIMARY]
```

When you are defining objects of type `xml`, either of two *facets* may be applied:

- ▶ **CONTENT**—This facet specifies that well-formed XML documents as well as fragments may be inserted into the `xml` column or variable. (`CONTENT` is the default and may be omitted from the definition.)

Fragments may have more than one top-level node (as is produced, by default, using `FOR XML`), and elements may be mixed with text-only nodes.

- ▶ **DOCUMENT**—This facet specifies that only well-formed, valid XML conforming to a specified schema collection may be stored. Updates to the column must also result in schema-valid, well-formed XML.

XML schema collections can be associated with `xml` variables, parameters, or columns. The name of the schema collection is specified directly after the chosen facet, as is done in `JobCandidate.Resume`.

The following code example defines a typed `xml` local variable that allows only valid `Resume` data to be stored in it:

```
DECLARE @ValidWellFormed xml (DOCUMENT HumanResources.HRRResumeSchemaCollection)
```

Trying to insert the following well-formed but invalid document throws an error that says the first (and only) `ThisBlowsUp` element in the document is not declared in any of the schemas in `HRRResumeSchemaCollection`:

```
SELECT @ValidWellFormed = '<ThisBlowsUp/>'
go
```

XML Validation: Declaration not found for element 'ThisBlowsUp'.
Location:/*:ThisBlowsUp[1]

When you change the facet to CONTENT (the default) and remove the schema association, the following is possible:

```
DECLARE @WellFormed xml
SELECT @WellFormed = '<ThisWorks/>'
go
Command(s) completed successfully.
```

When defining xml columns, you can specify defaults and constraints just as you do with relational columns. Consider the following example:

```
CREATE TABLE XmlExample
(
    XmlColumn xml NOT NULL DEFAULT CONVERT(xml,'<root/>',0)
)
```

This example creates an xml column called XmlColumn that starts out having an empty root node. Notice how the string '<root/>' is converted to the xml type. This is actually not necessary because conversions from literal strings and from varchar to xml are implicit.

The next example adds a table-level constraint to XmlColumn to make sure the root node always exists. It depends on a scalar-valued user-defined function to do its validation work:

```
CREATE FUNCTION dbo.fn_XmlColumnNotNull
(
    @XmlColumnValue xml
)
RETURNS bit
AS
BEGIN
    RETURN @XmlColumnValue.exist('/root')
END
GO
CREATE TABLE XmlExample
(
    XmlColumn xml NOT NULL DEFAULT CONVERT(xml,'<root/>',0)
)
GO
ALTER TABLE XmlExample WITH CHECK
ADD CONSTRAINT CK_XmlExample_HasRoot
CHECK (dbo.fn_XmlColumnNotNull(XmlColumn) = 1)
```

The following statement thus fails:

```
INSERT XmlExample SELECT '<foo/>'
```

But this statement succeeds:

```
INSERT XmlExample SELECT '<root><foo/></root>'
```

Let's say you manage the data for a company that has just upgraded from SQL Server 2000 to 2008. You already store all your XML inside `ntext` columns, and it's time to convert those columns to `xml`. You can do this easily if the stored XML is well formed, as in the following example:

```
CREATE TABLE NTextXml
(
    NTextXmlColumn ntext NULL
)
GO
INSERT NTextXml
SELECT
    '<feedback_review>
      <parts_order id="106">
        <customer_comment>Lot&apos;s of Junk!</customer_comment>
      </parts_order>
    </feedback_review>'
GO
ALTER TABLE NTextXml
ALTER COLUMN NTextXmlColumn xml NULL
```

Next, you would like to ensure that all your XML validates against a schema. To change the column from typed to untyped XML by associating a schema, you execute the following:

```
ALTER TABLE NTextXml
ALTER COLUMN NTextXmlColumn xml
(DOCUMENT HumanResources.HRRResumeSchemaCollection)
go
XML Validation: Declaration not found for element 'feedback_review'.
Location: /*:feedback_review[1]
The statement has been terminated.
```

Notice the error generated. The reason is that the tags used are not defined in the schemas of `HRRResumeSchemaCollection`, so the XML does not validate, and the `ALTER TABLE` statement fails. What you really want is for the XML to validate against your own schema, which is described in the next section.

Using XML Schema Collections

In this section, you define a simple XML schema, add it to a new schema collection stored on the server, and create a table where you can store instances of this schema. You also add a check constraint to ensure that the value of the `ProductId` attribute of the XML's root node matches the value of the `ProductId` column, using the `xml` data type `value()` method (discussed later in this chapter, in the section, "The Built-in `xml` Data Type

Methods”). The foreign key constraint you define on `ProductId` also serves to ensure that both `ProductId` values reference a primary key value in `HumanResources.Product`.

The real-world concept behind this sample schema is that it defines groups of customer feedback calls and subsequent corporate responses pertaining to different kinds of orders. Listing 47.14 shows the schema and table definition.

LISTING 47.14 An XSD and Table for Modeling and Storing Customer Feedback Reviews

```

use AdventureWorks2008
go
CREATE XML SCHEMA COLLECTION Sales.FeedbackSchemaCollection AS
'<?xml version="1.0"?>
<xsd:schema
  xmlns:xsd="http://www.w3.org/2001/XMLSchema"
  targetNamespace="urn:www-samspublishing-com:examples:feedback_review_xsd"
  xmlns="urn:www-samspublishing-com:examples:feedback_review_xsd"
  elementFormDefault="qualified"
  attributeFormDefault="unqualified">
  <xsd:element name="feedback_review" type="feedbackReviewType"/>
  <xsd:complexType name="feedbackReviewType">
    <xsd:sequence minOccurs="1" maxOccurs="unbounded">
      <xsd:element name="order" type="orderType"/>
    </xsd:sequence>
    <xsd:attribute
      name="product_id"
      type="xsd:integer"
      use="optional"/>
  </xsd:complexType>
  <xsd:complexType name="feedbackType" mixed="true">
    <xsd:attribute name="id" type="xsd:integer" use="required"/>
  </xsd:complexType>
  <xsd:complexType name="orderType">
    <xsd:choice minOccurs="0" maxOccurs="unbounded">
      <xsd:element name="customer_comment" type="feedbackType"/>
      <xsd:element name="company_response" type="feedbackType"/>
    </xsd:choice>
    <xsd:attribute name="id" type="xsd:integer" use="required"/>
    <xsd:attribute name="type" use="required">
      <xsd:simpleType>
        <xsd:restriction base="xsd:string">
          <xsd:enumeration value="parts"/>
          <xsd:enumeration value="product"/>
          <xsd:enumeration value="service"/>
        </xsd:restriction>
      </xsd:simpleType>
    </xsd:complexType>

```

```

        </xsd:attribute>
    </xsd:complexType>
</xsd:schema>'
GO
CREATE FUNCTION Sales.fnCheckProductId
(
    @FeedbackReviewXml xml
)
RETURNS int
AS
BEGIN
    DECLARE @ProductId int

    SELECT @ProductId = @FeedbackReviewXml.value('
        declare namespace
            fr="urn:www-sampublishing-com:examples:feedback_review_xsd";
            /fr:feedback_review[1]/@product_id', 'int')

    RETURN @ProductId
END
GO
CREATE TABLE Sales.FeedbackReview
(
    FeedbackReviewId int IDENTITY(1, 1) NOT NULL PRIMARY KEY,
    ProductId int NULL REFERENCES Production.Product,
    FeedbackReviewXml xml (DOCUMENT Sales.FeedbackSchemaCollection) NOT NULL,
    CONSTRAINT ProductIdMatches
    CHECK (Sales.fnCheckProductId(FeedbackReviewXml) = ProductId)
)
GO

```

Having created the xml column, you can now insert valid, well-formed documents into FeedbackReview in the following manner:

```

INSERT Sales.FeedbackReview
SELECT
    NULL,
    '<feedback_review
        xmlns="urn:www-sampublishing-com:examples:feedback_review_xsd">
        <order id="353" type="service">
            <customer_comment id="131">
                You guys said you&apos;d be here on Monday.
            </customer_comment>
            <company_response id="242">I said Wednesday!</company_response>
        </order>

```

```

    </feedback_review>'
GO
(1 row(s) affected)

```

Using INSERT, you can input XML into xml columns as varchar, xml, or literal string data, or you can insert the output of a subquery that returns these types.

The syntax used to create an XML schema collection is simple and straightforward:

```
CREATE SCHEMA COLLECTION schema_collection_name AS schema
```

The *schema* parameter can be either a string (as shown), or a variable that contains the text of the schema of type *varchar*, *nvarchar*, *varbinary*, *nvarbinary*, or *xml*.

Dropping a schema collection is just as easy:

```
DROP SCHEMA COLLECTION schema_collection_name
```

If you ever want to select your schema back out again, you simply call the system function `xml_schema_namespace`, as in the following example:

```
SELECT xml_schema_namespace(
    'Sales',
    'FeedbackSchemaCollection',
    'urn:www-sampublishing-com:examples:feedback_review_xsd'
)
```

To add additional schemas to the collection, you use ALTER XML SCHEMA COLLECTION:

```
ALTER XML SCHEMA COLLECTION
Sales.FeedbackSchemaCollection ADD another schema
```

To view some of the nodes in your stored XML schemas, you query `sys.xml_schema_collection` and its related catalog views. Here's an example:

```
use AdventureWorks2008
go
SELECT el.name, el.*, el.must_be_qualified
FROM sys.columns sc
JOIN sys.xml_schema_collections xs
ON sc.xml_collection_id = xs.xml_collection_id
JOIN sys.xml_schema_elements el
ON xs.xml_collection_id = el.xml_collection_id
WHERE sc.name = 'FeedbackReviewXml'
```

Given the name of the table's typed xml column (`FeedbackReviewXml`), you can find its associated schema collection by querying the catalog views as follows:

```
SELECT
    sc.name XmlColumnName,
```

```

        xs.name CollectionName,
        ns.name Namespace
from sys.columns sc
JOIN sys.xml_schema_collections xs
ON sc.xml_collection_id = xs.xml_collection_id
JOIN sys.xml_schema_namespaces ns
ON ns.xml_collection_id = sc.xml_collection_id
WHERE sc.name = 'FeedbackReviewXml'
go
XmlColumnName           CollectionName           Namespace
-----
FeedbackReviewXml      FeedbackSchemaCollection urn:www-sampublishing-
com:examples:feedback_review_xsd
    
```

You can accomplish the same thing by using the Object Browser in SSMS by viewing the properties of the xml column or by right-clicking the Modify menu choice on the table object, as shown in Figure 47.1.

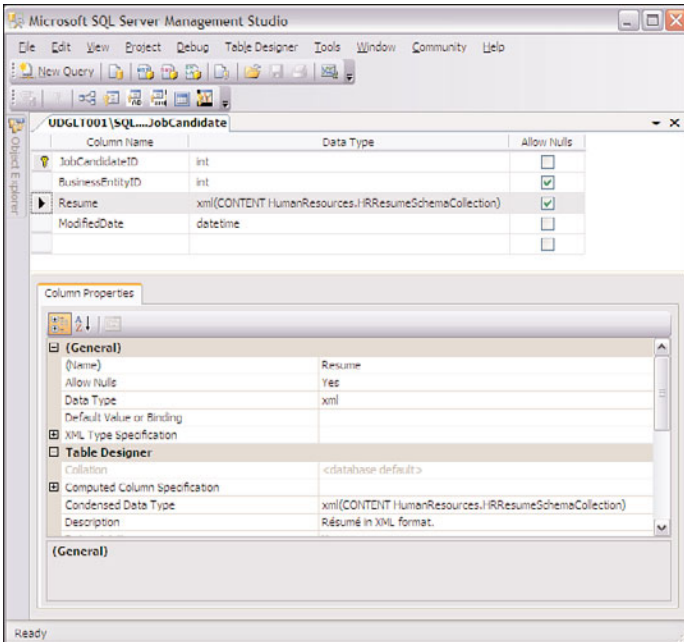

FIGURE 47.1 Viewing the properties of an **xml** column in SSMS.

You can control permissions on schema collections by using the standard ALTER, CONTROL, TAKE OWNERSHIP, REFERENCES, VIEW DEFINITION, and EXECUTE syntax. Here's an example:

```

GRANT ALTER ON XML SCHEMA COLLECTION::Sales.FeedbackSchemaCollection
TO some_login
    
```

There are a few unsupported XML schema features in schema collections. Check the Books Online article titled “Guidelines and Limitations of XML Schema Collections on the Server” for the most up-to-date information. Following are some notable limitations:

- ▶ The XSD constraints `key`, `keyref`, and `unique` are not supported.
- ▶ XSD `include` and `redefine` are not supported.
- ▶ Lax validation is not supported.

You can also manage XML schema collections using SSMS. To do so, you open the Object Browser and expand the main tree to the following node:

`ServerName\Databases\AdventureWorks2008\Programmability\Types\XML Schema Collections`. Then you right-click a schema collection to drop it or to add new schemas. You can also easily script schemas out for review whenever needed. Figure 47.2 shows the expanded Object Browser tree.

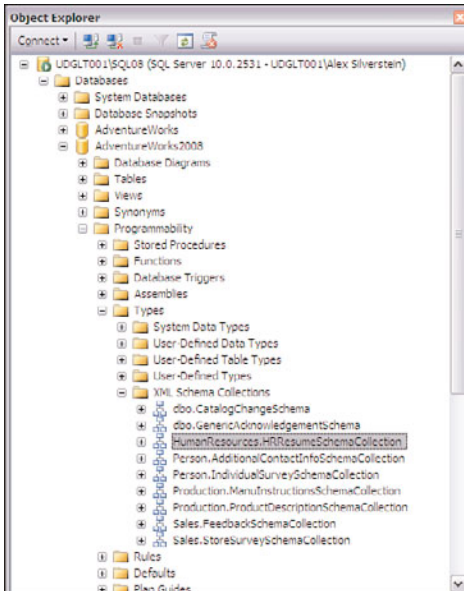

FIGURE 47.2 Using the Object Browser to manage XML schema collections.

The Built-in xml Data Type Methods

Now that you know how to create and manage typed and untyped xml columns, the next step is to learn how to query and modify stored XML content. Although SQL Server supports only a subset of the XQuery 1.0 recommendation, you’ll soon see that it’s plenty to get the job done.

Keep in mind that a mastery of XQuery is not a requirement for selecting out XML data; you can just specify the name of the `xml` column to select all the data back at once.

SQL Server provides five built-in methods on the `xml` data type: `query()`, `exists()`, `value()`, `nodes()`, and `modify()`. These methods are appended to the name of the `xml` column in question, using the `ColumnName.MethodName([MethodParameters])` syntax. These methods work on XML in the following ways:

- ▶ **query()**—Evaluates an XQuery expression into a node list, allowing for reshaping of the selected nodes. Results in untyped XML.
- ▶ **exists()**—Performs a Boolean test to see whether the result of an XQuery expression is empty (no matching nodes). Returns **1** (non-empty), or **0** (empty).
- ▶ **value()**—Extracts a single (that is, scalar) value from an XML node and casts it to a SQL Server relational data type (for example, `int`, `varchar`).
- ▶ **nodes()**—Uses an XQuery expression to decompose the XML input into a rowset; this is similar to the effect of `OPENXML`.
- ▶ **modify()**—Alters the content of an XML document using the `insert`, `replace value of`, and `delete` XQuery functions.

XQuery is a bit like T-SQL in that it uses similar `SELECT-FROM-WHERE-ORDER BY` semantics to find the required nodes. It also bears a resemblance to writing `foreach` loops with object iterators in a language such as C#. It is unique in that it combines the navigational power of XPath to locate nodes and (in the same expressions) allows for new XML generation on the fly, all in one tight syntax package built especially for processing XML.

To use XQuery effectively, you need to have at least a rudimentary understanding of XPath. A great starting point is the World Wide Web Consortium's (W3C's) site, at www.w3.org/TR/xpath20/. The following subsections assume such basic knowledge.

Selecting XML by Using `query()`

The job of `query()` is to retrieve XML nodes by using XQuery expressions. The result of `query()` is an instance of untyped `xml`. It takes a single parameter, a string literal containing the XQuery code itself.

NOTE

Like all the other four `xml` data type methods (and unlike most other T-SQL keywords), `query()` is case sensitive. This is in keeping with the case sensitivity of XML itself.

NOTE

The parameter to `query()` cannot be a variable; it must be a string literal. This puts something of a hold on dynamic XQuery expressions. However, declared T-SQL variables and column values are available for use in XQuery, using the functions `sql:variable()` and `sql:column()` (described later in this chapter).

Each XQuery query is broken into two distinct parts, separated by a semicolon. The first part is known as the *prolog*. This is the place where any namespaces used in the XPath expressions and selected nodes are declared. The second part is known as the *body*, and this is the place where XPath and XQuery expressions are evaluated.

The following example declares the `act` namespace in its query prolog and then selects any `act:eMail` nodes from `Person.Person.AdditionalContactInfo` in its body:

```
SELECT
    AdditionalContactInfo.query(
    ,
        declare namespace
            act="http://schemas.microsoft.com/sqlserver/2004/07/adventure-
works/ContactTypes";
        //act:eMail
    ,
    )
FROM Person.Person
WHERE ContactId = 2
go
<act:eMail
    xmlns:act="http://schemas.microsoft.com/sqlserver/2004/07/adventure-
works/ContactTypes">
    <act:eMailAddress>Joe@xyz.com</act:eMailAddress>
    <act:SpecialInstructions>
        Dont send emails for urgent issues. Use telephone instead.
    </act:SpecialInstructions>
</act:eMail>
```

Note that as with `FOR XML`, the result of `query()` can sometimes be an XML fragment (or an empty string). You can again use `FOR XML RAW`, `ROOT` to guarantee that this won't happen. Listing 47.15 illustrates this use, as well as the `WITH XMLNAMESPACES` statement.

LISTING 47.15 Using **WITH XMLNAMESPACES** with **FOR XML** and **query()**

```
WITH XMLNAMESPACES
(
    'http://schemas.microsoft.com/sqlserver/2004/07/adventure-works/ContactTypes'
    as act
)
SELECT
    FirstName,
    LastName,
    AdditionalContactInfo.query(
    ,
        //act:eMail
    ,
    )
```

```

)
FROM Person.Person
WHERE BusinessEntityID = 2
FOR XML RAW('ContactInfo'), ROOT('Contact')
go
<Contact xmlns:act="http://schemas.microsoft.com/sqlserver/2004/07/adventure-works/ContactTypes">
  <ContactInfo FirstName="Catherine" LastName="Abel">
    <act:eMail xmlns:act="http://schemas.microsoft.com/sqlserver/2004/07/adventure-works/ContactTypes">
      <act:eMailAddress>Joe@xyz.com</act:eMailAddress>
      <act:SpecialInstructions>
        Dont send emails for urgent issues. Use telephone instead.
      </act:SpecialInstructions>
    </act:eMail>
  </ContactInfo>
</Contact>

```

You can use `WITH XMLNAMESPACES` to declare namespaces for use in subsequent `SELECT` statements. Using this statement makes it possible to omit the prolog from the `query()`. It also has the desirable side effect of adding the `act` namespace declaration to the root `Contact` node in the resulting `FOR XML RAW` wrapper. It's a great keystroke saver and helps keep xml data type queries readable.

In addition to selecting nodes with simple XPath expressions, you can use `query()` to specify `WHERE` clause conditions on the selected nodes, iterate through the nodes using `for-each` semantics, order the nodes differently than in the original document, and return XML in any desired structure, based on the selection. This type of processing is known by its acronym `FLWOR` (pronounced *flower*), which stands for `for`, `let`, `where`, `order by`, `return`.

The `for` Clause The `for` clause establishes a variable that is bound to a node list for the purpose of iterating over each node. In each iteration of the `for` loop, this bound variable takes the value of the context node. It may be optionally typed (using as `XML_Schema_TypeName`) to a schema-declared type, and it is followed by the XPath used to match the nodes to be selected. The bound variable in the following example is `$ContextNode`:

```

SELECT Instructions.query('
  declare default element namespace
  "http://schemas.microsoft.com/sqlserver/2004/07/adventure-works/ProductModelManuInstructions";
  for $ContextNode in //Location
  return
    <LotSize>
      {$ContextNode/@LotSize}
    </LotSize>

```

```

') as Result
FROM Production.ProductModel
WHERE ProductModelID = 10
Go
<LotSize xmlns="http://schemas.microsoft.com/sqlserver/2004/07/adventure-
works/ProductModelManuInstructions" LotSize="100" />

```

This example also shows the use of the `declare default element namespace` statement, which allows the specified XPath expressions that follow it to omit any namespace prefixes.

In place of an XPath expression, you can use the bound variable to iterate through a sequence of values, rather than nodes, as in the following example:

```

SELECT Instructions.query('
    for $ContextNode in (1, 2, 3)
    return
        <Number>
            {$ContextNode }
        </Number>
') as Result
FROM Production.ProductModel
WHERE ProductModelID = 10
go
<Number>1</Number>
<Number>2</Number>
<Number>3</Number>

```

You can also specify more than one bound variable in the `for` clause. Bound variables subsequent to the first can be used in XPath queries against the first. In this manner, two related context nodes—one inner and one outer—can be created simultaneously. This is analogous to writing a nested `for` loop in a programming language, but here you need only declare both context variables by using a comma. Here's an example:

```

DECLARE @Xml xml
SET @Xml = '
    <outernode name="a">
        <innernode>1</innernode>
        <innernode>2</innernode>
        <innernode>3</innernode>
    </outernode>
    <outernode name="b">
        <innernode>4</innernode>
        <innernode>5</innernode>
        <innernode>6</innernode>
    </outernode>
'
SELECT @Xml.query('

```

```

    for $outer in /outernode,
      $inner in $outer/innernode
    return
      <Outside letter="{ $outer/@name }">
        <Inside number="{ $inner }"/>
      </Outside>
  ')
go
<Outside letter="a">
  <Inside number="1" />
</Outside>
<Outside letter="a">
  <Inside number="2" />
</Outside>
<Outside letter="a">
  <Inside number="3" />
</Outside>
<Outside letter="b">
  <Inside number="4" />
</Outside>
<Outside letter="b">
  <Inside number="5" />
</Outside>
<Outside letter="b">
  <Inside number="6" />
</Outside>

```

The let Clause New to SQL Server 2008, the `let` clause is the `L` in *FLWOR*. It performs the critical function of enabling variable value assignments in XQuery expressions. Here's an example:

```

WITH XMLNAMESPACES
(
  DEFAULT 'http://schemas.microsoft.com/sqlserver/2004/07/adventure-
works/StoreSurvey'
)
SELECT TOP 1
Demographics.query(
  '
    for $N in /StoreSurvey
    let $Total := ($N/AnnualRevenue + $N/AnnualSales)
    order by $N/AnnualSales
    return
      <Statement
        AnnualRevenue="{ $N/AnnualRevenue }"

```

```

        AnnualSales="{N/AnnualSales}"
        SalesPlusRevenue="{Total}" />
    ')
FROM Sales.Store
WHERE Demographics.exist(' (//AnnualRevenue[xs:integer(.)=300000])') = 1

```

The where Clause Just like the WHERE clause in T-SQL, XQuery's where clause restricts the nodes in the selected node list to those matching a certain expression. Here's an example:

```

SELECT TOP 1 Resume.query('
    declare namespace
    ns="http://schemas.microsoft.com/sqlserver/2004/07/adventure-works/Resume";

    for $ResumeNode in /ns:Resume
    where count($ResumeNode/ns:Employment) > 2
    return
        $ResumeNode/ns:Employment/ns:Emp.JobTitle
')
FROM HumanResources.JobCandidate
go
<ns:Emp.JobTitle
    xmlns:ns="http://schemas.microsoft.com/sqlserver/2004/07/adventure-works/Resume">
    Lead Machinist
</ns:Emp.JobTitle>
<ns:Emp.JobTitle
    xmlns:ns="http://schemas.microsoft.com/sqlserver/2004/07/adventure-works/Resume">
    Machinist
</ns:Emp.JobTitle>
<ns:Emp.JobTitle
    xmlns:ns="http://schemas.microsoft.com/sqlserver/2004/07/adventure-works/Resume">
    Assistant Machinist
</ns:Emp.JobTitle>

```

Here, you use the T-SQL-analogous count() aggregate function to restrict the result set to ns:Resume nodes having three or more ns:Employment children. The standard aggregate functions are available in XQuery expressions. They are max(), min(), avg(), sum(), and count().

The order by Clause Just like T-SQL's ORDER BY, XQuery's order by is used to reorder the selected nodes from the default document order to a new order, based on an expression. The order may be set to descending or ascending (the default).

The following example casts a node value to an instance of the `xs:date` type and orders the results from most to least recent date:

```

SELECT Resume.query('
  declare namespace
    ns="http://schemas.microsoft.com/sqlserver/2004/07/adventure-works/Resume";
  <Achievements>
  {
    for $EducationNode in //ns:Education
    order by xs:date(string($EducationNode/ns:Edu.EndDate[1])) descending
    return
      <Degree>
        <DateAwarded>
          { string($EducationNode/ns:Edu.EndDate[1]) }
        </DateAwarded>
        <Name>
          { string($EducationNode/ns:Edu.Degree[1]) }
        </Name>
      </Degree>
    }
  </Achievements>
')
FROM HumanResources.JobCandidate
WHERE JobCandidateId = 2
go
<Achievements>
  <Degree>
    <DateAwarded>1997-06-03Z</DateAwarded>
    <Name>Bachelor of Science</Name>
  </Degree>
  <Degree>
    <DateAwarded>1993-06-12Z</DateAwarded>
    <Name>Diploma</Name>
  </Degree>
</Achievements>

```

The expression `xs:date(string($EducationNode/ns:Edu.EndDate[1]))` requires some explanation. Working from the inside out: `ns:Edu.EndDate` is selected, using the child node of the node stored in the bound context variable `$EducationNode`. For the `string()` typecasting function to work, a *singleton*, or single node, must be specified; this is why the positional predicate `[1]` must be specified. Finally, the string is cast to `xs:date`. (Note that in the return statement, the string value of the same node is used.)

This example illustrates not only the type-related aspects of FLWOR expressions, but also the capability to generate a root node without using `FOR XML...ROOT`. All that is required is that a root node (in this case, `Achievements`), followed by curly braces, surround the entire FLWOR statement.

The return Clause Similar to T-SQL's SELECT statement, the return clause executes once for every selected context node. This is the section where you specify the structure and content of the resulting XML. The key aspect of it is the use of node *constructors*.

TIP

When using attribute constructors in the return clause, you need to make sure your curly braces are directly adjacent to the attribute's begin and end quotes, with no whitespace in between (for example, `attribute="{ $Node }"`), or SQL Server raises an error. The reason is that string literals (even blank spaces) cannot be mixed with attribute constructors.

Put simply, constructors create the nodes and node values to be output. There are two types of constructors:

- ▶ **Computed constructors**—These are placed inside curly-braced expressions and evaluated against the context node (for example, `attribute="{ $N }"`).
- ▶ **Direct constructors**—These are constant node strings used in the FLWOR statement (for example, `<Achievements>`). Listing 47.16 illustrates a variety of constructors.

LISTING 47.16 Using **XQuery** Constructors

```
SELECT Resume.query('
  declare namespace
    ns="http://schemas.microsoft.com/sqlserver/2004/07/adventure-works/Resume";

  for $N in //ns:Education
  return
    <NodeConstructor attributeConstructor="{string($N/ns:Edu.School[1])}">
      { $N/ns:Edu.Major }
      <?PI processing-instruction constructor PI?>
      <!-- comment constructor -->
    </NodeConstructor>
')
FROM HumanResources.JobCandidate
WHERE JobCandidateId = 1
go
<NodeConstructor attributeConstructor="Midwest State University">
  <ns:Edu.Major
    xmlns:ns="http://schemas.microsoft.com/sqlserver/2004/07/adventure-
works/Resume">
    Mechanical Engineering
  </ns:Edu.Major>
<?PI processing-instruction constructor PI?>
```

```
<!-- comment constructor -->
</NodeConstructor>
```

Exactly the same XML result can be generated a third way: using the alternative node-type-name constructors (for example, `element`, `attribute`, `text`) in a comma-delimited list within curly braces. Here's an example:

```
SELECT Resume.query('
    declare namespace
        ns="http://schemas.microsoft.com/sqlserver/2004/07/adventure-works/Resume";

    for $N in //ns:Education
    return
        element NodeConstructor
        {
            attribute attributeConstructor { string($N/ns:Edu.School[1])},
            text { string($N/ns:Edu.Major[1]) },
            <?PI processing-instruction constructor PI?>,
            <!-- comment constructor -->
        }
')
FROM HumanResources.JobCandidate
WHERE JobCandidateId = 1
```

TIP

Because `query()` returns an instance of `xml`, the `xml` data type methods can be stacked on its result, allowing for powerful XQuery subqueries, such as `query('').query('').exist('')`.

Testing XML by Using `exist()`

A common task when working with XML is the need to check for the existence of a node or node value. The `exist()` method does just that, returning 1 if the node test returns nonempty, or 0 if empty.

Listing 47.17 tests whether the annual revenue of a surveyed store exceeds \$100,000.

LISTING 47.17 Using `exist()` to Test for a Specific Node Value

```
WITH XMLNAMESPACES
(
    DEFAULT 'http://schemas.microsoft.com/sqlserver/2004/07/adventure-
works/StoreSurvey'
)
SELECT Demographics.query(
```

```

'
  for $N in /StoreSurvey
  order by $N/AnnualSales
  return
  if ($N/AnnualSales >= 3000000)
  then
    <Money
      Bank="{ $N/BankName}"
      AnnualRevenue="{ $N/AnnualRevenue}"
      AnnualSales="{ $N/AnnualSales}"
      Comments="really big bucks" />
  else
    <Money
      AnnualRevenue="{ $N/AnnualRevenue}"
      AnnualSales="{ $N/AnnualSales}"
      Comments="big bucks" />
')
FROM Sales.Store
WHERE Demographics.exist('
  (//AnnualRevenue[xs:integer(.)>100000])
') = 1
go
<p1:Money xmlns:p1="http://schemas.microsoft.com/sqlserver/2004/07/adventure-works/StoreSurvey" AnnualRevenue="150000" AnnualSales="1500000"
Comments="big bucks" />
<p1:Money xmlns:p1="http://schemas.microsoft.com/sqlserver/2004/07/adventure-works/StoreSurvey" AnnualRevenue="150000" AnnualSales="1500000"
Comments="big bucks" />
<p1:Money xmlns:p1="http://schemas.microsoft.com/sqlserver/2004/07/adventure-works/StoreSurvey" AnnualRevenue="150000" AnnualSales="1500000"
Comments="big bucks" />
<p1:Money xmlns:p1="http://schemas.microsoft.com/sqlserver/2004/07/adventure-works/StoreSurvey" AnnualRevenue="150000" AnnualSales="1500000"
Comments="big bucks" />
<p1:Money xmlns:p1="http://schemas.microsoft.com/sqlserver/2004/07/adventure-works/StoreSurvey" Bank="International Bank" AnnualRevenue="300000"
AnnualSales="3000000" Comments="really big bucks" />
{...}

```

Listing 47.17 also illustrates the use of the XQuery `if-then-else` construct, which is used to conditionally generate the `BankName` attribute and change the value of the `Comments` attribute. In the `WITH XMLNAMESPACES` statement that precedes the query, you use the `DEFAULT` keyword to specify a default namespace for the selection.

Converting a Node Value to a T-SQL Data Type by Using value()

The `value()` function allows for a selected node value to be cast to a T-SQL–data typed value. It has two parameters: the first is a string-literal XPath expression that selects the desired node value. The second is a string-literal T-SQL data type name.

The code in Listing 47.18 queries an Extensible Application Markup Language (XAML) document by using `value()` to select the `Height` attribute of `Canvas` nodes and cast them to decimal. Notice that the returned results are rows rather than XML.

LISTING 47.18 Using **value()** to Retrieve and Convert a Node Value

```
WITH XMLNAMESPACES
(
    'http://schemas.microsoft.com/winfx/2006/xaml' as x,
    DEFAULT 'http://schemas.microsoft.com/winfx/2006/xaml/presentation'
)
SELECT
    IllustrationID,
    Diagram.value('(/Canvas/@Height)[1]', 'decimal(16,4)') HeightAsSQLDecimal
FROM Production.Illustration
go
IllustrationID      HeightAsSQLDecimal
-----
3                   147.7061
4                   314.9819
5                   105.7393
6                   213.6152
7                   177.5449
(5 row(s) affected)
```

Accessing Relational Columns and T-SQL Variables in XQuery Expressions Besides `value()`, two other bridges between T-SQL and XQuery are the XQuery functions `sql:column()` and `sql:variable()`.

`sql:column()`, as the name implies, allows for the selection of a relational column value in a FLWOR statement. In Listing 47.19, contact name data is pulled from `Person.Person` into an XQuery element constructor and then selected back out again as a node value. In addition, the value of the declared T-SQL variable `TotalPurchaseYTD` is compared against the value of the node of the same name in the XQuery `where` clause, using `sql:variable()`.

LISTING 47.19 Using **sql:column()** and **sql:variable()** in XQuery

```
DECLARE @TotalPurchaseYTD decimal(6,2)
SET @TotalPurchaseYTD = 0
```

```

SELECT Demographics.query('
    declare default element namespace
        "http://schemas.microsoft.com/sqlserver/2004/07/adventure-
works/IndividualSurvey";
    for $IS in /IndividualSurvey
    where $IS/TotalPurchaseYTD[.= sql:variable("@TotalPurchaseYTD")]
    return
    element Contact
    {
        attribute ID { sql:column("C.BusinessEntityID") },
        attribute YTDTotal { sql:variable("@TotalPurchaseYTD") },
        element FullName { concat(sql:column("FirstName"), " ",
            sql:column("LastName")) }
    }
')
FROM Sales.SalesPerson I
JOIN Person.Person C ON
C.BusinessEntityID = I.BusinessEntityID
AND C.BusinessEntityID = 285

```

concat() is one of several string functions built into XQuery, in addition to contains(), substring(), and string-length().

Using the nodes () Method to Shred XML

In the section “XML as Relational Data: Using OPENXML,” earlier in this chapter, you learned how to decompose XML directly into relational rows that could be mapped to values in existing tables or used any other T-SQL way.

nodes() is kind of like OPENXML’s big brother: given an XML input document and an XQuery expression, it generates a table with an xml column against which subsequent XQuery queries can be run. nodes() can be applied to both xml variables and xml columns.

Each row in the generated table contains a copy of the original input content. The context node for each row is based on the XQuery expression parameter. It is possible to shred the input in multiple ways by running multiple XQuery queries on the generated column in the same SELECT statement. For example, one query might return a relational value from each context node, using the value() method. Another could transform and return each content node to a different XML schema.

Let’s examine a simple example that shows how this works. Listing 47.20 illustrates how an XML document is shredded into relational rows and columns by applying six different XQuery queries on each generated row, each of which creates a new relational column.

LISTING 47.20 Shredding XML Six Ways, Using **nodes()**

```

DECLARE @XmlVar xml
SET @XmlVar = '
<alphanumeric>
  <item>
    <alph name="A" val="65" />
  </item>
  <item>
    <alph name="B" val="66" />
  </item>
  <item>
    <alph name="C" val="67" />
  </item>
  <item>
    <num name="1" val="49" />
  </item>
  <item>
    <num name="2" val="50" />
  </item>
  <item>
    <num name="3" val="51" />
  </item>
</alphanumeric>'
SELECT
  XmlTable.XmlColumn.query('alph') AS ANode,
  XmlTable.XmlColumn.value('alph[1]/@name', 'char(1)') AS AName,
  XmlTable.XmlColumn.value('alph[1]/@val', 'int') AS AVAl,
  XmlTable.XmlColumn.query('num') AS NNode,
  XmlTable.XmlColumn.value('num[1]/@name', 'int') AS NName,
  XmlTable.XmlColumn.value('num[1]/@val', 'int') AS NVal
FROM @XmlVar.nodes('/alphanumeric/item') AS XmlTable(XmlColumn)

```

The syntax of `nodes()` is as follows:

```
nodes(XQuery) AS GeneratedTableName(GeneratedXmlColumnName)
```

Note that it is not possible to directly select the `xml` column generated by `nodes` without using one of the `xml` data type methods. Using the XML from the preceding example, the following code would raise an error:

```

SELECT XmlTable.XmlColumn
FROM @XmlVar.nodes('/alphanumeric/item') AS XmlTable(XmlColumn)

```

You can also use `nodes()` with `CROSS APPLY` or `OUTER APPLY` to execute `nodes()` once for every row returned in the outer table. In this way, you can combine relational data with multiple XQuery queries against a relational rowset. Listing 47.21 illustrates this technique.

LISTING 47.21 Using `nodes()` with **CROSS APPLY**

```

WITH XMLNAMESPACES(
    'http://schemas.microsoft.com/sqlserver/2004/07/adventure-works/Resume' as ns
)
SELECT
    JC.JobCandidateId,
    E.BusinessEntityID,
    ResumeTable.XmlColumn.value('ns:Emp.JobTitle[1]', 'nchar(50)') JobTitle

```

Using `modify()` to Insert, Update, and Delete XML

A frequent requirement when working with XML is the insertion, deletion, and modification of nodes and node values. These operations are known as *XML Data Modification Language* (XML DML) statements, and they are supported by the `xml` data type's `modify()` method.

When you are working with typed XML, `modify()` performs type and structural checks that allow operations to succeed only if they result in valid XML, so it's important to know your schema well.

When document order is important, it's also crucial to know the exact location and position of the nodes or values to be changed. In the case of untyped or loosely constrained typed XML, it may not matter all that much where a new node is placed.

XQuery provides a few functions and operators related to node order. `position()` returns the numeric position of a node (starting at 1). `last()` returns the numeric position of the last node in a selected node list. They are both performed against a context node.

In addition, you can use the node order comparison operators `<<` and `>>` to compare the relative positions of two selected nodes. The Boolean `is` operator is also provided to test whether two selected nodes are actually the same node.

`modify()` allows for three main operations in its XQuery expression parameter: `insert`, `replace value of`, and `delete`. Let's look at `delete` first.

Removing XML Nodes by Using delete `delete` uses its XPath parameter to locate the node to remove. In the example in Listing 47.22, any `alph` node that has a `name` attribute with a value of `B` is deleted. Then the remaining values for `alph/@name` are selected, using `nodes()` to illustrate the success of the deletion.

LISTING 47.22 Deleting Nodes Using **delete**

```

DECLARE @XmlVar xml
SET @XmlVar = '
<alphanumeric>
  <item>
    <alph name="A" val="65" />
  </item>
  <item>
    <alph name="B" val="66" />
  </item>
  <item>
    <alph name="C" val="67" />
  </item>
  <item>
    <num name="1" val="49" />
  </item>
  <item>
    <num name="2" val="50" />
  </item>
  <item>
    <num name="3" val="51" />
  </item>
</alphanumeric>'
SET @XmlVar.modify('delete(//item/alph[@name="B"])')
SELECT XmlTable.XmlCol.value('./@name', 'char(1)')
    as RemainingAlphNames
FROM @XmlVar.nodes('//item/alph') as XmlTable(XmlCol)
go
AlphNames
A
C
(2 row(s) affected)

```

Modifying XML with insert and replace value of You can insert and update new nodes in document trees by using `insert`. In these situations, node position counts most. Let's look at a real-world example for the scenarios in this section: say that a content author is building a structured document. Each node has both its respective level (or *depth*) and its order of appearance. Your DML operations must respect both. The markup

and table storage for such a scenario might look something like the untyped XML in Listing 47.23.

LISTING 47.23 Simple Untyped XML Markup for a Book

```
CREATE TABLE SimpleBook
    (BookId int IDENTITY(1,1) PRIMARY KEY CLUSTERED, BookXml xml)
GO
INSERT SimpleBook
SELECT
'<book book_id="1">
  <title>A Great Work</title>
  <chapter chapter_id="1">
    <title>An Excellent Chapter</title>
    <section id="1">
      <title>A Boring Section</title>
      <paragraph para_id="1">
        Something boring.
      </paragraph>
    </section>
    <section id="2">
      <title>Another Fine Section</title>
      <paragraph para_id="2">
        Another fine paragraph.
      </paragraph>
    </section>
  </chapter>
</book>'
```

In this listing, notice that the XML element content in the first section seems out of place, considering the laudatory content of the chapter and book titles. You can fix this by using `replace value of`, which has the following syntax:

`replace value of old_expression with new_expression`

NOTE

When you are updating typed xml values, the value specified in *new_expression* must be of the same XSD-declared type as the value selected in *old_expression*.

Here is the update for the book's incongruous content:

```
UPDATE SimpleBook
SET BookXml.modify('
```

```

        replace value of (/book/chapter/section[@id="1"]/title/text())[1]
        with "A Fine Section"
    ')
WHERE BookId = 1
GO
UPDATE SimpleBook
SET BookXml.modify('
    replace value of (/book/chapter/section/paragraph[@para_id="1"]/text())[1]
    with "A Fine Paragraph"
')
WHERE BookId = 1
(1 row(s) affected)
(1 row(s) affected)

```

You can also add a new section to the document by using the `insert` function, which has the following syntax:

```

insert new_node_expression (
    {{{as first | as last} into} | after | before}
    reference_node_expression )

```

In *new_node_expression*, you specify the nodes to be inserted, using the familiar direct or computed constructor syntax, discussed earlier in this chapter, in the section “Selecting XML by Using `query()`.” New to SQL Server 2008 is the capability to insert variable values of type `xml` using `insert`.

What’s different about `insert` is that it allows for the specification of where, with respect to the *reference_node_expression*, the constructed nodes are to be placed. To specify that the new nodes are to be inserted as children of the reference node, you use *as first into* when specifying the first child. You use *as last into* when specifying the last child.

To specify that the new node is to be inserted as a sibling of the reference node, you use *after* to specify the next sibling or *before* to specify that the new node is a previous sibling of the reference node (that is, the new node is now to be the leftmost sibling).

You can finish the sample document by adding a new chapter to the book, using the code in Listing 47.24.

LISTING 47.24 Inserting Nodes by Using **insert**

```

UPDATE SimpleBook
SET BookXml.modify('
    insert
        <chapter chapter_id="2">
            <title>This is Chapter 2</title>
        </chapter>
    after

```

```

        (/book/chapter[@chapter_id=1])[1]
    ')
WHERE BookId = 1
GO
UPDATE SimpleBook
SET BookXml.modify('
    insert
        <section id="3">
            <title>This is Section 3</title>
        </section>
    as last into
        (/book/chapter[@chapter_id=2])[1]
    ')
WHERE BookId = 1
GO
SELECT BookXml FROM SimpleBook
GO
<book book_id="1">
  <title>A Great Work</title>
  <chapter chapter_id="1">
    <title>An Excellent Chapter</title>
    <section id="1">
      <title>A Fine Section</title>
      <paragraph para_id="1">A Fine Paragraph</paragraph>
    </section>
    <section id="2">
      <title>Another Fine Section</title>
      <paragraph para_id="2">
        Another fine paragraph.
      </paragraph>
    </section>
  </chapter>
  <chapter chapter_id="2">
    <title>This is Chapter 2</title>
    <section id="3">
      <title>This is Section 3</title>
    </section>
  </chapter>
</book>

```

The first call to `modify()` inserts a new chapter after the first chapter, as its right-most sibling. The second call to `modify()` inserts a new section as the last child of the new section.

TIP

Both *reference_node_expression of insert* and *new_expression of replace value of* require a singleton to be matched in their XPath expressions; otherwise, SQL Server raises an error. Using a singleton here is sometimes hard to do because you have to think like an XML parser in terms of how many possible nodes may be matched.

Even though you may know that there's only one node in the instance document matching a complex predicate such as

```
/book/chapter/section/paragraph[@para_id="1"]/text(),
```

the parser knows that more than one is possible because the position of the nodes has not been specified.

It's usually best to enclose the matching XPath expression in parentheses and then apply the positional predicate (that is, [1]) to the entire sequence, as the examples illustrate. Otherwise, your XPath expressions need to look as ugly as the following, where the position is specified for every node in the sequence:

```
/book[1]/chapter[1]/section[1]/paragraph[1]
[@para_id="1" and position() = 1]/text()[1]
```

All three XML DML functions that use `modify()` have the side effect of causing any XML indexes on the `xml` column to be repropagated to reflect the changes, just as with relational indexes.

The next section covers how to create and maintain primary and secondary indexes on your `xml` columns.

Indexing and Full-Text Indexing of `xml` Columns

Just as with relational data, `xml` column data, whether typed or untyped, can be indexed.

Indexing `xml` Columns

Two levels of indexing are available for `xml` columns: primary and secondary. Three types of secondary indexing are available, based on the different kinds of XQuery queries that will be performed on the column: `PATH` for path-based querying, `PROPERTY` for property bag scenarios, and `VALUE` for value-based querying.

If you want to create a primary XML index on a table, it must meet a few requirements:

- ▶ The table must have a clustered primary key (with fewer than 16 columns in it). The reason is that the primary XML index contains a copy of the primary key for back referencing. It is also required for table partitioning because it ensures that the primary XML index is partitioned in the same manner as the table. The primary key of the table thus cannot be modified unless all the XML indexes on the table are dropped.

- ▶ Your SET options must have the following values when you're creating or rebuilding XML indexes or when you're attempting to use the `modify() xml` data type method, which triggers index maintenance:

```
SET ANSI_NULLS ON
SET ANSI_PADDING ON
SET ANSI_WARNINGS ON
SET ARITHABORT ON
SET CONCAT_NULL_YIELDS_NULL ON
SET NUMERIC_ROUNDABORT OFF
SET QUOTED_IDENTIFIER ON
```

Note that these are the SET values in a default SQL Server installation. You can view them by calling `DBCC USEROPTIONS` in T-SQL.

As with many other operations, indexes can be created both by using the dialogs in SSMS and also in T-SQL. The following syntax can be used to create a primary XML index on an xml column:

```
CREATE PRIMARY XML INDEX IndexName ON TableName(XmlColumnName)
```

For example, using the `SimpleBook` table from the previous section, you would execute

```
CREATE PRIMARY XML INDEX PrimaryXmlIndex_BookXml ON SimpleBook(BookXml)
```

To drop an XML index, you execute

```
DROP INDEX IndexName ON TableName
```

To do the same thing in SSMS, you right-click the table name in Object Explorer, click Modify, and then right-click the xml column and select XML Indexes. Then you use the Add or Delete buttons to create or drop indexes.

NOTE

Dropping the primary XML index also drops all secondary indexes because they are dependent on the columns of the shredded Infoset's table of the primary XML index (discussed in the next section).

You can disable XML indexes using the following syntax:

```
ALTER INDEX XmlIndexName on TableName DISABLE
```

You can rebuild them using the following syntax:

```
ALTER INDEX XmlIndexName on TableName REBUILD
```

You can also query XML indexes like other indexes, using the catalog view `sys.indexes`.

XML indexes are different from relational indexes in a few important ways. Let's consider their underlying structure and how they work at runtime.

Understanding XML Indexes

XML indexes store the `xml` column data for a table in a compressed B*tree (pronounced *B plus tree*) data structure. The XML data is stored there in its shredded rather than original XML format (remember the universal table?). XML Infoset *information items* (that is, nodes), the navigational paths used to find each item, and other crucial data are stored in the columns of the index.

NOTE

XML Infoset is a W3C recommendation defining an abstract data set and a corresponding set of terms used to refer to any item in any well-formed XML document. For example, each element in a document is considered to be an *element information item*, each attribute an *attribute information item*, and so forth.

A B*tree is a tree data structure that stores content such that the values for every node in the tree are exclusively kept in its leaves; the branches contain only pointers to the leaves. B*trees are optimized for fast insertion and removal of nodes.

When retrieving `xml`, SQL Server builds a query plan that consists of both the relational and XML portions of the query. The XML portion is built using the primary XML index. Secondary indexes are chosen based on cost after the query is optimized.

The Primary XML Index When the primary XML index is created, each `xml` column value is shredded into a relational representation of its Infoset and stored. The index itself is clustered on the column that contains the *ordpath*: a node labeling scheme that captures a document's order and hierarchy, which allows for insertion of new nodes without node relabeling and provides efficient access to nodes, using range scans.¹

Let's look at an example of how *ordpaths* work. Assume that some node is labeled 1.1. All nodes are initially labeled in document order during index creation, using odd numbers, allowing inserted nodes to be labeled with even numbers without changing the existing node labels. The original children of 1.1 would thus be labeled 1.1.1, 1.1.3, and so forth. Any children inserted after labeling would get an even number, such as 1.1.4. Each number in the *ordpath* represents a node, and each dot represents an edge of depth.

To see the actual columns of our primary XML index, you can run the following query:

```
SELECT *
FROM sys.columns sc
JOIN sys.indexes si ON
si.object_id = sc.object_id
AND si.name LIKE 'PrimaryXmlIndex_BookXml'
AND si.type = 1
```

¹ S. Pal, S., I. Cseri, O. Seeliger, M. Rys, G. Schaller, W. Yu, D. Tomic, A. Baras, B. Berg, D. Churin, and E. Kogan. "XQuery Implementation in a Relational Database System," in *Proceedings of the 31st International Conference on Very Large Data Bases (VLDB 2005)*, 1175-1186. New York: ACM Press, 2005.

Given the XML document used in Listings 47.23 and 47.24, the shredded rows for it in the index might look something like those shown in Table 47.1. The real index's column names are underlined beside the conceptual names; conceptual names and values are supplied to make the table easy to understand.

TABLE 47.1 Shredded Infoset Rows for the XML Instance in Listing 47.23²

<u>BookId</u> (pk1)	<u>Ordpath</u> (id)	<u>Tag</u> (nid)	<u>NodeType</u> (tid)	<u>Value</u> (value)	<u>PathId</u> (hid)
1	1	1 (book)	1 (Element)	Null	#1
1	1.1	2 (book_id)	2 (Attribute)	1	#2#1
1	1.3	3 (title)	1	'A Great Work'	#3#1
1	1.5	4 (chapter)	1	Null	#4#1
1	1.5.1	5 (chapter_id)	2	1	#5#1
1	1.5.3	6 (title)	1	'An Excellent Chapter'	#6#4#1
1	1.5.5	7 (section)	1	Null	#7#4#1
1	1.5.5.1	8 (id)	1	1	#8#4#1
1	1.5.5.3	9 (title)	1	'A Boring Section'	#9#7#4#1
1	1.5.5.5	10 (paragraph)	1	'Something Boring'	#10#7#4#1
1	1.5.5.5.1	11 (para_id)	2	1	#11#7#4#1
1	1.5.7	7 (section)	1	Null	#7#4#1
1	1.5.7.1	8 (id)	2	2	#8#4#1
1	1.5.7.3	9 (title)	1	'Another Fine Section'	#9#7#4#1
1	1.5.7.5	10 (paragraph)	1	'Another Fine Paragraph'	#10#7#4#1
1	1.5.7.5.1	11 (para_id)	2	2	#11#7#4#1

² S. Pal, I. Cseri, O. Seeliger, M. Rys, G. Schaller, W. Yu, D. Tomic, A. Baras, B. Berg, D. Churin, E. Kogan, "XQuery Implementation in a Relational Database System," *Proceedings of the 31st International Conference on Very Large Data Bases (VLDB 2005)*, ACM Press, New York (2005), pp. 1175-1186.

The `NodeType` column holds an integer based on the Infoset type of the node. The `Value` column holds the value of the node (if any) or a pointer to that value. The `Tag` column holds a nonunique integer assigned to each Infoset item. These numbers repeat for similar items, as when a second section or `para_id` appears in the content. The `PathId` column is computed based on the path from the root to the current item. For example, the section element with `Ordpath` value 1.5.5 has the same `Tag` value as the section element with `Ordpath` value 1.5.7.

When calculating `PathId`, SQL Server recognizes that the path from either section back to the root is the same. That is, from either section (`Tag = 7`), through chapter (`Tag = 4`), to book (`Tag = 1`), the path is the same: `#7#4#1`. The `Tag` and `PathId` values for these groups of rows are thus the same. Another way of looking at this is to consider that the XPath `/book/chapter/section` would return both section nodes, regardless of their text values or positions.

The `PathId` value is stored with the path in reverse order for the purpose of optimizing when the descendant-or-self (`//`) XPath axis is specified in the queries; in that case, only the final node names in a path such as `//section/title` are known.

When XQuery queries are executed against the `xml` columns, they are translated into relational queries against this Infoset table. First, the primary key of the table (in this case, `BookId`) is scanned to find the group of rows that contain the nodes. Then the `PathId` and `Value` columns are used to find the matching paths and values requested in the XPath of the XQuery. When found, the resulting nodes are serialized up from the Infoset table and reassembled into XML.

The Secondary XML Indexes Secondary XML indexes are useful when specific types of XQuery queries are run against the XML documents.

The syntax for creating a secondary XML index is as follows:

```
CREATE XML INDEX SecondaryXmlIndexName ON TableName(XmlColumnName)
USING XML INDEX PrimaryXmlIndexName FOR ( PROPERTY | VALUE | PATH)
```

Secondary XML indexes are dropped in the same way as primary XML indexes.

The PATH Secondary XML Index Generally speaking, the `PATH` secondary index is useful when the bulk of your queries attempt to locate nodes via a simple path to the node (for example, `/book/chapter/section/title`).

At runtime, the XPath is translated to the value of `PathId` in the Infoset table, and then the matching `PathId` values are used to retrieve the unique `Ordpath` of the matching nodes. Note that `Value` is used secondarily to `PathId` in this type of index.

The VALUE Secondary XML Index When many of the XPath queries to the XML are value based, meaning that the value of an element or attribute is specified in a predicate, a `VALUE` secondary index may improve seek times. In this case, the `Value` column of the Infoset table is primarily relied on during index searches, and then `PathId`.

The following example shows how to use a value-based XQuery:

```
SELECT BookXml.query('
/book[@book_id=1]/chapter[@chapter_id=1]//paragraph[contains(text()[1], "fine")]
```

```

')
FROM SimpleBook
WHERE BookId = 1
go
<paragraph para_id="2">Another fine paragraph.</paragraph>
(1 row(s) affected)

```

The PROPERTY Secondary XML Index When the XML in the xml column is used to encapsulate multiple properties of an object (for example, in an object serialization scenario) and these properties are often retrieved together, it may be useful to create a PROPERTY secondary index.

For example, if your markup resembles

```

DECLARE @objectXml xml
SET @objectXml =
'<object id="111">
  <name>MyObject</name>
  <value>Value 1</value>
  <coordinateX>24</coordinateX>
  <coordinateY>636</coordinateY>
</object>'

```

and your XQuery queries often retrieve multiple values simultaneously, such as

```

SELECT
  @objectXml.value('/object/name)[1]', 'varchar(20)') as OName,
  @objectXml.value('/object/value)[1]', 'varchar(20)') as OValue,
  @objectXml.value('/object/coordinateX)[1]', 'int') as X,
  @objectXml.value('/object/coordinateY)[1]', 'int') as Y
WHERE @objectXml.exist('/object[@id=111])[1]') = 1

```

the PROPERTY index should help to optimize index seek time. The reason is that PROPERTY indexes rely primarily on the Value column of the index and secondarily on PathId.

NOTE

Every call to value() requires an additional SELECT statement against the Infoset table, so it's important to try to index for this scenario, when applicable.

XML Index Performance Considerations

You know that indexing works well with untyped XML, but it actually works better with typed xml columns. When the XML is untyped, node values are stored internally as Unicode strings. Each time a value comparison must be made, those strings must be cast to the corresponding SQL for the XML type used in the XQuery. This type conversion must also be made for every possible value match in Infoset table, and this operation

grows proportionally more costly as the number of rows of the table grows. It also prevents the value range scans possible when matching against typed values.

When the types of all the nodes are declared in an associated XML schema, the values are stored as the corresponding SQL type (not as strings), and runtime typecasting is not necessary.

Following are some other points for performance consideration:

- ▶ When retrieving an entire XML instance, it is faster to select the `xml` column by name, without using `query()` or `nodes()`, because serialization of the XML up from the shredded Infoset format is costly.
- ▶ XML indexes are not used during execution of check constraints on `xml` columns.
- ▶ You should use the `exist()` method whenever possible to restrict the range of data being scanned.

Full-Text Indexing

`xml` columns can be full-text indexed, just like relational columns. The big difference is that for `xml` columns, the word *boundary* is not whitespace but element delimiters (`<`, `>`). Element text is indexed; attribute values are ignored.

It's important to use `exist()` when using a full-text T-SQL function such as `CONTAINS` to reduce unnecessary scans on the XML columns that don't contain the text you are looking for.

NOTE

To generate a full-text index, a unique, non-null, single column index is required. The constraint name `PK__SimpleBook__2F2FFC0C` shown in the following example represents the automatically generated primary key index name for the primary key of `SimpleBook`. Your instance of SQL Server will likely generate a different name for this index.

Here's an example of how to generate and utilize a full-text index on an xml column:

```
CREATE FULLTEXT CATALOG FullTextXmlCatalog
GO
CREATE FULLTEXT INDEX ON SimpleBook(BookXml)
KEY INDEX PK__SimpleBook__2F2FFC0C
ON FullTextXmlCatalog
GO
SELECT 'End of Chapter'
FROM SimpleBook
WHERE CONTAINS(BookXml, 'Excellent')
AND
BookXml.exist('(/book/chapter/title[contains(text())[1], "Excellent"])[1]')=1
GO
End of Chapter
```

Summary

Within reason, there's nothing you can't do with XML in SQL Server 2008. The Microsoft team has addressed nearly every XML complaint and wish-list item gathered from the days of SQL Server 2000 and 2005.

For the beginner and expert alike, SQL Server 2008 offers much to master in the realm of XML processing. The sheer quantity of new features may seem challenging at first. Remember that you need only utilize those features that are appropriate to your current application needs. How your applications develop and grow from there is entirely up to you.

In Chapter 48, "SQL Server Web Services," shows how to expose T-SQL routines to Internet clients using native XML Web services.

This page intentionally left blank

CHAPTER 48

SQL Server Web Services

Web services address a problem domain that is crucial to business-driven programming: the need for application and platform-independent Remote Procedure Calls (RPC). They also provide one of the few ways in which non-Microsoft clients can consume SQL Server data over the Internet.

This chapter provides all the details necessary to get native web services up and running on your instance of SQL Server 2008. It includes examples of both the client- and server-side code needed to make things happen at runtime.

What's New in SQL Server Web Services

Microsoft first made it possible to expose T-SQL query batches, stored procedures, and scalar-valued functions as web services with the release of SQLXML 3.0, an add-on package for SQL Server 2000 that allowed for the interchange of relational data as Extensible Markup Language (XML).

Over the past few years, the SQLXML packages have addressed the growing dependence of data-driven, distributed applications on XML and have kept SQL Server 2000 current with the explosion of progress in the world of XML.

The good news is that we no longer need SQLXML to create SQL Server web services because SQL Server 2008 supports them natively. The bad news is that this feature has been deprecated in SQL Server 2008. Although it is true that sometimes SQL Server features are deprecated for several versions before being removed, it seems more likely

IN THIS CHAPTER

- ▶ What's New in SQL Server Web Services
- ▶ Web Services Migration Path
- ▶ Web Services History and Overview
- ▶ Building Web Services
- ▶ Examples: A C# Client Application
- ▶ Using Catalog Views and System Stored Procedures
- ▶ Controlling Access Permissions

that native web services will be removed from the next version of SQL Server due to security concerns.

Web Services Migration Path

Although SQL Server 2008 supports native web services, it's important to plan your migration path to another web service technology as soon as possible. The first step in moving away from this technology is to identify your web service endpoints. There are several ways to accomplish this. The easiest is to use SQL Server Upgrade Advisor, which includes deprecation warnings in its reports. SQL Server's installer generates warnings when you upgrade from SQL Server 2005 to 2008. The database engine generates warnings (such as "Avoid using this feature in new development work") upon service startup and when you create HTTP endpoints using SQL Server Management Studio (SSMS) or a similar tool. You may also view deprecation warnings generated at runtime using SQL Profiler (be sure to include the `Deprecation: Warning` event in the properties of your trace template).

Now that you know how to identify your endpoints, the next step is choosing a replacement technology. Microsoft ASP.NET provides comprehensive support for web services, as does Windows Communication Foundation (WCF). There are also a number of related technologies to choose from, such as services developed using Representational State Transfer (a.k.a. RESTful services) and ADO.NET Data Services (formerly known as *Astoria*). The choice is really about what works for you, your organization, and your applications. Discussion of these technologies is beyond the scope of this book. SQL Server web services generates runtime errors or produces unexpected behaviors if the underlying data transmitted by the service is typed as one of the newly introduced SQL Server 2008 data types, such as `date`, `time`, `hierarchy_id`, `datetime2`, `datetimeoffset`, `geometry`, or `geography`.

If you use these data types either in results returned by a stored procedure (exposed via an endpoint), or in its input parameters, SQL Server generates a SOAP fault at runtime. These types also end up commented out of the types section of the WSDL that SQL Server generates for your web services. All data types supported by SQL Server 2005, however, continue to work as expected.

In the following sections, we describe how to develop web services using SQL Server 2008 (or SQL Server 2005). Keep in mind that the services you build, while supported today, may not be supported in the near future.

Web Services History and Overview

Web services are supported on most major software platforms and can be built using Integrated Development Environments (IDEs) that comply with a few key World Wide Web Consortium (W3C) recommendations:

- ▶ **Web Services Description Language (WSDL)**—WSDL is the XML grammar used to specify the functions and types (known as its *interface*) of a web service.
- ▶ **Simple Object Access Protocol (SOAP) 1.2**—SOAP is the network transport-layer protocol for web services.

Until now, Open Database Connectivity (ODBC) and Tabular Data Stream (TDS; a proprietary protocol developed by Sybase) were the only means available for clients to access SQL Server data. But because the web service standards are nonproprietary (although there are proprietary extensions), web service clients don't need to install Microsoft Data Access Components (MDAC), ODBC, SQL Server Client Tools, or any open source variants of these.

NOTE

Some of the examples in this chapter assume that you have a rudimentary knowledge of HTTP, a touch of coding savvy (some examples utilize Visual Studio 2008 and the C# .NET programming language), and a general understanding of how XML is used to describe and encapsulate data.

The Web Services Pattern

Web services follow a stateless request/response model that corresponds directly with the client/server model of Hypertext Transfer Protocol (HTTP). The following summary illustrates this programming pattern:

- ▶ A client application discovers that a server application hosts a web service that exposes one or more web methods. This process, known as *discovery*, is accomplished in one or more of the following ways:
 - ▶ Microsoft's Universal Description, Discovery, and Integration (UDDI) service, an online catalog for publishing web services, facilitates this process.
 - ▶ More commonly, the developer of the hosted web service provides the network address and web method descriptions to the developer of the client application that will consume it (that is, call its methods). This is still the dominant way web services are exposed because most provide data that is strictly confidential.
- ▶ The client then asks the discovered web service to describe its methods and their types, parameters, and return values, using the standard WSDL XML vocabulary. This is usually performed via an HTTP request to the web service in the form `http[s]://ServerDomainName/WebServiceName?wsdl`.
- ▶ The web service responds by providing the WSDL (an XML document).
- ▶ The client application (or, in some cases, the IDE of the client, such as Visual Studio) creates a code class based on the server-generated WSDL. This class is known as a *stub*, or *proxy*, because it merely contains callable references to the actual remote methods of the web service, wrapped in the formal language semantics of the client's software platform. (The actual implementation of those methods is held on the server application.)
- ▶ The client invokes a web service method over some protocol (usually HTTP). This invocation is an HTTP request encoded in the SOAP XML vocabulary.
- ▶ The web service responds (it is hoped) with a SOAP-encoded response.

NOTE

Content and metadata pertaining to these stateless communications are always encoded in XML-tagged documents known as SOAP *envelopes*. For complete information on SOAP, visit the SOAP messaging framework specification, available online from the W3C, at www.w3.org.

The W3C is the organizational body responsible for creating and maintaining World Wide Web standards, including XML. The W3C website is a great place to get accurate and up-to-date information on Web standards.

To recap: UDDI or word-of-mouth provides a discovery mechanism for web services. WSDL provides the web methods, types, and metadata of the web service. Stateless requests and responses are invoked over HTTP (or perhaps TCP) and transmitted in SOAP-encoded format.

Before SQL Server 2005, developers had to use the Internet Information Services Virtual Directory Management (IISVDM) for SQL Server utility to create SOAP-typed virtual names to expose their data. (Incidentally, this could also be accomplished using a language such as Visual Basic .NET with the `SQLVDir` object model that came with IISVDM.)

Today, this process is far easier. SQL Server no longer relies on IISVDM or even IIS to publish web services. It ties directly in with operating-system-level (or *kernel-mode*) HTTP, listening by way of the HTTP API (sometimes referred to as `http.sys`). This means that under the covers, SQL Server registers the virtual paths (also known as URIs, such as `www.myserver.com/urlpath`) specified in endpoint creation syntax with `http.sys` in the same way that IIS registers virtual directories. The operating system then farms out incoming HTTP requests to IIS or SQL Server, based on the path of the incoming request.

SQL Server also includes the entire SOAP messaging stack in its binaries. You might say that to a certain degree, SQL Server is now a web server with limited applications.

NOTE

It is possible to create SQL Server endpoints for use with database mirroring schemes, network connectivity, and SQL Server Service Broker. This chapter focuses strictly on web service endpoints.

Building Web Services

Let's delve right into the process of building a web service in SQL Server 2008.

The first step is to decide which data or T-SQL functionality to expose to the clients who will ultimately call the web methods.

For this first example, you should create the stored procedure shown in Listing 48.1, which returns a row of data from the `AdventureWorks2008` sample database. The purpose is to reveal a few attributes of an employee, given his or her unique `EmployeeId`.

LISTING 48.1 A Stored Procedure for Your First Web Service

```

use AdventureWorks2008
GO
CREATE PROC dbo.GetEmployeeBasics
(
    @EmployeeId int
)
AS
SELECT
    e.BusinessEntityID,
    FirstName,
    LastName,
    e.JobTitle
FROM HumanResources.Employee e
JOIN Person.Person p ON
    e.BusinessEntityID = p. BusinessEntityID
WHERE BusinessEntityID = @EmployeeId

```

To expose this procedure as a web method of your web service, you use the `CREATE ENDPOINT` T-SQL statement, which falls under the formal SQL category of Data Definition Language (DDL). An *endpoint* can be defined as simply an entity on one end of a connection over a communication protocol, such as HTTP. SOAP endpoints have an additional nickname: *nodes*. SOAP nodes consist of a SOAP *sender* and a SOAP *receiver*, following the request-response model.

To create a SOAP-based HTTP endpoint, you use the fairly complex T-SQL syntax shown in Listing 48.2.

LISTING 48.2 **CREATE ENDPOINT** T-SQL Syntax

```

CREATE ENDPOINT EndPointName [ AUTHORIZATION login ]
STATE = { STARTED | STOPPED | DISABLED }
AS HTTP
(
    PATH = 'url'
        , AUTHENTICATION =( { BASIC | DIGEST | INTEGRATED | NTLM | KERBEROS }
        [ ,...n ] )
        , PORTS = ( { CLEAR | SSL } [ ,... n ] )
    [ SITE = { '*' | '+' | 'webSite' },]
    [ , CLEAR_PORT = clearPort ]
    [ , SSL_PORT = SSLPort ]
    [ , AUTH_REALM = { 'realm' | NONE } ]
    [ , DEFAULT_LOGON_DOMAIN = { 'domain' | NONE } ]
    [ , RESTRICT_IP = { NONE | ALL } ]
    [ , COMPRESSION = { ENABLED | DISABLED } ]

```

```

[ , EXCEPT_IP = ( { <4-part-ip> | <4-part-ip>:<mask> } [ ,...n ] )
)
FOR SOAP
(
[ { WEBMETHOD [ 'namespace' .] 'method_alias'
( NAME = 'database.owner.name'
[ , SCHEMA = { NONE | STANDARD | DEFAULT } ]
[ , FORMAT = { ALL_RESULTS | ROWSETS_ONLY } ]
)
} [ ,...n ] ]
[ BATCHES = { ENABLED | DISABLED } ]
[ , WSDL = { NONE | DEFAULT | 'sp_name' } ]
[ , SESSIONS = { ENABLED | DISABLED } ]
[ , LOGIN_TYPE = { MIXED | WINDOWS } ]
[ , SESSION_TIMEOUT = timeoutInterval | NEVER ]
[ , DATABASE = { 'database_name' | DEFAULT } ]
[ , NAMESPACE = { 'namespace' | DEFAULT } ]
[ , SCHEMA = { NONE | STANDARD } ]
[ , CHARACTER_SET = { SQL | XML } ]
[ , MAX_SOAP_HEADERS_SIZE = { int | DEFAULT } ]
)

```

Before running the examples that follow, you should create a dedicated Windows login to use in the authorization scheme; this user should own and be able to access the database objects you create. In the examples that follow, this user is indicated as *MyDomain\SQLWebServicesClient*. Replace this name with your own.

Listing 48.3 contains the endpoint creation DDL that exposes *dbo.GetEmployeeBasics* to its web consumers.

LISTING 48.3 T-SQL for Creating a SQL Server Web Service Endpoint

```

CREATE ENDPOINT EPT_SQL2008UnleashedExamples
AUTHORIZATION [MyDomain\SQLWebServicesClient]
STATE = STARTED
AS HTTP
(
    AUTHENTICATION = (INTEGRATED),
    PATH = '/opensql/',
    PORTS = (CLEAR, SSL),
    CLEAR_PORT = 80,
    SSL_PORT = 443,
    SITE = '*',
    COMPRESSION = ENABLED
)
FOR SOAP
(

```

```

WEBMETHOD 'urn:www-sampublishing-com:examples'. 'WM_GetEmployeeBasics'
(
    NAME = 'AdventureWorks2008.dbo.GetEmployeeBasics',
    SCHEMA = STANDARD,
    FORMAT = ALL_RESULTS
),
WSDL = DEFAULT,
BATCHES = DISABLED,
SCHEMA = STANDARD,
LOGIN_TYPE = WINDOWS,
SESSION_TIMEOUT = 120,
DATABASE = 'AdventureWorks2008',
NAMESPACE = 'urn:www-sampublishing-com:examples',
CHARACTER_SET = XML
)

```

In this listing, the name of the endpoint (EPT_SQL2008UnleashedExamples) immediately follows the keywords CREATE ENDPOINT.

NOTE

Using EPT_ as a prefix is a naming convention chosen to delineate endpoints from other types of user-created objects. Any valid database object name is acceptable here.

The endpoint name is also conveniently used to drop the endpoint from the server, as follows:

```
DROP ENDPOINT EPT_SQL2008UnleashedExamples
```

But don't drop the endpoint until you've finished trying out all the examples!

One caveat when creating endpoints: if the server name, port, and path you choose are already reserved or in use by another application (such as IIS) on your server, you may need to call the new stored procedure `sp_reserve_http_namespace`. This procedure explicitly reserves the URL of your choosing with `http.sys` so that you may use it for your endpoints. Here's an example:

```
EXEC sp_reserve_http_namespace N'http://localhost:80/opensql'
```

Next in the DDL, the `AUTHORIZATION` keyword is used to specify the name of the login (either of authorization type Windows or SQL Server) that owns the endpoint. You can change the name of the login later by using the `ALTER AUTHORIZATION` statement, as in the following example:

```
ALTER AUTHORIZATION ON ENDPOINT::EPT_SQL2008UnleashedExamples
TO MyDomain\SomeOtherUser
```

Next, the `STATE` keyword indicates the initial state of the endpoint.

Much as in Windows services, the possible states are `STOPPED`, `STARTED`, and `DISABLED`. (For security's sake, `STOPPED` is the default.)

To change the state of any endpoint, you again invoke the `ALTER ENDPOINT` syntax. The following example stops the endpoint:

```
ALTER ENDPOINT EPT_SQL2008UnleashedExamples STATE = STOPPED
```

Again, don't do this until you are done with the examples!

The AS HTTP Keyword Group

The `AS HTTP` statements describe the protocol, ports, virtual path, and TCP/IP bindings for the endpoint. This keyword group is of interest to security professionals because this is where you can implement IP restrictions, authentication, and other lockdown mechanisms.

In the example shown in Listing 48.3, `HTTP` is the transport protocol. But you could just as easily use `TCP` if your application demands it: when creating a `TCP` endpoint, you specify `AS TCP` instead of `AS HTTP`. Then you add the following parameters:

- ▶ **LISTENER_PORT**—Specifies an integer-valued port number on which the server listens for incoming requests. The default is **4022**.
- ▶ **LISTENER_IP**—Specifies an incoming IP address on which the `TCP` listener accepts connections. The default is the keyword **ALL** (that is, listening on all IP addresses).

Next, you specify that the `AUTHENTICATION` method is `INTEGRATED`. Microsoft recommends `INTEGRATED` (which includes both `KERBEROS` and `NTLM`) and `KERBEROS` as the most secure ways of authenticating to endpoints, although they are not necessarily platform-independent ways. This approach is in contrast to using `BASIC` or `DIGEST` authentication. In case the endpoint consumer requires `BASIC` authentication, SQL Server requires that the `HTTP` port of the web service be secured via Secure Sockets Layer (SSL).

NOTE

Using `BASIC` authentication allows for the additional keyword `DEFAULT_LOGON_DOMAIN` to specify the domain under which users will authenticate.

`DIGEST` authentication is also available, but only a domain-level account may be used in the `AUTHORIZATION` section for the endpoint to be successfully created.

TIP

The prerequisite of a domain-level account is also true for all other authentication methods (KERBEROS, BASIC, INTEGRATED, and NTLM): SQL Server does not register the endpoint if authorization checks fail at DDL execution time.

Using DIGEST allows for the additional keyword AUTH_REALM, whose string value represents the challenge hint required by this type of authentication.

NOTE

In contrast to SQLXML, there is no way for web anonymous users (such as *IUSR_MACHINENAME*) to access SQL Server 2008 endpoints. This is an uncommonly proactive security move for Microsoft, and database administrators will applaud it.

Next, you specify the PATH (`/opensql`) to the web service. PATH is simply the part of the URL that follows the server and domain name portion of a URL (for example, `http://ServerDomainName/PATH`). Paths are sometimes also referred to as *virtual names*. Clients connecting to the HTTP endpoint thus access it via the URL `http://ServerDomainName/opensql`.

This method of specifying the PATH is similar to the way virtual directories are used with IIS, and the reason is that IIS and SQL Server register their endpoints similarly with the HTTP API. When the web service is called by a client, the HTTP API responds by farming the request out to SQL Server.

NOTE

You cannot register a value for PATH that is already registered by SQL Server, IIS, or any other application that uses the HTTP API. If you attempt to do so, SQL Server raises the following error:

The URL specified by endpoint '*ENDPOINTNAME*' is already registered to receive requests or is reserved for use by another service.

Next in the syntax, you specify the PORTS on which SQL Server listens for requests for this endpoint. The example in Listing 48.3 specifies both CLEAR (the unsecured standard HTTP port, which defaults to 80) as well as SSL (the standard SSL port, which defaults to 443). You can also specify nondefault numeric values for CLEAR_PORT and SSL_PORT, but this example simply restates the default for clarity.

Note that it is essential you do not use port numbers owned by other network services (such as email, telnet, and so on), although SQL Server may allow you to do so. Only one port can be specified each for `CLEAR_PORT` and `SSL_PORT`.

In addition to specifying ports, you can restrict or grant endpoint access to specific IP addresses by using a combination of the keywords `RESTRICT_IP` and `EXCEPT_IP`. `RESTRICT_IP` defaults to `NONE` (that is, no IP addresses are restricted), but you can change this to `ALL` to prevent users from accessing the endpoint (which is useful during offline maintenance periods). For `EXCEPT_IP`, you can add specific client IP addresses in parentheses. Here's an example:

```
CREATE ENDPOINT EPT_SQL2008UnleashedIPExample
AUTHORIZATION [MyDomain\SQLWebServicesClient]
STATE = STARTED
AS HTTP
(
    AUTHENTICATION = (INTEGRATED),
    PATH = '/opensql2/',
    PORTS = (CLEAR, SSL),
    CLEAR_PORT = 80,
    SSL_PORT = 443,
    SITE = '*',
    COMPRESSION = ENABLED,
    RESTRICT_IP = ALL,
    EXCEPT_ID = 192.168.10.1
)
FOR SOAP
(
    WEBMETHOD 'urn:www-sampublishing-com:examples'. 'WM_GetEmployeeBasics2'
    (
        NAME = 'AdventureWorks2008.dbo.GetEmployeeBasics',
        SCHEMA = STANDARD,
        FORMAT = ALL_RESULTS
    ),
    WSDL = DEFAULT,
    BATCHES = DISABLED,
    SCHEMA = STANDARD,
    LOGIN_TYPE = WINDOWS,
    SESSION_TIMEOUT = 120,
    DATABASE = 'AdventureWorks2008',
    NAMESPACE = 'urn:www-sampublishing-com:examples',
    CHARACTER_SET = XML
);
```

TIP

It is assumed that for most endpoints, you want to implement some level of IP filtering. It is recommended that you use the modifiers described here to prevent broad access.

Next, you use the `SITE` keyword to specify the hostname(s) used on the server hosting the endpoint. In this case, `'*'` restates the default (that is, all hostnames reserved by the local machine), but you can use a specific host name (such as `'hostname'`) or all hostnames (that is, `'+'`). This capability is useful (and necessary) when multiple host headers are in play for the same IP address.

The `NAMESPACE` keyword indicates to clients that the web method originates from a specific organizational entity. This prevents confusion when comparing the XML generated by this web service with that of any other organization that might expose a web method of the same name on an endpoint of the same name (which is an entirely possible situation).

TIP

Specifying the company name in uniform resource name (URN) format is standard practice for namespace naming. A URN differs from a uniform resource locator (URL) in that it specifies just the name of a resource, independent of its location. Using the URN is useful because the name of a resource is usually valid longer than the lifetime of any particular URL.

`COMPRESSION` is an interesting optional keyword because, when specified, it tells SQL Server to decompress its incoming SOAP requests if they have been compressed using gzip; then, in turn, it tells SQL Server to use gzip on the outgoing responses. You might think that web services over SOAP are too slow for the average application because of the sheer byte count of SOAP XML documents. However, using gzip on an XML file usually results in a compression ratio of greater than 80%.

When `COMPRESSION` is set to `ENABLED`, both the client and server must support gzip compression for web service compression to work properly, although the web service can still process uncompressed requests with uncompressed responses even with the setting turned on.

To enable compression on IIS 6 (on Windows 2003 Server, Standard Edition), you follow these steps:

1. Open the IIS Manager, expand the main tree, right-click the `Web Sites` node, and choose `Properties`.
2. When the `Web Sites Properties` dialog appears, click on the `Service` tab and check the `Compress Application Files` and `Compress Static Files` check boxes.

3. Add a web service extension for the .gzip file extension and edit the metabase appropriately, if necessary.

The Web Sites Properties dialog box should look something like the one in Figure 48.1 when these steps are complete.

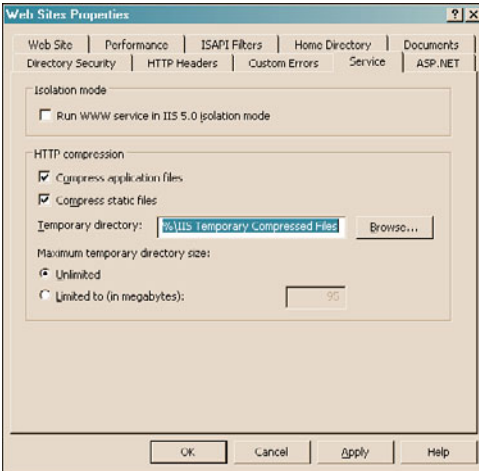

FIGURE 48.1 Enabling compression on IIS 6.

The FOR SOAP Keyword Group

The second major section of the DDL begins after the end parenthesis of the AS clause, with the FOR SOAP group, whose keywords appear in parentheses.

First, you assign the namespaced-name 'urn:www:sampublishing-com:examples'. 'WM_GetEmployeeBasics' to WEBMETHOD. This name is specified in two parts to ensure its uniqueness:

- ▶ A namespace as a string in URN format (followed by a period)
- ▶ The string name of the web method

NOTE

In Listing 48.3, the naming convention WM_ is used simply to differentiate the web method from other database objects. Later in this chapter, you see how this convention makes objects easy to pick out in query results on the endpoint catalog views in the section “Using Catalog Views and System Stored Procedures.”

The following keyword options are used inside the parenthetical group following WEBMETHOD:

- ▶ **NAME**—The string value represents the SQL Server scalar-valued user-defined function (UDF) or stored procedure that will be executed via the web service.
- ▶ **SCHEMA**—This keyword choice describes the quality of XML schema produced to describe the transmitted XML data.

CAUTION

The **SCHEMA** keyword occurs twice in the **FOR SOAP** group. This first occurrence of **SCHEMA** relates specifically to inline schema generation for the web method. It tells the compiler how to generate (or not generate) an XSD schema within the SOAP response envelope that describes the types used by this particular **WEBMETHOD**.

These are the valid keyword values for **SCHEMA**:

- ▶ **NONE**—Do not include web method–specific schema information in the SOAP response.
- ▶ **STANDARD**—Generate a standard schema.
- ▶ **DEFAULT**—Use the value of the **SCHEMA** keyword that is specified (somewhat confusingly, a second time) after the end of the **WEBMETHOD** clause.
- ▶ **FORMAT**—This option specifies which kinds of objects are returned to the web method’s caller. Following are the valid keyword values for **FORMAT**:
 - ▶ **ALL_RESULTS**—Include two or more objects in the SOAP response, including the following:
 - ▶ The result set itself (in .NET, deserialized as `DataSet`; or, in the case of web methods that return XML, one or more `sqlresultstream:SqlXml` nodes deserialized as `XmlElement`s)
 - ▶ A row count of the result set (in .NET, deserialized as a `SqlRowCount` object; or, in the case of XML results, a `sqlresultstream:SqlRowCount` node deserialized as an `XmlElement`)
 - ▶ A result code (in .NET, an integer; or, in the case of XML results, a `sqlresultstream:SqlResultCode` node deserialized as an `XmlElement`)
 - ▶ Any SQL Server errors or warnings, if generated at runtime (in .NET, deserialized as `SqlMessage` objects)
 - ▶ **ROWSETS_ONLY**—Return just the result sets, if any.
 - ▶ **NONE**—Do not mark up the output data in SOAP-typed envelope data. **NONE** is an advanced setting and should be used with the following caveat: no output

parameters or UDFs are allowed with this option, and WSDL for the web method is not generated.

- ▶ **BATCHES**—Setting this switch to `ENABLED` or `DISABLED` allows or disallows ad hoc T-SQL statements to be executed on the endpoint. This means that any number of SQL statements (with associated parameters) may be run via the special `sqlbatch()` web service proxy method, explained later in this chapter.

TIP

Although convenient, the `BATCHES` feature has some security implications because a wide range of T-SQL may be executed; thus, many administrators want it kept off. (It is disabled by default.) There are, however, some valid situations for using it, including

- ▶ During the design and testing phases of a website
- ▶ When implementing highly customized remote database administrative tools
- ▶ For ad hoc-query-dependent features

- ▶ **LOGIN_TYPE**—You use this setting to set the SQL Server Authentication mode for the endpoint to either `MIXED` (both Windows and SQL Server) or `WINDOWS` (the default). As with `BASIC` authentication, SSL is required to be both implemented on the server and specified after the `PORTS` keyword for the statement to compile.
- ▶ **WSDL**—You use this setting to determine whether SQL Server will generate WSDL for methods on the endpoint. You specify `DEFAULT` to do so or `NONE`. When you require specific WSDL to be generated, you specify a string value corresponding to the name of the custom stored procedure that generates the home-grown WSDL. Here's an example:

```
WSDL 'wsdl_generating_stored_procedure_name'
```

Note that for the C# web service client example later in this chapter to work, the value for `WSDL` must be `DEFAULT`. The reason is that the Visual Studio .NET IDE uses the generated WSDL to create web references as the basis for generating proxy classes used to call them.

TIP

The built-in system stored procedures that SQL Server uses to generate WSDL are `sp_http_generate_wsdl_complex`, `sp_http_generate_wsdl_simple`, `sp_http_generate_wsdl_defaultcomplexorsimple`, and `sp_http_generate_wsdl_defaultsimpleorcomplex`. You can test them by executing them with varying parameters to see how they work.

For more information on generating custom WSDL, see the Books Online topic “Implementing Custom WSDL Support.”

WSDL on SQL Server comes in two different flavors: the default and simple. To see an example of simple WSDL, try the following URL (after you create the sample endpoint by running the code in Listing 48.3): `http[s]://ServerDomainName/opensql?wsdlsimple`.

- ▶ **SESSIONS**—You use this setting to specify whether SOAP sessions managed by SQL Server are **ENABLED** or **DISABLED** (the default). Managing SOAP sessions on the client side requires a fair amount of programming in an environment such as Visual Studio 2008 for successful implementation. Not all SOAP clients require sessions.
- ▶ **SESSION_TIMEOUT**—You use this setting to specify how long (in seconds) before a SQL Server SOAP session times out.
- ▶ **DATABASE**—You use this setting to specify the database (named with a string value) in whose context the web methods of this endpoint are executed. Note that the keyword **DEFAULT** is also an option. Using it tells SQL Server to execute the web methods in the context of the default database of the login accessing the endpoint.
- ▶ **SCHEMA**—This is the second occurrence of this keyword in the **CREATE_ENDPOINT** DDL. This time around, it applies to schema generation for all SOAP responses of all web methods on the endpoint, not merely of a particular web method. These are the possible values:
 - ▶ **NONE**—Do not generate an inline XML schema in the SOAP response.
 - ▶ **STANDARD**—Generate an inline schema.
- ▶ **CHARACTER_SET**—The XML specification specifies a set of characters that are invalid in element and attribute values; they are `<`, `>`, `"`, `'`, and `&`. The reason for this is that XML parsers would have a hard time figuring out whether these characters represent markup or text values because they are used to delimit XML information items. For example, they are used in element tagging (for example, `<element>`), attribute naming (for example, `attribute="value"`), and entity naming (for example, `&entity;`).

The two keyword values for **CHARACTER_SET** treat these and other special characters (when found in markup) in distinct ways:

- ▶ **XML**—If a SOAP response is sent and the special XML characters are not escaped into their valid entity equivalents (`<`, `>`, `"`, `'`, and `&`) the response generates an error. This is the default.
- ▶ **SQL**—Any invalid XML characters are transformed into their respective entity representations (a process called *entitization*) before response transmission.

Other special characters are not permitted in the names of XML attributes or elements (known formally as *qualifying names*, or *QNames*) but may nevertheless end up in XML documents. SQL Server automatically escapes them by taking their Unicode hexadecimal values and preceding them with the string `#x[4-digit hex value]`. The asterisk (*) character, for example, would be converted to the character string `#x002A`.

NOTE

This character conversion may not be cross-platform compatible because not all parsers approve of it, but it is far better to convert characters than have your SQL connection closed due to an XML parsing error.

One of the ways that such special character entitization may occur is when you use SQL column (or other object) aliases that, though legally named in T-SQL, are not valid QNames (for example, `SELECT ColumnName AS '*' FROM TableName FOR XML RAW`).

- **MAX_SOAP_HEADERS_SIZE**—Optionally, you can set the maximum size of the header section of each transmitted SOAP envelope. (The default is 8KB.) Transmitting a larger header than specified in this setting thus causes a server error.

As you can see, the `CREATE ENDPOINT` syntax offers a feast of options. Thankfully, it is easy to choose the ones you need, depending on your application's requirements.

Examples: A C# Client Application

After you execute the DDL in Listing 48.3, you can call your SOAP endpoint. In the following sections, you learn how to call the endpoint's web methods using a simple C# client application.

If you do not want to try your hand at C#, you can skip to the next section, but working through the following examples is recommended so that you have a complete understanding of both sides of the web service pattern.

Example 1: Running a Web Method Bound to a Stored Procedure from C#

Using Visual Studio 2008, create a new web application or website and name it `SQLWebServicesClient`. Next, add a web reference to the SQL Server web service created in Listing 48.3. To do this, you right-click the project name in the Server Explorer window and select Add Web Reference. In the dialog that appears, you type the following in the URL text box, replacing *ServerDomainName* with the server name of your SQL Server instance:

```
http[s]://ServerDomainName/opensql?wsdl
```

Next, you click the green Go arrow button. You may be required to Windows-authenticate to the machine hosting the SQL web service. Be sure to use an account that has a matching SQL Server login. After you do so, the Add Web Reference dialog should look something like the one shown in Figure 48.2.

Notice in the dialog that the browser box (directly below the URL text box) contains the endpoint name you used in the DDL (`EPT_SQL2008UnleashedExamples`), located on top and in quotation marks. It is followed by the name of the web method you added (`WM_GetEmployeeBasics`).

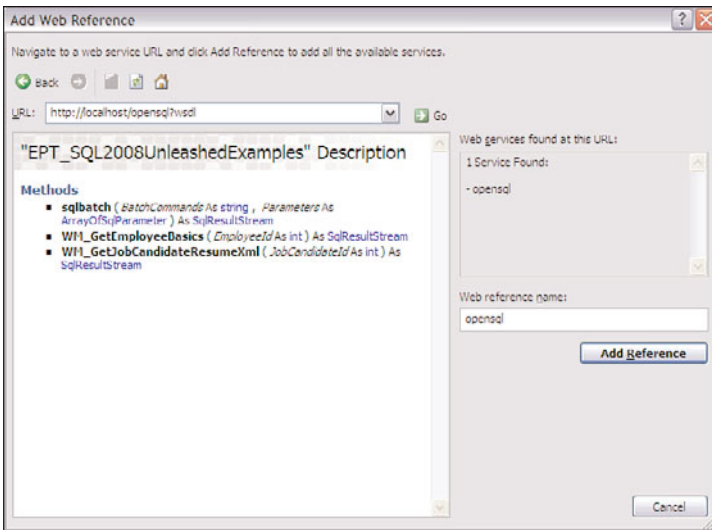

FIGURE 48.2 Adding a web reference by using Visual Studio 2008.

Also note how on the right side of the dialog, under the heading **Web Services Found at This URL**, the value you specified for **PATH** (`opensql`) is displayed. You need to type `opensql` in the **Web Reference Name** text box and click the **Add Reference** button. Next, you open the automatically created `default.aspx` file in design mode and add `GridView`, `TextBox`, `Label`, and `Button` controls to the form. Using the **Properties** dialog, you should name the label `lblResults`, the text box `txtEmployeeId`, the grid view `gvData`, and the button `btnGetValue`.

Next, you need to double-click `btnGetValue`. The IDE exits design mode and enters the code region of the C# partial class `default.aspx.cs`. The following empty event handler is autogenerated:

```
protected void btnGetValue_Click(object sender, EventArgs e) {}
```

At the top of this file, you type the following C# using statement:

```
using SQLWebServicesClient.opensql;
```

This statement tells the compiler to import the names culled from the WSDL of the web service into this C# class. The namespace contains a C# stub class with the same name as the endpoint (`EPT_SQL2008UnleashedExamples`); the .NET runtime (CLR) uses this name to call the SQL Server HTTP endpoint.

At this point, you need to type the code in Listing 48.4 inside the empty body of `btnGetValue_Click()`.

LISTING 48.4 Calling a SQL Server Web Method from C#

```

if (txtEmployeeId.Text != string.Empty)
{
    EPT_SQL2008UnleashedExamples SQLEndpointProxy =
        new EPT_SQL2008UnleashedExamples();
    SQLEndpointProxy.Credentials = System.Net.CredentialCache.DefaultCredentials;
    int EmployeeId = int.Parse(txtEmployeeId.Text);
    object[] ReturnArray = SQLEndpointProxy.WM_GetEmployeeBasics(EmployeeId);

    foreach (object Obj in ReturnArray)
    {
        if (Obj is DataSet)
        {
            DataSet ds = (DataSet)Obj;
            if (ds.Tables.Count == 0)
            {
                lblResults.Text = "(No Results Found)";
            }
            else
            {
                lblResults.Text = "(" +
                    ((SqlRowCount)ReturnArray[1]).Count + " Result(s) Found)";
                gvData.DataSource = ds;
                gvData.DataBind();
            }
        }
    }
}
}

```

After you test whether the text box `txtEmployeeId` is nonempty, you instantiate the WSDL-based stub class `opensql.EPT_SQL2008UnleashedExamples` and name it `SQLEndpointProxy`. Next, you set the credentials used by the web service to those of the currently logged-on user.

NOTE

When using SQL Server (not Windows) Authentication, instead of assuming the default credentials, you need to add web services security (WS-Security) username and password headers to the SOAP request. Note that the password will be sent in clear text, so SSL is required to be installed and turned on for your web service.

Anonymous web access is completely disabled for SQL Server web services, and Visual Studio turns on NTLM authentication by default for the sample web application's virtual directory.

Depending on your system's security policy configuration, the following line might be required in the configuration section of your `web.config` (or `machine.config`) file:

```
<identity impersonate="true" userName="SQLWebServicesClient" password="wsdl" />
```

This line tells the CLR to run the web application under the credentials of the user `SQLWebServicesClient` (created earlier and also specified after the `AUTHORIZATION` keyword in the DDL). The client application thus *impersonates* `SQLWebServicesClient` in its requests to the web service, regardless of the credentials of the logged-in Windows user.

When `btnGetValue` is clicked in the running browser window, the text typed into `txtEmployeeId` is typecast to an integer value. This value represents the `EmployeeId` of the employee about whom the web method's stored procedure returns data.

You pass this value into the call to the SQL Server web method with the code:

```
opensql.WM_GetEmployeeBasics(EmployeeId)
```

Notice that `WM_GetEmployeeBasics` is exactly the same name you specified in `WEBMETHOD` (minus the namespace prefix). `EmployeeId` corresponds to the input parameter of the stored procedure `@EmployeeId`.

The next line of Listing 48.4 illustrates how the SOAP results returned from SQL Server are deserialized from XML into .NET Framework objects.

As mentioned earlier in this chapter, when `ALL_RESULTS` is specified for the `FORMAT` statement of the web method, you get back the array object[] `ReturnArray` that has two or more elements:

- ▶ The result set (if any) of the stored procedure, deserialized by the CLR into `System.Data.DataSet`. `SELECT` queries on relational data (as opposed to XML data) are always returned as .NET `DataSets`.
- ▶ An object of type `SqlRowCount`, representing the number of records in the result set.
- ▶ Any errors or warnings (or the value `0`, if none occur), typed as `SqlMessage` objects.

Also possible in the object array are the following objects (not returned in this example):

- ▶ The results of `SELECT . . . FOR XML` statements are deserialized into `System.Xml.XmlElement` objects.
- ▶ Output parameters of a SQL Server web method-bound stored procedure are deserialized as `SqlParameter` objects.

Because you don't always know at runtime which objects are in which position in an array, it is best to iterate through the objects, testing to see which class they are before using them. This is the purpose of the `foreach` loop in the code example.

At this point, you need to run the web application by clicking the IDE's Run toolbar button or by pressing `F5`. When the browser is up and running, you enter a number in `txtEmployeeId` and click `btnGetValue`. If any tables are returned in the `DataSet` (for

example, if `(ds.Tables.Count == 0)` the `DataSet` is bound to `GridView`, and the resulting data is displayed.

With a little visual sprucing up, your webpage should look a lot like Figure 48.3.

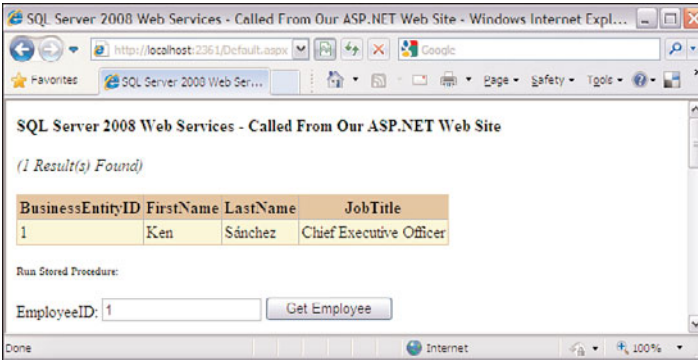

FIGURE 48.3 Calling a SQL Server web service from a C# web application.

Listing 48.5 contains the HTML built in `default.aspx` so far. (You add to this code as you continue through the examples.)

LISTING 48.5 ASP.NET HTML Code in **default.aspx**

```
<%@ Page Language="C#" AutoEventWireup="true" CodeFile="Default.aspx.cs"
Inherits="_Default" %>
<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.1//EN"
"http://www.w3.org/TR/xhtml11/DTD/xhtml11.dtd">
<%@ Page Language="C#" AutoEventWireup="true" CodeFile="Default.aspx.cs"
Inherits="_Default" %>
<html xmlns="http://www.w3.org/1999/xhtml" >
<head runat="server">
    <title>SQL Server 2008 Web Services - Called From Our ASP.NET Web Site</title>
</head>
<body>
    <form id="form1" runat="server">
    <div>
        <h4>SQL Server 2008 Web Services - Called From Our ASP.NET Web Site</h4>
        <asp:Label ID="lblResults"
            runat="server" Text="" Font-Italic=true</asp:Label>
        <br />
        <br />
        <asp:GridView ID="gvData" runat="server"
            BackColor="LightGoldenrodYellow"
            BorderColor="Tan" BorderWidth="1px"
```

```

        CellPadding="2" ForeColor="Black">
        <FooterStyle BackColor="Tan" />
        <PagerStyle BackColor="PaleGoldenrod"
            ForeColor="DarkSlateBlue" HorizontalAlign="Center" />
        <SelectedRowStyle BackColor="DarkSlateBlue" ForeColor="GhostWhite" />
        <HeaderStyle BackColor="Tan" Font-Bold="True" />
        <AlternatingRowStyle BackColor="PaleGoldenrod" />
    </asp:GridView>
<br />
<h6>Run Stored Procedure:</h6>
EmployeeID: <asp:TextBox ID="txtEmployeeId" runat="server">1</asp:TextBox>
<asp:Button ID="btnGetValue" runat="server"
    OnClick="btnGetValue_Click" Text="Get Employee" /><br />

```

Example 2: Running Ad Hoc T-SQL Batches from a SQL Server Web Service

For this example, you need to execute a batch of T-SQL statements by adding a new web method to the endpoint and changing it to accept query batches.

The syntax for making changes to SOAP endpoints is similar to that for CREATE ENDPOINT. The differences are shown in Listing 48.6.

LISTING 48.6 ALTER ENDPOINT T-SQL Syntax

```

ALTER ENDPOINT endpointname
<same as above>
AS HTTP
(
    <same as above>
    <except>
        ADD EXCEPT_IP = (ip-address)
        DROP EXCEPT_IP = ( { <4-part-ip> | <4-part-ip>:<mask> } [ ,...n ] )
        ADD WEBMETHOD webmethodname
        ALTER WEBMETHOD webmethodname
        DROP WEBMETHOD webmethodname
    )
FOR SOAP
(
    <same as above>
)

```

The following bullets explain the keywords used with ALTER ENDPOINT:

- ▶ ADD and DROP EXCEPT_IP allow you to update the list of IP addresses allowed to connect to the web service.
- ▶ ADD WEBMETHOD allows a new web method to be added to the web service.
- ▶ ALTER WEBMETHOD permits changes in the attributes of an existing web method.
- ▶ DROP WEBMETHOD permanently drops the named web method from the endpoint.

Now you can change your endpoint and set BATCHES to ENABLED so you can run ad hoc queries on the web service:

```
ALTER ENDPOINT EPT_SQL2008UnleashedExamples
FOR SOAP
(
    BATCHES = ENABLED
)
```

At this point, you need to return to Visual Studio and right-click the App_WebReferences node under the project name in the Solution Explorer. Then you select Update Web References from the context menu. This causes the IDE to re-request the WSDL from SQL Server to check for changes to the service description.

The .NET IDE recognizes that batching has been turned on by adding the sqlbatch() method to the proxy class. All the behind-the-scenes work for SQL batching is done via this magical .NET method. When BATCHES is enabled, SQL Server adds some special elements to the WSDL XML to make this happen.

A peek at the WSDL in opensql1.wsdl (found under the App_WebReference node in Solution Explorer) serves to illustrate some of the special batching XML nodes:

```
<wsdl:message name="sqlbatchSoapIn">
    <wsdl:part name="parameters" element="s0:sqlbatch" />
</wsdl:message>
<wsdl:message name="sqlbatchSoapOut">
    <wsdl:part name="parameters" element="s0:sqlbatchResponse" />
</wsdl:message>
```

You should now open default.aspx once again in design mode and add an additional TextBox control to the form named txtSQLBatch and set its TextMode property to MultiLine. Then you need to add a second Button control named btnRunBatch. Next, you double-click btnRunBatch and add the code in Listing 48.7 to the empty event handler (btnRunBatch_Click()) generated by the IDE.

LISTING 48.7 Calling Ad Hoc T-SQL Batches from C#

```

EPT_SQL2008UnleashedExamples SQLEndpointProxy =
    new EPT_SQL2008UnleashedExamples();
SQLEndpointProxy.Credentials = System.Net.CredentialCache.DefaultCredentials;
opensql.SqlParameter[] sqlParams =
    new opensql.SqlParameter[1];
// note: using opensql.SqlParameter avoids namespace collisions
//       with System.Data.SqlClient.SqlParameter
sqlParams[0] = new opensql.SqlParameter();
sqlParams[0].name = "EmployeeId";
sqlParams[0].Value = int.Parse(txtEmployeeId.Text);
object[] ReturnArray = SQLEndpointProxy.sqlbatch(txtSQLBatch.Text, ref sqlParams);
if (ReturnArray.Length > 0)
{
    foreach (Object Obj in ReturnArray)
    {
        if (Obj is DataSet)
        {
            DataSet ds = (DataSet)Obj;
            if (ds.Tables.Count == 0)
            {
                lblResults.Text = "(No Results Found)";
            }
            else
            {
                gvData.DataSource = ds;
                gvData.DataBind();
            }
        }
    }
}
else
{
    lblResults.Text = "(No Results)";
}

```

As in the first example, the first and second code lines in Listing 48.7 create the proxy object and set its credentials. Next, an array of `opensql.SqlParameter` objects of length 1 is created, and its single parameter (`EmployeeID`) is assigned the value of `txtEmployeeId.Text`, typecast to an integer. You use this value as a declared parameter to your SQL batch.

Instead of calling any web method by name, you instead call `SQLEndpointProxy.sqlbatch()`, passing in the text of the T-SQL statement and the value of `txtEmployeeId.Text`. With a little visual sprucing up, the running webpage should look something like the one in Figure 48.4.

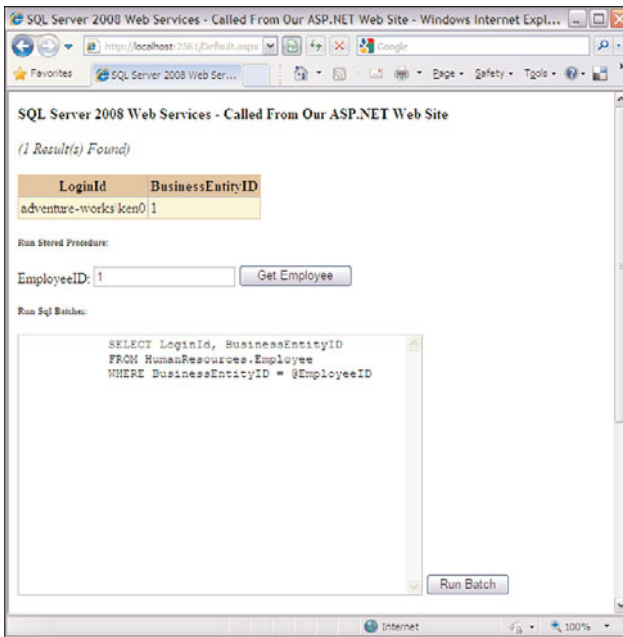

FIGURE 48.4 Running T-SQL batches on a web service by using `sqlbatch()`.

Now you need to append the HTML code in Listing 48.8 to `default.aspx` just below the last line entered.

LISTING 48.8 Additional ASPNET HTML Code for `default.aspx`

```
<br />
<h6>Run Sql Batches:</h6>
<asp:TextBox
    ID="txtSQLBatch" runat="server"
    Height="280px" TextMode="MultiLine"
    Width="437px">SELECT LoginId, BusinessEntityID
    FROM HumanResources.Employee
        WHERE BusinessEntityID = @EmployeeID
</asp:TextBox>
<asp:Button ID="btnRunBatch" runat="server" OnClick="btnRunBatch_Click"
    Text="Run Batch" />
```

When `btnRunBatch` is clicked at runtime, the text of the query stored in `txtSQLBatch.Text` is executed. The parameter `@EmployeeId` is populated from `txtEmployeeId.Text` (in this case, typecast to the integer value 1), and the batch is run. The web service responds with SOAP flowing over HTTP, and the envelope is deserialized into an array of objects.

The resulting DataSet is again bound to the GridView `gvData`. Any `SqlMessages` in the `ReturnArray` are appended to the text of `lblResults` for viewing on the page.

This type of querying just touches the tip of what can be accomplished via ad hoc web services queries using `sqlbatch()`. You can use your imagination to take it as far as you want.

Example 3: Calling a Web Method–Bound Stored Procedure That Returns XML

For your third and final web method, you create a stored procedure that returns XML from an `xml` column, using the new `FOR XML PATH` syntax. To do this, you need to create the stored procedure in Listing 48.9 in the context of the `AdventureWorks2008` database.

LISTING 48.9 A Stored Procedure That Returns XML

```

use AdventureWorks2008
GO
CREATE PROC dbo.GetJobCandidateResumeXml
(
    @JobCandidateId int
)
AS
SELECT
    Resume.query('
        declare namespace
            ns="http://schemas.microsoft.com/sqlserver/2004/07/adventure-works/Resume";
        /ns:Resume/ns:Name
    ') as "Name",
    Resume.query('
        declare namespace
            ns="http://schemas.microsoft.com/sqlserver/2004/07/adventure-works/Resume";
        /ns:Resume/ns:Skills
    ') as "Skills"
FROM HumanResources.JobCandidate
WHERE JobCandidateId = @JobCandidateId
FOR XML PATH('CandidateQuickView')

```

The `Resume` column of `HumanResources.JobCandidate` is of the new SQL data type `xml`. The `.query()` syntax used in `GetJobCandidateResumeXml` is part of the XQuery language, which is newly supported in SQL Server 2008. Chapter 47, “Using XML in SQL Server 2008,” describes these features in detail.

Now you need to bind the stored procedure to the existing endpoint, using the T-SQL in Listing 48.10.

LISTING 48.10 ALTER ENDPOINT Syntax for Adding a Web Method That Returns XML

```
ALTER ENDPOINT EPT_SQL2008UnleashedExamples
FOR SOAP
(
    ADD WEBMETHOD
        'urn:www-sampublishing-com:examples'. 'WM_GetJobCandidateResumeXml'
    (
        NAME = 'AdventureWorks2008.dbo.GetJobCandidateResumeXml',
        FORMAT = ALL_RESULTS,
        SCHEMA = STANDARD
    )
)
)
```

You need to return to Visual Studio and update the web reference of the project, as described in Example 1. Then you switch `default.aspx` to design mode and add another Button control, named `btnGetXml`, to the bottom of the page.

In the HTML Source view of `default.aspx`, you append to the page the lines of ASP.NET code found in Listing 48.11.

LISTING 48.11 The Final ASPNET HTML Code in `default.aspx`

```
<h6>Run Xml-Based Stored Procedure:</h6>
Job Candidate Id:
<asp:TextBox ID="txtJobCandidateId" runat="server" Text="1"></asp:TextBox>
<asp:Button ID="btnGetXml" runat="server" Text="Get Xml" OnClick="btnGetXml_Click" />
<hr />
<textarea style="font-size:11px;" rows="10" cols="80" ID="textareaXml"
runat="server"></textarea>
<hr />
<h6>SqlRowCount=<asp:Label ID="lblRowCount" runat="server" /></h6>
<h6>SqlResultCode=<asp:Label ID="lblResultCode" runat="server" /></h6>
```

At this point you should double-click `btnGetXml`. In `btnGetXml_Click()`, you type or copy the C# code found in Listing 48.12.

LISTING 48.12 Consuming a Web Method That Returns XML in C#

```
opensql.EPT_SQL2008UnleashedExamples SQLEndpointProxy =
    new opensql.EPT_SQL2008UnleashedExamples();
SQLEndpointProxy.Credentials =
    System.Net.CredentialCache.DefaultCredentials;
```

```

object[] XmlResult =
    SQLEndpointProxy.WM_GetJobCandidateResumeXml(int.Parse(txtJobCandidateId.Text));

if (XmlResult.Length == 3)
{
    lblRowCount.Text = ((SqlRowCount)XmlResult[1]).Count.ToString();
    lblResultCode.Text = XmlResult[2].ToString();
    XmlElement CandidateQuickViewXmlElement = (XmlElement)XmlResult[0];
    textareaXml.Value = CandidateQuickViewXmlElement.OuterXml;
}

```

For this example to compile, you must add the following C# using statement to the top of default.aspx.cs:

```
using System.Xml;
```

The final output should display the XML result of the GetJobCandidateResumeXml stored procedure in an HTML text area, as shown in Figure 48.5.

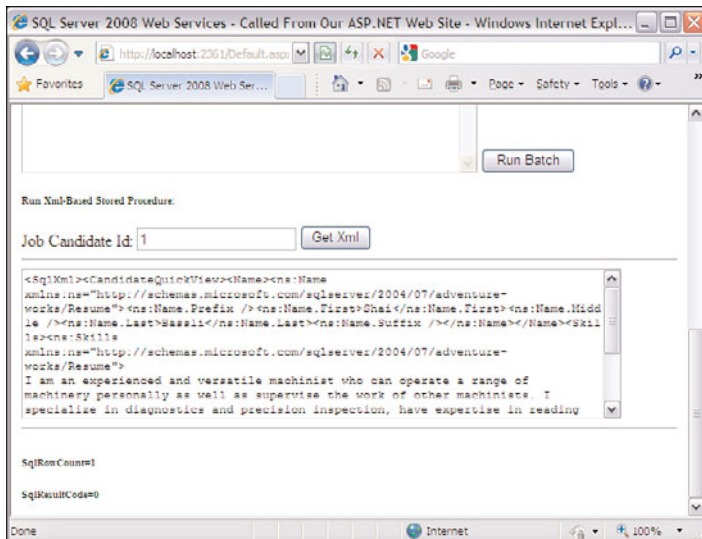

FIGURE 48.5 Returning XML from a stored procedure to a SQL Server web service C# client.

Using Catalog Views and System Stored Procedures

SQL Server provides a set of stored procedures and catalog views directly related to endpoint functionality. With them, you can find out anything you need to know about what endpoints exist on the server, the states they are in, the web methods associated with them, the settings used in their DDL, and so on.

To get a result set of all the registered endpoints for a server, you execute the following simple T-SQL statement against `sys.endpoints` in a new query window in the context of the master database:

```
SELECT name, endpoint_id, protocol_desc, type_desc, state_desc
FROM sys.endpoints
```

```
Go
name                endpoint_id  protocol_desc  type_desc  state_desc
-----
Dedicated Admin Connection      1    TCP           TSQL       STARTED
TSQL Local Machine              2    SHARED_MEMORY TSQL       STARTED
TSQL Named Pipes                3    NAMED_PIPES  TSQL       STARTED
TSQL Default TCP                4    TCP           TSQL       STARTED
TSQL Default VIA                5    VIA           TSQL       STARTED
EPT_SQL2008UnleashedExamples  65536  HTTP          SOAP       STARTED
(6 row(s) affected)
```

As the result set illustrates, listeners for the basic SQL Server network protocols (for example, T-SQL named pipes, T-SQL default TCP) are also registered as endpoints.

After you ascertain the `endpoint_id` of the endpoint (65536), you can get all the details about it by querying the catalog view `sys.http_endpoints`:

```
SELECT name, site, url_path, clear_port, ssl_port
FROM sys.http_endpoints
WHERE endpoint_id = 65536
```

```
Go
name                site  url_path  clear_port  ssl_port
-----
EPT_SQL2008UnleashedExamples  *    /openssl/  80          443
(1 row(s) affected)
```

To see all of the endpoint's web methods and their DDL-defined settings, you can try the following query against the view `sys.endpoint_webmethods`:

```
SELECT
    method_alias,
    result_schema_desc as [schema],
    result_format_desc as [format]
FROM sys.endpoint_webmethods
```

```
WHERE namespace = 'urn:www-samspublishing-com:examples'
AND endpoint_id = 65536
```

```
Go
```

method_alias	schema	format
WM_GetEmployeeBasics	STANDARD	ALL_RESULTS
WM_GetJobCandidateResumeXml	STANDARD	ALL_RESULTS

(2 row(s) affected)

To see all endpoints defined using FOR SOAP and some of the settings used in their FOR SOAP clause, you can use the following:

```
SELECT name, principal_id, type_desc, login_type, header_limit
FROM sys.SOAP_endpoints
```

```
Go
```

name	principal_id	type_desc	login_type	header_limit
EPT_SQL2008UnleashedExamples	259	SOAP	WINDOWS	4096

(1 row(s) affected)

Controlling Access Permissions

An important task in endpoint management is the granting, revoking, and denying of endpoint permissions. To control whether a login may connect to (and thus consume) an endpoint, you use the following syntax:

```
{ GRANT | DENY | REVOKE } CONNECT ON ENDPOINT:: <EndPointName> TO <login>
```

For example, to give a login called MyDomain\MyUserName connect permission on your endpoint, you would use this statement:

```
GRANT CONNECT ON ENDPOINT::EPT_SQL2008UnleashedExamples TO MyDomain\MyUserName
```

Note that whenever the login specified in the AUTHORIZATION keyword of the endpoint DDL isn't the same as the login consuming the service, you must grant connect permission to that login. To control whether a given login may create endpoints on your SQL Server instance, you use the following syntax:

```
{ GRANT | DENY | REVOKE } CREATE ENDPOINT TO <login>
```

For example, to prevent your test user from creating more endpoints, you execute the following statement:

```
REVOKE CREATE ENDPOINT TO [MyDomain\SQLWebServicesClient]
```

NOTE

The main difference between DENY and REVOKE is that REVOKE removes both currently granted and currently denied permissions, but DENY also prevents permissions from being inherited through role assignment.

To allow a login permission to alter endpoints, you use the following syntax:

```
{ GRANT | DENY | REVOKE } ALTER ANY ENDPOINT TO <login>
{ GRANT | DENY | REVOKE } ALTER ON ENDPOINT:: <EndPointName> TO <login>
{ GRANT | DENY | REVOKE } CONTROL ON ENDPOINT:: <EndPointName> TO <login>
```

For example, to allow server-wide endpoint altering to a login, you execute the following:

```
GRANT ALTER ANY ENDPOINT TO [MyDomain\MyUserLogin]
```

And to disallow ALTER permission on a specific endpoint, you execute the following statement:

```
DENY ALTER ON ENDPOINT::EPT_SQL2008UnleashedExamples TO [MyDomain\MyUserLogin]
```

The CONTROL keyword changes whether a given login may transfer ownership of, alter, drop, or connect to a specific endpoint. To revoke control for a specific endpoint, you execute the following:

```
REVOKE CONTROL ON ENDPOINT::EPT_SQL2008UnleashedExamples TO [MyDomain\MyUserLogin]
```

The following syntax controls the ability for a login to see the metadata of an endpoint via the catalog views:

```
{GRANT|DENY|REVOKE} VIEW DEFINITION ON ENDPOINT:: <EndPointName> TO <login>
```

Finally, you use the following syntax to allow a login the ability to take ownership of an endpoint, using the AUTHORIZATION keyword in endpoint DDL:

```
{ GRANT | DENY | REVOKE } TAKE OWNERSHIP ON ENDPOINT:: <EndPointName> TO <login>
```

To allow a given login the ability to take ownership of your endpoint, you execute the following:

```
GRANT TAKE OWNERSHIP ON ENDPOINT::EPT_SQL2008UnleashedExamples
    TO [MyDomain\MyUserLogin]
```

At the time of this writing, there are just a few limitations in SQL Server web services worth noting:

- ▶ Table-valued user-defined functions cannot be specified as web methods. However, you can solve this problem by simply calling a table-valued UDF inside a stored procedure exposed as a web method.

- ▶ SQL Server's SOAP engine allows for XML processing instructions embedded in SOAP envelopes (contrary to the SOAP specification). SQL Server ignores these processing instructions, so this shouldn't be an issue for most applications.
- ▶ SOAP over HTTP is simply slower (by up to 30%, according to Microsoft) than the native TDS protocol. So for applications in which speed is key, TDS is still the protocol of choice.

Summary

Using the new functionality in SQL Server 2008, applications built and running on varying software platforms can now communicate with SQL Server with little or no dependence on expensive, proprietary middleware. And they can do so with minimal client configuration. In providing custom HTTP endpoint support, SQL Server 2008 is also pushing the bounds of what it means to be a traditional database server.

Chapter 49, "SQL Server Service Broker," describes a key component of SQL Server 2008 that is responsible for creating your own asynchronous messaging services.

This page intentionally left blank

CHAPTER 49

SQL Server Service Broker

This chapter takes a look at one of the newer features of SQL Server: SQL Server Service Broker (SSB). Service Broker provides a native SQL Server infrastructure that supports asynchronous, distributed messaging between database-driven services. Service Broker handles all the hard work of managing coordination among the constructs required for distributed messaging, including transactional delivery and storage, message typing and validation, multithreaded activation and control, event notification, routing, and security.

This chapter examines each of the objects that make up the plumbing of Service Broker applications, and you build a sample program along the way to put them all together.

What's New in Service Broker

With the release of SQL Server 2008, Service Broker includes the following new features:

- ▶ A new diagnostic command-line utility called `ssbdiagnose`
- ▶ Prioritization of conversations
- ▶ Additional performance counters (for use with System Monitor)
- ▶ Enhanced configurability via SQL Server Management Studio (SSMS)

Although in versions of SQL Server prior to SQL Server 2005, it was possible to create structures analogous to some of the new database objects used with Service Broker (for example, using a table as a work queue), such implementa-

IN THIS CHAPTER

- ▶ What's New in Service Broker
- ▶ Understanding Distributed Messaging
- ▶ Designing a Sample System
- ▶ Understanding Service Broker Constructs
- ▶ Service Broker Routing and Security
- ▶ Troubleshooting SSB Applications with `ssbdiagnose.exe`
- ▶ Related System Catalogs

tions do not even come close to providing the reliability, ease of use, and scalability of Service Broker. This chapter introduces SQL Server's native messaging-oriented framework.

Understanding Distributed Messaging

If you have experience with Microsoft Message Queuing (MSMQ) or IBM's MQSeries, you already know the paradigm in play: two or more distinct database-driven applications reside on one or more servers, yet they need to collaborate, acting as a single unit to successfully complete a set of tasks. These applications may have varying implementations, but they are still considered to be part of the same *distributed* system. The constraints on these systems are such that the applications involved must be able to communicate in the freest, most reliable way possible.

Free, in this context, means that the applications cannot make synchronous method calls (or even asynchronous callbacks) to each other; they must be able to send or receive messages without having to wait for the other to reply or acknowledge. Such applications are said to be *loosely coupled*.

Reliable, in this context, means that even if one partner in the collaboration isn't up and running when the other needs to send or receive a message, they must still be able to do so in such a way that the message will be stored for later processing, with its integrity and send order guaranteed.

For any of this to happen, a basic infrastructure must be in place that such applications can rely on—one that is independent of and yet enables such communications. This is Service Broker's reason for being.

The Basics of Service Broker

A default instance of Service Broker exists for every database you create. To find it by using the SQL Server Management Studio Object Browser, you look under the `Service Broker` node directly under your database's root node.

NOTE

When you expand the `Services` node under the `Service Broker` node, it becomes readily apparent that, under the covers, SQL Server uses Service Broker services to implement some of its other built-in functionality, including Database Mail.

If you expand a few subnodes under the `Service Broker` node, you can see most of the new Service Broker constructs:

- ▶ **Messages**—These (optionally typed) envelopes contain the data to be interchanged.
- ▶ **Contracts**—These rules define the flow of messages (that is, which message types can flow from service to service).
- ▶ **Queues**—These are storage facilities for messages.

- ▶ **Services**—Services are endpoints in a Service Broker application that send and/or receive messages.
- ▶ **Routes**—These are associations between network addresses and services running on remote machines.
- ▶ **Remote service bindings**—These are associations between database principals and remote services for authorization and message encryption (using certificates).

A few constructs are not directly named in the subnodes:

- ▶ **Conversations**—These are communications between two or more services.
- ▶ **Dialogs**—These are conversations between exactly two services.
- ▶ **Conversation groups**—A conversation group consists of one or more related conversations.

The sections that follow cover all these objects in detail. But before you get to that, you need to set up the entities required to execute this chapter's examples. The first step is to configure a new database (as well as AdventureWorks2008) to work with Service Broker. Note that Service Broker is turned off by default. You configure Service Broker at the database level by using a few new Data Definition Language (DDL) options:

- ▶ **DISABLE_BROKER**—This option turns off Service Broker for a database.
- ▶ **ENABLE_BROKER**—This option turns on Service Broker for the database. (You can check to see whether Service Broker is enabled by querying the `is_broker_enabled` column in `sys.databases`.)
- ▶ **ERROR_BROKER_CONVERSATIONS**—This option turns on Service Broker and drops an error message in all queues for active conversations when the database is attached, giving Service Broker services a chance to respond to this special message and gracefully self-terminate.
- ▶ **NEW_BROKER**—This option changes the unique identifier for Service Broker in the database instance (that is, the value of `service_broker_guid` in `sys.databases`), effectively terminating any running conversations with an error message. This is essentially a plug-pulling mechanism. Note that each Service Broker instance gets its own unique identifier, which Service Broker services use for inter-database messaging (which is described later in this chapter).

Note that you can set these options only by using `CREATE DATABASE` when performing an attach; therefore, you need to create the database as you normally would and then use `ALTER DATABASE`, providing one of the options just described. To turn on Service Broker for AdventureWorks2008 (which is required for the examples in this chapter), you execute the following:

```
USE Master
GO
ALTER DATABASE AdventureWorks2008 SET ENABLE_BROKER
```

You also need to set the TRUSTWORTHY option to ON (it is OFF by default) for databases involved with messaging and to create an encrypted MASTER KEY for every database (as explained later in this chapter, in the section “Service Broker Routing and Security”):

```
USE Master
GO
ALTER DATABASE AdventureWorks2008 SET TRUSTWORTHY ON
GO
USE AdventureWorks2008
GO
-- Note: Password validation using a password as simple as the following
-- will fail when Group Policy demands strong validation.
CREATE MASTER KEY
ENCRYPTION BY PASSWORD = 'AdventureWorks2008';
```

You need to create a sample database that resides on the same SQL Server 2008 instance as AdventureWorks2008. The concept behind this example is that a bicycle manufacturer and seller (AdventureWorks Cycles) must provide new and updated parts data to a sister company (Extreme Catalog Management, a.k.a. XCatMgmt) that implements a leading catalog management system on the same network. AdventureWorks Cycles must keep XCatMgmt up-to-date with its product model data; otherwise, it could lose market share or end up receiving orders from distributors based on out-of-date catalog information. The reason is that the AdventureWorks Cycles products are featured in several of XCatMgmt’s publications, which industry resellers use to choose what to buy. Listing 49.1 shows how you create the entities for the XCatMgmt sample database.

LISTING 49.1 DDL for a Service Broker–Enabled Simplified Product Catalog Database

```
CREATE DATABASE XCatMgmt WITH TRUSTWORTHY ON
GO
ALTER DATABASE XCatMgmt SET ENABLE_BROKER
GO
USE XCatMgmt
GO
CREATE MASTER KEY
ENCRYPTION BY PASSWORD = 'XCatMgmt';
GO
CREATE SCHEMA Publication
CREATE TABLE Publication.BaseCatalog
(
    CatalogId int IDENTITY(1,1) PRIMARY KEY,
    CatalogName varchar(100) NOT NULL,
    LastPublicationDate datetime
)
CREATE TABLE Publication.Product
```

```

(
    ProductId int IDENTITY(1,1) PRIMARY KEY,
    ProductName varchar(100) NOT NULL,
    SourceProductId int NOT NULL,
    ManufacturerId int NOT NULL,
    Price money NOT NULL,
    ProductDetailXml xml,
    CreateDate datetime NOT NULL,
    LastUpdateDate datetime DEFAULT GETDATE()
)
CREATE TABLE Publication.ProductCatalogType
(
    ProductCatalogTypeId int PRIMARY KEY,
    Description varchar(100)
)
CREATE TABLE Publication.ProductCatalog
(
    ProductCatalogId int IDENTITY(1,1) PRIMARY KEY,
    ProductCatalogTypeId int NOT NULL
        REFERENCES Publication.ProductCatalogType(ProductCatalogTypeId),
    ProductId int NOT NULL
        REFERENCES Publication.Product(ProductId),
    CatalogId int NOT NULL
        REFERENCES Publication.BaseCatalog(CatalogId)
)
GO
INSERT Publication.ProductCatalogType
SELECT 1, 'Mountain Bicycles and Parts'
INSERT Publication.BaseCatalog (CatalogName)
SELECT 'The Complete Catalog of Wholesale Mountain Bike Parts'
INSERT Publication.Product
(
    ProductName,
    SourceProductId,
    ManufacturerId,
    Price,
    ProductDetailXml,
    CreateDate
)
SELECT 'AdventureWorksProductName', 749, 1, 99.99, '<empty/>', GETDATE()
INSERT Publication.ProductCatalog
SELECT 1, 1, 1

```

Designing a Sample System

The sample messaging system used in this chapter has the following design: an update stored procedure in `AdventureWorks2008.Production.ProductModel` starts up a service that initiates a conversation with a service in `XCatMgmt`. It does this by sending a message to the inbound work queue of `XCatMgmt`. When the transaction surrounding the initial send is complete, Service Broker transmits the message, signaling that a catalog change for an `AdventureWorks Cycles` product model is ready for processing.

In response to the arrival of this new message, Service Broker executes a stored procedure associated with a catalog maintenance service for `XCatMgmt`, known as its service program. This process is known as internal activation; it is internal because the stored procedure resides in and is activated by SQL Server.

Because a Service Broker program might not always be a stored procedure, external activation is also available when you use event notification with the `QUEUE_ACTIVATION` event. You can create an event notification service and map it to your Service Broker service and queue by using syntax such as the following:

```
CREATE QUEUE NotificationQueue
GO
CREATE SERVICE EventNotificationService
ON QUEUE NotificationQueue
([http://schemas.microsoft.com/SQL/Notifications/PostEventNotification])
GO
CREATE EVENT NOTIFICATION NotifyMe
ON QUEUE NotificationQueue FOR QUEUE_ACTIVATION
TO SERVICE 'EventNotificationService', 'broker-instance-guid'
```

Note that you need to retrieve your database's Service Broker unique identifier and replace `'broker-instance-guid'` with it for the example to work. To do this, you run the following query:

```
SELECT service_broker_guid
FROM sys.databases
WHERE NAME = 'AdventureWorks2008'
go
service_broker_guid
-----
3036906E-8B9E-4266-A8C6-DD4E01B656CA
(1 row(s) affected)
```

You should keep this query in mind because you need it later in this chapter when you're working on service conversations.

Let's return to the sample system's description. When the catalog maintenance service's work is done, it sends an acknowledgment message back to the sender's inbound queue.

To accomplish everything included in the design so far, you need to represent the following kinds of objects in the system:

- ▶ Two types of messages: one defining product model catalog changes and one for acknowledgments
- ▶ Two queues, one for each service
- ▶ One contract that defines the message flow between the services
- ▶ Two services, each representing an endpoint in the system
- ▶ At least one conversation and its related conversation group

The following sections describe how to define and build on all these new constructs, and you learn how they work together in the orchestration of Service Broker applications.

Understanding Service Broker Constructs

To introduce the new Service Broker constructs you'll be using, Figure 49.1 shows the interrelations between the constructs described in the upcoming subsections.

FIGURE 49.1 Service Broker concepts illustrated.

Figure 49.1 illustrates the fact that a dialog is a conversation between two services. These services exchange typed (or untyped) messages by sending them to queues according to the rules of a contract. Each service can have a service program activated by Service Broker to receive messages from a queue. Every conversation belongs to a conversation group. Messages are always sent with respect to a conversation group. One or more conversation groups make up a Service Broker application.

Defining Messages and Choosing a Message Type

For the AdventureWorks2008 database to communicate with the XCatMgmt database via Service Broker, a dialog between two services must take place. Within this conversation, each service sends messages to or receives messages from queues, providing the indirection needed for the underlying systems to stay loosely coupled.

The dialog messages are typed to constrain and (optionally) validate their content. You use the new SQL Server database object `MESSAGE` to represent a typed message. Defining the messages to be transmitted is the first step in building a Service Broker application.

You create SQL Server messages by using the following syntax:

```
CREATE MESSAGE TYPE [ AUTHORIZATION UserName ]
[ VALIDATION = {
    NONE | EMPTY | WELL_FORMED_XML |
    VALID_XML WITH SCHEMA COLLECTION XMLSchemaCollectionName
} ]
```

You can alter message types by using the intuitive `ALTER MESSAGE TYPE` syntax. Before you create the first message type, you need to create a Windows user on the local server and associate a SQL Server login with it, giving it `db_owner` permissions in both `AdventureWorks2008` and `XCatMgmt`. You need to specify this user in the `AUTHORIZATION` clause of any object you create that includes this clause. In the examples in this chapter, this is exemplified as `SSBTestUserName`.

Messages can be validated based on the following options:

- ▶ **NONE**—Do no validation; any message content is acceptable.
- ▶ **EMPTY**—Transmitted messages must be empty.
- ▶ **WELL_FORMED_XML**—Transmitted messages must be any well-formed XML.
- ▶ **VALID_XML WITH SCHEMA COLLECTION**—Transmitted messages must be valid XML corresponding to any schema in the XML schema collection specified in `XMLSchemaCollectionName`.

It is highly recommended that applications use either `WELL_FORMED_XML` or `VALID_XML WITH SCHEMA COLLECTION`. You don't want just any old message structure coming across the pipe because your application will almost certainly be looking for specific values in a specific location. XML is appropriate because it is the ubiquitous standard today. Note that the XML content of messages is actually stored as `varbinary(MAX)`. (XML schema collections are covered in the section "Using XML Schema Collections" in Chapter 47, "Using XML in SQL Server 2008.")

Now you should go ahead and create your two message types, both of which should be set to `VALID_XML`. The first deals with catalog entries and/or changes (that is, updates and deletions), and the second is a generic message type you use for all acknowledgments. Listing 49.2 shows the schemas for these message types, along with the necessary schema collection and message type creation syntax.

LISTING 49.2 DDL for Creating the Sample Message Types and Their Associated XML Schema Collections

```
-- Note:
-- Execute the T-SQL below, and then change the USE statement
-- to 'USE AdventureWorks2008' and execute it again.
```

```

[//samspublishing.com/SS2008/SSB/MessageTypes/GenericAck]
AUTHORIZATION [SSBTestUserName]
VALIDATION = VALID_XML
WITH SCHEMA COLLECTION GenericAcknowledgementSchema
```

Note that the message types and schema collections should be created (as the Listing 49.2 comment indicates) in both participating databases, AdventureWorks2008 and XCatMgmt. The reason is that when you create the XML messages, you might want to temporarily store them as local typed XML variables to ensure that they are validated before being sent. However, it is only necessary to create the schema collections on the database where the message will be received because the receiving instance of Service Broker performs the validation.

In the MESSAGE TYPE DDL, you should use this standard naming convention for Service Broker objects: *//DomainName/Path/Object Type/ObjectName*. This convention will help you identify your objects later. (Don't worry if the name is long; you can use Object Explorer's drag-and-drop feature to drag the name into your scripts.) If you're curious, you can view the newly created objects in Object Explorer by selecting the Service Broker node and then expanding the Message Types node. You can find the XML schema collections by selecting the Programmability node and then selecting the Types node and expanding the XML Schema Collections node.

Note that there are several built-in message types that any queue can receive from Service Broker. Service programs should be built to handle these as well as the specific message types defined in their contracts. You can view them all in the Object Browser (they all begin with <http://schemas.microsoft.com/SQL/ServiceBroker/>). When receiving messages from a queue, you should filter them based on the message_type_name column of the queue to be sure you handle each one correctly. You can expect to see these types in your queues:

- ▶ **Error**—This type is enqueued by Service Broker whenever an error is encountered. Alternatively, a user program can choose to create these types.
- ▶ **EndDialog**—This type is enqueued by Service Broker when a conversation ends in response to calls to END CONVERSATION (as explained later in this chapter).

Service programs can also send messages of the built-in type DialogTimer. Service Broker delivers these messages to the specified queue when a specific time period has elapsed. To tell Service Broker to send a DialogTimer message to the queue associated with a service after 5 minutes has elapsed, for example, you execute the following T-SQL during a conversation in the service program:

```
BEGIN CONVERSATION TIMER (@ConversationHandle) TIMEOUT = 600
```

In this code, you replace @ConversationHandle with the unique identifier assigned to your conversation (as explained later in this chapter).

Now that all your message types are in place and you know which built-in messages to expect, you can create the contract that defines the message flow in this system.

Setting Up Contracts for Communication

You use contracts to specify which messages can flow from which endpoints to which queues. Two new T-SQL keywords come into play here:

- ▶ **INITIATOR**—This service begins a messaging conversation.
- ▶ **TARGET**—This service engages in (or accepts) conversations with an initiator.

As described earlier, the sample system is initiated by a stored procedure in *AdventureWorks2008* that sends a message of type *CatalogChangeMessage* to a queue in *XCatMgmt*. Every *CatalogChangeMessage* is thus sent by a conversation initiator.

The catalog management service that receives these messages sends an acknowledgment reply message of type *GeneralAck* when it completes the requested change. *GeneralAck* messages in this case are thus sent by the target of the original initiated message.

To create the contract that represents this message flow, you need to execute the following code in both databases:

```
-- Note: Change SSBTestUserName to a user on your system,
-- and run this code on both AdventureWorks2008 and XCatMgmt
CREATE CONTRACT
[//samspublishing.com/SS2008/SSB/Contracts/BasicCatalogChangeContract]
AUTHORIZATION [SSBTestUserName]
(
    [//samspublishing.com/SS2008/SSB/MessageTypes/CatalogChangeMessage]
        SENT BY INITIATOR,
    [//samspublishing.com/SS2008/SSB/MessageTypes/GenericAck]
        SENT BY TARGET
)
```

This code for creating contracts also allows for message types to be sent by either the initiator or the target, in which case, you need to specify `SENT BY ANY`. A service can also be bound to more than one contract. Note that there is also a built-in contract called `DEFAULT` (as well as a message type of `DEFAULT`) that you use during conversations that do not specify a contract.

Contracts cannot be altered because only `DROP CONTRACT` exists.

Now that your contract and message types are ready, the next step is to create the queues needed to store the messages.

Creating Queues for Message Storage

Queues represent a layer of communication indirection between services, allowing them to send and receive messages independently of each other. A queue is a first-class database object, internally implemented as a table that has some unique behaviors.

NOTE

You can select values from any queue by using standard syntax, such as `SELECT * FROM QueueName WITH (NOLOCK)`. This has no effect on the data in the queue, nor does it imply a message receive operation. It does, however, cause blocking on the internal queue table, so you should always use the `NOLOCK` hint. Data Manipulation Language (DML) statements on queues are not permitted.

The following is the syntax for creating a queue:

```
CREATE QUEUE DatabaseName.SchemaName.QueueName
[ WITH
    [ STATUS = { ON | OFF } [ , ] ]
    [ RETENTION = { ON | OFF } [ , ] ]
    [ ACTIVATION (
        [ STATUS = { ON | OFF } , ]
        PROCEDURE_NAME = SPName,
        MAX_QUEUE_READERS = Number,
        EXECUTE AS { SELF | 'UserName' | OWNER }
    ) ]
]
[ ON { filegroup | [ DEFAULT ] } ]
```

This syntax contains the following options:

- ▶ **STATUS**—This option turns the queue on or off, meaning that it may or may not be used. (This capability is useful with `ALTER QUEUE` when a queue must be temporarily put offline.) It defaults to `ON`.
- ▶ **RETENTION**—This option turns message retention on or off during active conversations that use the queue. It defaults to `OFF`. You might need to turn this feature on at some point if you need to see messages that have already been processed. The reason is that the normal message receive operation implicitly deletes a message when the transaction that surrounds it commits. When `RETENTION` is set to `ON`, the value in the status column for the queue is changed to 1 after a receive instead of a deletion. In addition, sent messages are copied to the sender's queue (duplicated) and given a status value of 3, to fully audit the message flow in both directions.
- ▶ **ACTIVATION**—This clause is used to specify the following options regarding the internally activated stored procedure (described earlier):
 - ▶ **STATUS**—This option is used to turn activation on or off. (You may want to temporarily turn off activation when updating a procedure.) It defaults to `ON`.
 - ▶ **PROCEDURE_NAME**—This option specifies the name of the activated procedure.

- ▶ **MAX_QUEUE_READERS**—This option supplies an integer that indicates to Service Broker the maximum number of instances of the activated procedure to create. This setting hints at the fact that Service Broker uses multithreading to instantiate additional queue readers when unread messages in the queue build up faster than the existing instances can process them. This is a great boon to developers because they no longer have to develop and maintain the multithreaded code to perform this task. To do this, Service Broker internally creates queue monitors that keep an eye on the number of unread messages in the queue. Keep this number the same as the number of processor cores you have in your system.
- ▶ **EXECUTE AS**—This option specifies the name of the user under which the initiated procedure runs.

You need two queues for the application so far: one used by each service. The T-SQL in Listing 49.3 creates them.

LISTING 49.3 T-SQL for Creating Queues and Their Activated Stored Procedures

```
USE XCatMgmt
GO
CREATE PROC Publication.CatalogChangeQueueReader
AS
GO
CREATE QUEUE Publication.CatalogChangeQueue
WITH
STATUS = ON,
ACTIVATION
(
    STATUS = ON,
    PROCEDURE_NAME = Publication.CatalogChangeQueueReader,
    MAX_QUEUE_READERS = 10,
    EXECUTE AS 'SSBTestUserName'
)
GO
USE AdventureWorks2008
GO
CREATE PROC Production.CatalogChangeAckQueueReader
AS
GO
CREATE QUEUE Production.CatalogChangeAckQueue
WITH
STATUS = ON,
ACTIVATION
(
    STATUS = ON,
    PROCEDURE_NAME = Production.CatalogChangeAckQueueReader,
```

```

MAX_QUEUE_READERS = 10,
EXECUTE AS 'SSBTestUserName'
)

```

The code in Listing 49.3 declares an empty stored procedure for each queue. You can fill this shell after you define the services.

Defining Services to Send and Receive Messages

Services represent the endpoints in Service Broker applications. You can think of them as the glue that binds contracts with queues. This binding ensures that the typed messages specified in the contract end up in the appropriate queues.

Here is the DDL syntax for creating services:

```

CREATE SERVICE ServiceName
[AUTHORIZATION OwnerName]
ON QUEUE [SchemaName.]QueueName
([ ContractName | [ DEFAULT ] [ ,...n ] ]) [;]

```

For this example, you need to create two services: the initiator in AdventureWorks2008 and the target in XCatMgmt.

This is the initiator in AdventureWorks2008:

```

USE AdventureWorks2008
GO
CREATE SERVICE
[//samspublishing.com/SS2008/SSB/Services/CatalogChangeInitiatorService]
AUTHORIZATION [SSBTestUserName]
ON QUEUE
Production.CatalogChangeAckQueue
([//samspublishing.com/SS2008/SSB/Contracts/BasicCatalogChangeContract])

```

And this is the target in XCatMgmt:

```

USE XCatMgmt
GO
CREATE SERVICE
[//samspublishing.com/SS2008/SSB/Services/CatalogMaintenanceService]
AUTHORIZATION [SSBTestUserName]
ON QUEUE
Publication.CatalogChangeQueue
([//samspublishing.com/SS2008/SSB/Contracts/BasicCatalogChangeContract])

```

As you can see, creating services is simple. Now that all the plumbing is in place, you can begin the dialog between the services.

Planning Conversations Between Services

A *conversation* is a dialog between two services. The purpose of this dialog is, of course, the sending and receiving of messages, which ultimately leads to the completion of a task.

A powerful feature of Service Broker messaging is that it guarantees exactly-once-in-order (EOIO) messaging. This means that messages are sent exactly once; there's no chance that a message can be sent twice because of a system issue, so the receiver doesn't have to check whether a message has already been processed. It also means that messages are always ordered in their queue in the same order in which they were sent. (The `queuing_order` column of the queue indicates this order.) Service Broker makes sure of this, even in cases in which the send order somehow gets out of sync.

Transactions are an integral part of Service Broker conversations. When a message is sent within the scope of a transaction, it is not actually moved to the destination queue unless the transaction commits. This has to do with the fact that before being placed in a queue, messages are stored in internal tables called *transmission queues* (which are viewable via the catalog view `sys.transmission_queue`). Similarly, a message is not deleted from a queue after it is received unless the transaction commits (except in cases in which the `RETENTION` flag for the queue is set to `ON`). This point is very important because it means that any database operations as well as any messaging operations belong to the same transaction, and they are controlled by the same transactional system. This is a unique feature of messaging with Service Broker and is part of the rationale for having messaging built in to the database.

The `BEGIN CONVERSATION DIALOG` statement is the cornerstone of the process of creating conversations. It specifies the services participating (`TO SERVICE` and `FROM SERVICE`) and the contract to which they will be adhering during the dialog (`ON CONTRACT`). It also enables the correlation of messages because it is the thread that relates them to each other. This relationship is achieved through the use of a conversation, or dialog, handle. A *dialog handle* is a variable of type `uniqueidentifier` that identifies the dialog.

You use the following syntax to start a dialog:

```
BEGIN DIALOG [ CONVERSATION ] @DialogHandle
FROM SERVICE InitiatingServiceName
TO SERVICE 'TargetServiceName'
    [ , { 'service_broker_guid' | 'CURRENT DATABASE' } ]
[ ON CONTRACT ContractName ]
[ WITH
[ { RELATED_CONVERSATION = RelatedDialogHandle |
    RELATED_CONVERSATION_GROUP = RelatedConversationGroupId } ]
[ [ , ] LIFETIME = DialogLifetimeInSeconds ]
[ [ , ] ENCRYPTION = { ON | OFF } ] ]
[ ; ]
```

The items in the syntax are as follows:

- ▶ **@DialogHandle**—This is an output parameter of type `uniqueidentifier` that is returned by the statement. You use this option later in this chapter to relate conversations.
- ▶ **InitiatingServiceName**—This is the name of the (local) service acting as the initiator.
- ▶ **'TargetServiceName'**—This is the name of the service acting as the target. Note that this is a case-sensitive string (technically of type `nvarchar(256)`), for purposes of name resolution against non-SQL Server services (for later extensions); a byte-level comparison is made for name resolution. If this value is incorrectly provided, messages remain in the transmission queue. Note that `sys.transmission_queue.to_service_name` holds this value.

A Service Broker globally unique identifier (GUID) may be optionally specified after `'TargetServiceName'`, and it is required when you are doing inter-database messaging (as a later example in this chapter illustrates). The `'CURRENT_DATABASE'` string indicates the current Service Broker GUID.

- ▶ **ContractName**—This is the name of the contract that the services use.
- ▶ **WITH**—This clause allows you to specify a related conversation group to which the current conversation is related, either via a conversation handle or a conversation group ID.

NOTE

When a new conversation is created, in addition to being assigned a new conversation (or dialog) handle, that conversation is also joined to a new conversation group behind the scenes, unless the group ID of an existing conversation group is specified.

Conversation groups are incredibly important because queues are locked at the conversation group level. A queue used by any services in a group of related conversations is locked on that group during receives, ensuring that messages are always received serially by all the services in the group. `BEGIN CONVERSATION DIALOG` implicitly locks the conversation group it specifies (or the implied group it creates).

If locking did not work this way, a service program could receive a message lower in the queue order before a second instance of the same service program finished receiving a message higher in the order. If that lower message needed data that was dependent on the other uncommitted receive, you would end up with a referential integrity issue.

It is thus a rather questionable practice to spread related and/or dependent data across multiple messages or to do so without doing the appropriate checks in the code.

The following options are available for the `WITH` clause:

- ▶ **RELATED_CONVERSATION**—This option relates the current conversation to the conversation group created for the specified conversation handle.

- ▶ **RELATED_CONVERSATION_GROUP**—This option relates the current conversation to the conversation group created for the specified conversation group ID. (This has the same effect as the `RELATED_CONVERSATION` keyword, with a different parameter.) If the value provided for `RelatedConversationGroupId` is invalid, a new conversation group is created to which the dialog is related.
- ▶ **LIFETIME**—This option specifies the number of seconds for which the dialog will remain open; it defaults to the maximum value of `int`, which is approximately 68 years. If this option is specified, both services must call `END_DIALOG CONVERSATION` before this time is up, or an error is raised.
- ▶ **ENCRYPTION**—This option specifies whether messages transmitted beyond the current SQL Server instance (within the conversation) are encrypted. It defaults to `ON`, meaning that message transmissions between databases on different instances are encrypted by default. Encryption requires the use of certificates, discussed later in this chapter, in the section “Using Certificates for Conversation Encryption.”

Creating the Conversation Initiator

It’s finally time to create the stored procedure that initiates the dialog between the services. Listing 49.4 contains the code to do this.

LISTING 49.4 Using **BEGIN CONVERSATION DIALOG** in a Stored Procedure

```
CREATE PROCEDURE Production.ProductModelUpdate
GO
USE AdventureWorks2008
GO
DROP PROC Production.ProductModelUpdate
GO
CREATE PROCEDURE Production.ProductModelUpdate
(
    @ProductId int,
    @NewName Name
)
AS
DECLARE @DialogHandle UNIQUEIDENTIFIER
DECLARE @CatalogChangeXml xml (DOCUMENT dbo.CatalogChangeSchema)
DECLARE @RemoteSSBGuid uniqueidentifier

-- Get the SSB guid for the target service's db
SELECT @RemoteSSBGuid = service_broker_guid
FROM sys.databases
WHERE name = 'XCatMgmt';

BEGIN TRAN;
```

```

UPDATE Production.ProductModel
SET Name = pm.Name -- change this to @NewName to actually modify the data
FROM Production.ProductModel pm
JOIN Production.Product p on
p.ProductModelId = pm.ProductModelId
WHERE p.ProductId = @ProductId;

if @@ERROR != 0
BEGIN
    ROLLBACK TRAN
    RAISERROR('(Initiator) Error during table update', 16, 1)
    RETURN
END;

BEGIN TRY;

MESSAGE TYPE
[//samspublishing.com/SS2008/SSB/MessageTypes/CatalogChangeMessage]
(@CatalogChangeXml)
PRINT '(Initiator) Message Sent Successfully.'
COMMIT TRAN

```

This UPDATE procedure exemplifies several key concepts. A variable for the dialog handle is declared for later storage during the call to `BEGIN DIALOG`. After the actual database update, a typed XML variable—that matches the same XML schema collection as the message type of which it will become an instance—is populated, using an XQuery statement.

The call to `CatalogDescription.query()` transforms the original XML into XML that matches the schema in `CatalogChangeSchema`. This way, if there are any validation errors,

you find out about them before the message is sent (implicitly terminating the open transaction). This makes it virtually impossible to send an invalid message.

The new value for `ProductModel.Name` is inserted into the XML via the attribute constructor `Name="{sql:column('pm.Name')}"`. The value of the attribute `ChangeType="2"` corresponds to the enumeration in the schema where `id="Update"`. Because you use this value (as you'll soon see), the service for `XCatMgmt` knows what the sender intended by the message.

In the new `SEND` statement, the saved GUID for the Service Broker instance on `XCatMgmt` is used to locate the target service when sending the message. `SEND` has the following syntax:

```
SEND ON CONVERSATION ConversationHandle
[ MESSAGE TYPE MessageType ]
[ ( MessageBody ) ][ ; ]
```

As you can see, the `SEND` statement requires `ConversationHandle` for message correlation. The type specified in `MessageType` must match the appropriate type specified in the contract for the sending service. `MessageBody` must be of a data type that can be converted to `varbinary(max)`, such as `xml`.

If any issues arise during the sending of a message, you can find the text of the reason for the problems in `sys.transmission_queue.transmission_status`. This is a great place to look for transmission-related information because the messages in it are reasonably user-friendly.

You also need to consider the use of the `END CONVERSATION` statement, which, predictably, ends the conversation. This is its syntax:

```
END CONVERSATION ConversationHandle
[
  [ WITH ERROR = ErrorPositiveInt DESCRIPTION = 'ErrorMsg' ]
  |
  [ WITH CLEANUP ]
][ ; ]
```

If desired, you can specify an error message value in `ErrorPositiveInt` and an error message of your choosing when ending the conversation. Ending a conversation with an error drops all the unsent messages currently in the transmission queue, and Service Broker sends a message to the target service of type `Error`.

You can specify the `WITH CLEANUP` clause to clean up the transmission queue's unsent messages related to the conversation and to clear the queue owned by this service (in this case, `Production.CatalogChangeAckQueue`).

Note that until both services in the conversation call `END CONVERSATION`, the conversation is not complete. When only one side calls `END CONVERSATION` or when the `LIFETIME` setting of the conversation has been met, the other endpoint can continue to use the

invalid conversation handle until the two sides receive the EndDialog message (if messages are sent after the EndDialog message has been received, a runtime error is raised).

Creating the Conversation Target

After you create the initiator, the next step is to create the service program in XCatMgmt that is activated when messages arrive. This step involves a bit more work because this program needs to receive messages of at least three types (Error, EndDialog, and CatalogChangeMessage), create and send acknowledgment messages, and perform local database DML.

The example in Listing 49.5 contains a stored procedure that receives correlated messages from the initiator. Note that this procedure is the same (empty) one you specified in Listing 49.3.

LISTING 49.5 Using **GET CONVERSATION DIALOG, RECEIVE,** and **SEND ON CONVERSATION** in an Service Broker–Activated Stored Procedure

```

use XCatMgmt
GO
DROP PROC Publication.CatalogChangeQueueReader

```

One issue you might notice when testing the code in Listing 49.5 is that the PRINT statements in the activated procedure do not show up in the SSMS query window. You need to use SQL Profiler (which is discussed in Chapter 6, “SQL Server Profiler”) to aid in debugging activated code because it always runs on background threads. To help you out, a Service Broker event group is available in SQL Profiler for tracing all the new Service Broker events’ message transmission, activation, conversation beginning and ending, and so on. You can use this new event group along with the T-SQL and stored procedure event groups to trace the code path. Print statements are included in the code in Listing 49.5 to make debugging easier.

The code in Listing 49.5 introduces three new SQL statements: GET CONVERSATION DIALOG, RECEIVE, and GET CONVERSATION GROUP.

The purpose of GET CONVERSATION DIALOG is to lock the next available conversation group associated with the messages in Publication.CatalogChangeQueue. Conventional use of GET CONVERSATION DIALOG requires that the WAITFOR statement be used to make the initiated program wait a specified number of milliseconds (or infinitely, as specified in TIMEOUT) before continuing on in the program logic. If the conversation group ID has been

received within the specified time, the code successfully locks that conversation group (that is, locks the specified queue for receiving). If not, @ConversationGroupId is NULL.

After this call, the program attempts to receive the next message in the queue by using the RECEIVE statement, whose syntax is similar to that of SELECT, except that instead of specifying a table name, you specify a queue name.

Next, the code checks the received message type and takes the appropriate action. If the message type is Error, it ends the dialog, reporting the error. If the message type is EndDialog, it simply ends its side of the dialog. If it is a catalog change message, it updates Publication.Product so that the related row in Publication.ProductCatalog (which associates products with catalogs) now points to the newest data.

Just as with the initiator code, the target code first declares its outgoing messages as a typed XML variable (@AckXml). This helps in making sure that the outgoing message will be received without error.

One issue to be mindful of is that all this code is executing in the scope of a single transaction. If any part of the code fails, the ROLLBACK statement rolls back any DML as well as message sends and receives. To test the code, you can execute the following statement:

```
EXEC Production.ProductModelUpdate 749, 'A Super Product'
```

NOTE

You might want to come up with a clever way of populating the body of the responding Production.CatalogChangeAckQueueReader stored procedure to deal with the incoming acknowledgment messages sent by the target.

Prioritizing Services

The next issue to consider is conversation priority. A safe assumption is that some of your software applications are more important than others. Likewise, some of your SSB services are mission-critical (and should be configurable as such) and others may be only for casual use. You can easily set a numeric priority for these services so that when system resources are scarce (during periods of high server and network utilization), messages for your critical applications are processed first.

SQL Server 2008 offers a simple syntax for accomplishing this. The following example illustrates how to set the priority to level 1 for messages transmitted from our SSB initiator (local) service to our target (remote) service:

```
CREATE BROKER PRIORITY CatChangeInitToTarget
FOR CONVERSATION
SET
(
    CONTRACT_NAME =
        [//samspublishing.com/SS2008/SSB/Contracts/BasicCatalogChangeContract],
    LOCAL_SERVICE_NAME =
```

```

        [//samspublishing.com/SS2008/SSB/Services/CatalogChangeInitiatorService],
REMOTE_SERVICE_NAME =
        N'//samspublishing.com/SS2008/SSB/Services/CatalogChangeNotifyTarget',
PRIORITY_LEVEL = 1
)

```

Next, you need to learn how to set up Service Broker messaging applications to run on multiple instances of SQL Server.

Service Broker Routing and Security

The following sections detail how to set up the Service Broker constructs you need for your applications to work in a secure, distributed environment.

Using Certificates for Conversation Encryption

In Listing 49.4, you might have noticed that you set the `ENCRYPTION = OFF` flag in the code of the initiator. You had to do this because Service Broker relies heavily on certificate-based encryption. If you had left the encryption flag set to its default of `ON`, your messages would not have left their transmission queue, and Service Broker would have raised an error.

Service Broker services running on multiple SQL Server instances communicate across the network via endpoints that are secured using certificates. Certificates are the foundation of secure network communications. They are used for securing email (PGP), FTP (S/FTP), HTTP (SSL), .NET assemblies (strong naming), and more. The basic premise of certificates is the use of public key cryptography: When a digital certificate is created, a public key (shared openly) and a private key (never shared) are created simultaneously via a special algorithm such as RSA. Data to be securely transmitted is first encrypted by the sender, using the *receiver's* public key, acquired either through a registration authority (RA) or otherwise. When the encrypted data is received, the receiver decrypts the data by using its private key.

SQL Server provides the DDL statement `CREATE CERTIFICATE` for creating certificates. This statement provides several methods for doing so, but in this chapter you use it only to create *self-signed* certificates—that is, certificates signed by their creator, not by a trusted external authority (such as VeriSign), known as a certificate authority (CA).

Before you create a certificate, you need to create a master key for the master database (just as you did with `AdventureWorks2008` and `XCatMgmt`) that can be used to protect the private keys you'll create. You also need to create certificates on `master` for use with the endpoint you need (as described later in this section). Note that you have to perform this step and subsequent steps on all the instances of SQL Server that will be communicating via Service Broker. In the sample code, by convention, the objects created on the first instance all terminate with the string `I1`, and in the second instance, they terminate with `I2`. In addition, we refer to the first SQL Server instance as `I1` and the second as `I2`.

The following T-SQL creates a master key in the master database:

```
USE master
GO
CREATE MASTER KEY ENCRYPTION BY PASSWORD = 'masterI1'
```

Now you can create your first certificate in master on I1. (Note that SUBJECT is a metadata field defined in the certificate standard X.509.) Here's how you do it:

```
CREATE CERTIFICATE SSBMasterCertI1
WITH SUBJECT = 'SSBMasterCertOnInstance1',
START_DATE = '2008-10-02 07:30:35';
-- Note: The start date must not be in the future,
-- or the certificate is not useful
```

Next, you need to create a TCP endpoint that enables Service Broker in I1 to communicate with Service Broker in I2. (The CREATE ENDPOINT syntax is shown in Chapter 54, “Managing Linked and Remote Servers,” for use in creating web services.) This endpoint uses the keys in the certificate you just created to communicate securely. You use the following code to create the endpoint:

```
CREATE ENDPOINT SSBEndpointI1
STATE = STARTED
AS TCP (LISTENER_PORT = 4022) -- the default SSB port; TCP-based
FOR SERVICE_BROKER
(ENCRYPTION = REQUIRED, AUTHENTICATION = CERTIFICATE SSBMasterCertI1)
GO
GRANT CONNECT ON ENDPOINT::SSBEndpointI1
TO [SSBTestUserName]
```

For I2 to encrypt messages using the public key that resides in MasterCertI1, that public key must be exported from the database to a file and then imported into a new certificate on I2. You can use the new BACKUP CERTIFICATE command to accomplish the export to file, and then you can perform the same steps on I2 to import MasterCertI1's public key into a matching certificate:

```
BACKUP CERTIFICATE SSBMasterCertI1 TO FILE = 'c:\temp\MasterCertI1_PK.cer'
```

Now you need to switch over to the second SQL Service instance and run the following code:

```
USE master
GO
CREATE MASTER KEY ENCRYPTION BY PASSWORD = 'masterI2'
GO
CREATE CERTIFICATE SSBMasterCertI2
WITH SUBJECT = 'MasterCertOnInstance2',
START_DATE = '2008-10-02 07:30:35';
```

```

GO
CREATE ENDPOINT SSBEndpointI2
STATE = STARTED
AS TCP (LISTENER_PORT = 4022)
FOR SERVICE_BROKER
(ENCRYPTION = REQUIRED, AUTHENTICATION = CERTIFICATE SSBMasterCertI2)
GO
GRANT CONNECT ON ENDPOINT::SSBEndpointI2
TO [SSBTestUserName]
GO
BACKUP CERTIFICATE SSBMasterCertI2
TO FILE = 'c:\temp\SSBMasterCertI2_PK.cer'
GO
CREATE CERTIFICATE SSBMasterCertI1
AUTHORIZATION [SSBTestUserName]
FROM FILE = 'C:\temp\SSBMasterCertI1_PK.cer'

```

The last statement in this code creates a certificate on I2 that has the same name and contains the same public key as *SSBMasterCertI1*. It also performs an essential function: it assigns that public key to *SSBTestUserName* by using the *AUTHORIZATION* keyword.

Now you can return to the first instance to do the same there, using *SSBMasterCertI2*'s public key:

```

CREATE CERTIFICATE SSBMasterCertI2
AUTHORIZATION [SSBTestUserName]
FROM FILE = 'C:\temp\SSBMasterCertI2_PK.cer'

```

Note that you set up *SSBTestUserName* as a domain user and then add this user as a login with *db_owner* permissions on both instances. You don't need to create *SSBTestUserName* in *XCatMgmt* because this user is already (or should be) there. For purposes of this discussion, you can assume that both instances can use the path *c:\temp*.

The next step is to create a new database on I2 called *XBikeDistribution*. The concept behind this database is that *XBikeDistribution* is a subscriber to one of the catalogs published by *XCatMgmt*. When a product in that catalog changes, *XBikeDistribution* needs to know about it. You can use the following code to create this database so that it is as lean as possible:

```

USE master
GO
CREATE DATABASE XBikeDistribution
WITH TRUSTWORTHY ON
GO
ALTER DATABASE XBikeDistribution SET ENABLE_BROKER
GO
USE XBikeDistribution
GO

```

```

CREATE MASTER KEY ENCRYPTION BY PASSWORD = 'XBikeDistributionPW'
GO
CREATE SCHEMA Cataloging
CREATE TABLE Cataloging.CatalogSimple
(
    CatalogId int IDENTITY(1,1) PRIMARY KEY,
    CatalogXml xml NOT NULL,
    LastUpdateDate datetime DEFAULT GETDATE()
)
GO
CREATE USER [SSBTestUserName]

```

The next step is to add the XML schema collection you used in previous examples (GenericAcknowledgementSchema; found in Listing 49.2) to XBikeDistribution. Then you need to set up certificates for use in the Service Broker dialogs that will take place between the catalog change service running in XCatMgmt and a new service you need to set up in XBikeDistribution. On I2, you run the following code to set up a certificate for use in Service Broker conversations:

```

CREATE CERTIFICATE SSBDialogCertI2
WITH SUBJECT = 'SSBDialogCertOnInstance2',
START_DATE = '2008-10-02 07:30:35'
ACTIVE FOR BEGIN_DIALOG = ON;
GO
BACKUP CERTIFICATE SSBDialogCertI2
TO FILE = 'c:\temp\SSBDialogCertI2_PK.cer'

```

Now you need to switch back to I1, change to XCatMgmt, and create two more certificates, one for each side of the exchange:

```

USE XCatMgmt
GO
CREATE CERTIFICATE SSBDialogCertI1
WITH SUBJECT = 'SSBDialogCertOnInstance1',
START_DATE = '2008-10-02 07:30:35'
ACTIVE FOR BEGIN_DIALOG = ON;
GO
BACKUP CERTIFICATE SSBDialogCertI1
TO FILE = 'c:\temp\SSBDialogCertI1_PK.cer'
GO
CREATE CERTIFICATE SSBDialogCertI2
AUTHORIZATION [SSBTestUserName]
FROM FILE = 'C:\temp\SSBDialogCertI2_PK.cer';

```

Note that the second certificate in this code contains the public key you just created and exported to file in SSBDialogCertI2.

Now you need to return to I2 and import the public key in `SSBDialogCertI1` and associate it with `SSBTestUserName`:

```
CREATE CERTIFICATE SSBDialogCertI1
AUTHORIZATION [SSBTestUserName]
FROM FILE = 'C:\temp\SSBDialogCertI1_PK.cer';
```

By the time you're done creating all these certificates, you should have the following .cer files in your directory: `SSBMasterCertI1_PK.cer`, `SSBMasterCertI2_PK.cer`, `SSBDialogCertI2_PK.cer`, and `SSBDialogCertI1_PK.cer`. By now, the pattern of certificate creation and public key user association should be quite clear.

The next step is to set up the Service Broker constructs. You need to start on I2 in `XBikeDistribution` because it has no constructs yet. First, you create the `GenericAcknowledgementSchema` XML schema collection in `XBikeDistribution`, as shown earlier in Listing 49.2. Note that in this Service Broker conversation, a service in `XCatMgmt` plays the role of initiator, and a service in `XBikeDistribution` is the target. (Because you've seen this all before, the following examples lump a lot of the DDL together.)

Next, you need to switch to I2 and run the code in Listing 49.6.

LISTING 49.6 T-SQL for Creating All the Service Broker Constructs on a Second SQL Server Instance

```
USE XBikeDistribution

GO

```

```
GRANT SEND ON
SERVICE::[//samspublishing.com/SS2008/SSB/Services/CatalogChangeNotifyInitiator]
TO [SSBTestUserName]
```

If you look closely at Listings 49.6 and 49.7, you see that they introduce two new Service Broker constructs: routes and remote service bindings.

Building Routes to Map Conversations Between SQL Server Instances

Routes are used to map a Service Broker service to a TCP address for use when conversing between different SQL Server instances. They provide a useful level of abstraction because the address of a route can be changed without having to change any of the constructs that depend on it. In this way, it is possible to change a route and, as long as the message types, required XML schema collections, contracts, queues, and services exist in the databases on the machines involved, only the route needs to be updated. Routes can also be used when only a single SQL Server instance is involved so that it can easily be changed to work when a new instance comes into play.

NOTE

For the routes in this example to work, the TCP port specified earlier in CREATE END-POINT (port 4022) must be open on any firewalls involved.

The routes created in Listings 49.6 and 49.7 are thus necessary because the initiator needs to be able to locate the target service to send messages, and the target service needs to be able to do the same.

Creating Remote Service Bindings for Conversations

When initiating a conversation with a service on a nonlocal SQL Server instance, you need to create a remote service binding. A *remote service binding* associates a local database user with a remote service. When messages are transmitted between the instances, Service Broker encrypts them, using the public key of the local user's certificate. They are then decrypted on the other end, using the private key. Because you have created matching pairs of certificates and associated them with the user in the master database and in all participating databases on both instances (and you have also turned off anonymous access), you can be certain that communications will happen securely over the network.

A Final Note on the Sample System

If you like, you can create the initiator and target service programs for the final example in this chapter. For example, you could create an update trigger (as the initiator) on `XCatMgmt.Publication.ProductCatalog` that sends a `CatalogChangeNotifySimple` well-formed XML message to `XBikeDistribution.Cataloging.CatalogChangeNotifyReceiveQueue`. You fill in the body of the target's activated procedure `XBikeDistribution.Cataloging.CatalogChangeNotifyQueueReader` to receive these

messages and reply by sending a message of type `GenericAck` to the existing `Production.CatalogChangeAckQueue`. Remember that you need to acquire the `service_broker_guid` of the remote SQL Server instance's Service Broker instance to send messages successfully. Also, you need to be sure to set the `ENCRYPTION` flag to `ON` (the default) when calling `BEGIN DIALOG CONVERSATION`.

Troubleshooting SSB Applications with `ssbdiagnose.exe`

SQL Server 2008 comes with a new command-line application, `ssbdiagnose.exe`. You use this advanced utility to monitor SSB conversations or to check application configuration status, both across databases and between computers. It supports a variety of authentication and configuration options and generates either plain text or XML as its output.

The general syntax for `ssbdiagnose.exe` has three parts:

- ▶ Output format and error level
- ▶ Connection information
- ▶ Application-specific settings

You can leverage the full syntax of `ssbdiagnose.exe` by simply executing it from the command line with no options (it is located in the folder `[SQL Server installation root]\[version number]\Tools\Binn`). To run it, open a command window (run the `CMD.exe` program) and then navigate to your installation location using the `CD` command. As an exercise, you can execute any of the examples that follow.

In the following example, you connect to the current SSB application (as developed in Listings 49.1 through 49.7) and check on the services' configuration status. Remember that the application lives in two databases (`AdventureWorks2008` and `XCatMgmt`), so you need to provide parameters to check on both sides of the service contract. Because the service and contract names are quite long, we suggest enclosing the command-line contents in a batch file and running it from there.

Execute the following command, substituting connection credentials with those appropriate for your environment:

```
SSBdiagnose.exe
-U SSBTestUserName -P SSBTestUserName CONFIGURATION FROM SERVICE
"//samspublishing.com/SS2008/SSB/Services/CatalogChangeInitiatorService"
-S localhost\SQL08 -d AdventureWorks2008 TO SERVICE
"//samspublishing.com/SS2008/SSB/Services/CatalogMaintenanceService"
-S localhost\SQL08 -d XCatMgmt ON CONTRACT
"//samspublishing.com/SS2008/SSB/Contracts/BasicCatalogChangeContract"
```

If you've executed all the sample code and listings in this chapter, you should see no errors in the `ssbdiagnose.exe` output. For troubleshooting, refer to the next section to learn how to explore the system catalogs for SSB.

Now that you have a sense of what you can accomplish with this utility, you should take some time to explore it further by monitoring the status of a conversation of the service you set up in the `xBikeDistribution` database. Further information is available in the MSDN article “`ssbdiagnose` Utility.”

Related System Catalogs

A few of the system catalogs and dynamic management views (DMVs) might be of interest to you if you’re debugging Service Broker applications or simply seeking a greater understanding of how Service Broker works under the hood. Let’s take a look at some of them.

You’ve already seen `sys.transmission_queue`, which is used to store undelivered messages in a particular database. This table is very useful because it provides the reason a message is undeliverable (in `transmission_status`), the date sent (in `enqueue_time`), a conversation identifier (in `conversation_handle`), contract and service names (in `service_contract_name`, `to_service_name`, `from_service_name`), and more.

Another useful catalog is `sys.service_queues`, which holds the definitions of the queues defined in a particular database. It has a few interesting columns:

- ▶ **activation_procedure**—This column contains the name of the activated service program that is bound to the queue.
- ▶ **max_readers**—This column contains the integer value specified in the `CREATE QUEUE` of `MAX_QUEUE_READERS`.
- ▶ **is_retention_enabled**—This column contains the Boolean value of the `RETENTION` flag in `CREATE QUEUE`.

You can use the value in the `object_id` column to figure out which queue is being referenced in a particular error message, such as the following, which you may find in your transmission queue someday: This message could not be delivered because the destination queue has been disabled. Queue ID: 325576198. This error occurs when your activated code throws an error in its body after receiving a message, rolls back the receive, is activated again, and so on, until Service Broker intervenes and disables the queue. (It usually takes three failures for this to happen.) A similar error is raised if you set `ENCRYPTION = ON` and don’t set up certificates.

To see all the services in a particular database, you can query `sys.services`. To see all the active conversations, you can query `sys.conversation_groups`. The following query shows how to use these tables together:

```
SELECT
    sq.name as QueueName,
    ss.name as ServiceName,
    cg.conversation_group_id as CGId
FROM sys.services ss
JOIN sys.service_queues sq
ON ss.service_queue_id = sq.object_id
```

```
LEFT JOIN sys.conversation_groups cg
ON cg.service_id = ss.service_id
```

To see all the contracts in a particular database, you can query `sys.service_contracts`. To see all the message types, you can query `sys.service_message_types`. These catalog views are brought together in the system table `sys.service_contract_message_usages` (showing message types by contract). You can also link them to `sys.service_contract_usages` (showing contracts by service) via the following query:

```
SELECT
    s.Name ServiceName,
    sc.Name ContractName,
    smt.Name as MsgTypeName,
    scmu.is_sent_by_initiator,
    scmu.is_sent_by_target
FROM sys.services s
JOIN sys.service_contract_usages scu
ON scu.service_id = s.service_id
JOIN sys.service_contracts sc
ON sc.service_contract_id = scu.service_contract_id
JOIN sys.service_contract_message_usages scmu
ON scmu.service_contract_id = sc.service_contract_id
JOIN sys.service_message_types smt
ON smt.message_type_id = scmu.message_type_id
```

In addition, you can view any certificates you have created by querying `sys.certificates`, routes via `sys.routes`, and remote service bindings via `sys.remote_service_bindings`. Each side of a conversation is known as an *endpoint*, and you can view endpoints by querying `sys.conversation_endpoints`.

Five DMVs may be of interest in debugging live Service Broker applications:

- ▶ **sys.dm_broker_activated_tasks**—Each row refers to a stored procedure being activated.
- ▶ **sys.dm_broker_connections**—Each row refers to an in-use Service Broker network connection.
- ▶ **sys.dm_broker_forwarded_messages**—Each row refers to a message currently being forwarded.
- ▶ **sys.dm_broker_queue_monitors**—Each row refers to the current behavior of a SQL Server background task known as a queue monitor, which is responsible for activation.
- ▶ **sys.dm_broker_transmission_status**—Each row refers to the status of a message being transmitted.

To see all the activated stored procedures in a given database, for example, you can try the following:

```

SELECT
    d.name DBName,
    sq.name QueueName,
    dmbat.spid SPID,
    dmbat.procedure_name ProcName
FROM sys.dm_broker_activated_tasks dmbat
JOIN sys.databases d ON
d.database_id = dmbat.database_id
AND dmbat.database_id = DB_ID()
JOIN sys.service_queues sq
ON dmbat.queue_id = sq.object_id

```

Summary

Like the addition of native Web services, the addition of Service Broker pushes SQL Server even further outside the bounds of being a pure database server and into the application server realm.

Because it is built directly into SQL Server databases, Service Broker inherently provides backup and restoration, replication and failover, and single-mode transactions, which together give Service Broker an edge over competing messaging technologies. Plus, as you've seen, it's extremely easy to set up and begin coding, because you need to do very little groundwork; all the ingredients are already "in there."

One issue not covered in this chapter is the fact that service programs may be written in managed code that makes use of SQL Server CLR integration. At the time of this writing, there is no officially released .NET Framework library for the Service Broker objects, so this chapter does not cover the subject. However, Microsoft may release a Windows Communication Foundation (WCF) channel that provides a Service Broker interface.

In Chapter 50, "SQL Server Full-Text Search" (on the CD), looks at how SQL Server's Full-Text Search feature enables you to create an index of and perform specialized queries against all textual data in your tables.

CHAPTER 50

SQL Server Full-Text Search

This chapter looks at how to use SQL Server 2008 Full-Text Search (FTS). SQL Server FTS allows you to do extremely fast searches of textual contents stored in columns of the `char`, `nchar`, `varchar`, `nvarchar`, `varchar(max)`, `nvarchar(max)`, `xml`, and `text` data types and binary content stored in `image` and `varbinary(max)` data types (if you have an `IFilter` for the data stored in the `image` or `varbinary(max)` data types).

SQL Server FTS has considerable advantages over a search based on a `LIKE` clause because it is faster, can search binary content, and has language features that a `LIKE` clause does not support. SQL Server FTS also allows you to include a wildcard at the end of a word (for example, doing a search on `test*` to match `test`, `testing`, `tester`, and `testament`). However, SQL Server FTS does not allow a wildcard at the beginning of a word; for these types of prefix-based searches, you still have to use a `LIKE` clause.

SQL Server FTS creates an index similar to one you can find at the back of any book. It contains a list of words, with pointers to the tables and rows that contain the words. SQL Server consults this index, called a *full-text index*, when you issue a full-text query; it returns a list of rows that contain the words in your search phrase.

SQL Server FTS ships, by default, in all versions of SQL Server except SQL CE/Mobile and SQL Express. There are several versions of SQL Server Express. If you want a version of SQL Server Express with Full-Text Search, you need to download SQL Server 2008 R2 Express with Advanced Services.

IN THIS CHAPTER

- ▶ Full-Text Search Troubleshooting

What's New in SQL Server 2008 Full-Text Search

Microsoft spent more than five years developing SQL Server 2008 R2. The developers at Microsoft spent that time improving the engine, tools, and performance and making this version more user friendly. SQL Server 2008 introduces the following for Full-Text Search:

- ▶ Full-text catalogs are now stored inside the database. In previous versions, they were stored in the filesystem.
- ▶ SQL Server execution plans are able to make intelligent queries against the full-text catalogs.
- ▶ Stop lists (also known as noise words files) are now stored in the database. You can create any number of stop word lists; each full-text index table or indexed view can have its own specific stop list.
- ▶ You are able to use two DMVs to troubleshoot indexing.
- ▶ More languages are now supported for Full-Text Search. SQL Server 2008 supports 48 languages, up from the 23 supported in SQL Server 2005.
- ▶ Full-text catalogs in log-shipped or mirrored databases do not need to be repopulated when you fail over. In previous versions of SQL Server, if you log shipped or mirrored a database that was full-text indexed, you would have to repopulate the full-text indexes when you failed over to the secondary or mirror. In SQL Server 2008, this step is no longer necessary; on failover, the full-text indexes are immediately accessible and queryable.
- ▶ FTS works with the FILESTREAM property of varbinary(max) columns.
- ▶ A new external engine performs the content extraction and indexing (it is called FDHost also known as Filter Daemon Host).
- ▶ DBCC CHECKDB validates SQL Full-Text structures but does not validate its contents, however.
- ▶ Considerable performance improvements have been made.

These new features are covered throughout this chapter.

Upgrade Options in SQL Server 2008

When you upgrade SQL Server from a previous version to SQL Server 2008, or if you attach or restore a SQL 2005 database to SQL Server 2008, you are prompted to upgrade your full-text catalogs.

There are three options:

- ▶ Import
- ▶ Rebuild
- ▶ Reset

In an import, the full-text catalog is imported from the SQL Server 2005 instance in the case of an upgrade. In the case of a database attach or restore, the SQL 2005 full-text catalogs are stored in the database in a different file group.

An import is faster than a rebuild; however, the import does not use the new word breakers (described later), so for some languages where the word breakers have been improved, you may not get consistent results when compared with catalogs that have been rebuilt. In SQL Server 2008, if your full-text key is not an integer, the full-text engine builds a document map mapping the full-text key with a more efficient integer-based key. If you import your full-text catalog and your full-text key is not an integer key, your full-text queries are not able to take advantage of this efficiency.

A rebuild takes advantage of the new word breakers and other capabilities of SQL Server 2008. However, the rebuild may take longer than an import.

A reset drops the SQL 2005 catalogs but retains the metadata, so your full-text indexes are intact but not populated until you start a population in SQL Server 2008.

A rebuild is the preferred option but results in the full-text catalog being rebuilt; consequently, full-text queries will be out of date until the rebuild is complete.

How SQL Server FTS Works

As mentioned previously, in SQL Server 2008, the catalogs are now stored inside the full-text engine. This redesign has resulted in many architectural changes in SQL Server 2008 Full-Text Search.

The two main components of Full-Text Search are as follows:

- ▶ **Indexing** Extracts the textual content from your data and stores the words or tokens in inverted file indexes
- ▶ **Searching** Queries these inverted file indexes and returns the rows that match the query

Indexing

The indexing engine connects to your database and extracts the content from the tables you are full-text indexing. It then sends this stream to COM components called filters (or *IFilters*). These COM components are run in an out-of-process service called the *FT Daemon Host*. These filters are able to understand the content and can extract text data from them. For example, if you store XML or Word documents in your database, these filters can understand this data or binary data and emit words and/or tokens it finds in there. The filters chosen are the default text ones if you are using char, varchar, or text data types or XML if you are using the xml data type. If you are indexing varbinary documents, the indexing engine reads the document type column and launches the filter corresponding to the value stored in the document type column.

If you are storing Word documents in a varbinary data type column, and in your full-text creating statement you specified a document type column called `DocumentType`, the contents of this column for that row should be `doc`, `.doc`, `docx`, or `.docx`.

You can obtain a list of filters in use by querying as follows:

```
select document_type from sys.fulltext_document_types
```

Each filter understands the file format of the type of document it indexes. For example, the Word filter understands the file formats for Word documents and emits the textual data it finds in the Word documents; the XML filter understands the XML documents and emits the textual data it finds in them.

If you need to index documents for which the file type does not appear in the results of `sys.fulltext_document_types`, you need to install that filter on the server running SQL Server 2008 and then allow SQL Server 2008 to use them.

To allow SQL Server to use these third-party iFilters, you need to issue the following command:

```
sp_FullText_Service 'load_os_resources',1
```

This command loads the filter if it is installed on the OS. In most cases, this is sufficient. In many cases, SQL Server wants to verify the signature/certificate embedded in the COM component/filter. This can cause problems in two ways. First, the filter may not have a certificate, and when SQL Server tries to validate the certificate with the issuing authority, it is unable to do so. Second, the performance impact of having to validate the certificate/signature causes the initial queries to take a long time as the validation process proceeds. For these two reasons, you might want to disable the certificate/signature check by using the following command:

```
sp_FullText_Service 'verify_signature',0
```

Microsoft has published documentation on how to develop your own filters. For more information on how to do this, consult

<http://msdn2.microsoft.com/en-us/library/ms916793.aspx>

The filters then send the stream of textual data emitted by them to another component called *word breakers*. Word breakers respect the language you specified to be used to index your columns' content.

The neutral word breaker basically breaks words at whitespace boundaries and at punctuation (, . ; ' " ! -) and indexes only alphanumeric characters.

The English (U.S) and British (or International English) word breakers index hyphenated words without the hyphens and as their component words, so *data-base* is indexed as *data*, *base*, and *database*. They also index acronyms as single letters and the whole word if they are capitalized. For example, *F.B.I.* is indexed as *f*, *b*, *i*, and *fbi* (words are indexed lowercase).

The English and British English word breakers are nearly identical, with the exception that during the searching process, different stems may be used. In U.S. English speakers may say *oriented*, whereas British English speakers may say *orientated* (in Canada *oriented* is now more common; however in the rest of the English-speaking world—with the exception of the United States—*orientated* is more common).

The German and Dutch word breakers index compound words as the compound and constituent words. For example, the German word *Volkswagen* is indexed as *volks* and *wagen*.

For Far Eastern languages, the word breakers break the sentence at whitespace and then go through the “words” and extract characters. In some Far Eastern languages, characters appear contiguous to each other in blocks that appear to Westerners as words. In fact, each character is a word unto itself, and characters can be combined to form new words. These characters may be indexed singly or in multiple character combinations.

By default, the word breaker used by the indexing process is the language specified in `sp_configure` unless you specify that you want the contents of the columns you are full-text indexing to be indexed in a different language:

```
exec sp_configure 'show advanced options',1
reconfigure with override
exec sp_configure 'default full-text language'
```

Refer to the sections titled “Using the Full-Text Indexing Wizard to Build Full-Text Indexes and Catalogs” and “Using T-SQL Commands to Build Full-Text Indexes and Catalogs.”

Some documents have language-specific tags in them that launch different word breakers than the ones you specify on your server or in your full-text index creation statement. For example, Word and XML documents have language tags embedded in them. If your Word documents are in German, and you specify in your full-text index creation statement to use the French word breakers, your Word document are indexed in German, not French.

When the word breakers have done their work, the stop lists are applied and the stop lists are removed. Then the words are sent to the full-text indexes. The full-text indexes store positional information, so they know where a word occurs in a document. These word positions also reflect stop list words that were removed.

At any one time, there may be multiple temporary memory resident full-text indexes. At certain periods, these temporary full-text indexes are consolidated into a single master full-text index. This process is called a *master merge*. You can force a master merge by reorganizing a catalog (using the T-SQL statement `ALTER FULLTEXT CATALOG MyCatalog REORGANIZE`, where your catalog is name `MyCatalog`) or optimizing (an option available to you in the Catalog Properties dialog).

Searching

Although the indexer launches word breakers and filters as out-of-process SQL Server components, the search process is entirely within the SQL Server engine. To query the full-text indexes, you need to use `CONTAINS` or `FREETEXT` predicates or their rowset analogs (`CONTAINSTABLE`, `FREETEXTTABLE`).

Just as the indexer applies the default server full-text language for indexing, it also applies the default full-text language for searching. Consider a search on the French word *courir* (to run). If you were to search in English on this word, it would search on *courir* and *courirs*. However, on a server with the default full-text language setting for French, your search would be conducted on *couraient*, *courais*, *courait*, *courant*, *coure*, *courent*, *coures*, *courez*, *couriez*, *courions*, *courir*, *courons*, *courra*, *courrai*, *courraient*, *courrais*, *courrait*, *courras*, *courrez*, *courriez*, *courrions*, *courrons*, *courront*, *cours*, *court*, *couru*, *courue*, *courues*, *courumes*, *courumes*, *coururent*, *courus*, *courusse*, *courussent*, *courusses*, *courussiez*, *courussions*, *courut*, *courutes*.

Now that you understand the architecture of Full-Text Search, let's discuss how to create full-text catalogs.

NOTE

The examples in this chapter are based on the SQL Server 2005 version of the AdventureWorks database. The 2005 version of the AdventureWorks database can be installed using the same installer that installs the AdventureWorks2008 or AdventureWorks2008R2 database. If you didn't install AdventureWorks when you installed either of these sample databases, simply relaunch the installer and choose to install the AdventureWorks OLTP database.

For more information on downloading and installing the AdventureWorks sample databases, see the Introduction chapter.

Implementing SQL Server 2008 Full-Text Catalogs

In SQL Server 2005 and previous versions, full-text catalogs were containers for your full-text indexes. In SQL Server 2008, they are really virtual containers on which you can tag various settings and have these settings apply to all indexes placed in that catalog (for example, accent sensitivity) or rebuild all indexes in a catalog at one time.

To create a full-text catalog, you first need to full-text enable your database. To do this, issue the following query in your database:

```
sp_fulltext_database 'enable'
```

You can also right-click on your database, select Properties, and then click on the Files tab. Check Use Full-Text Indexing and then click OK.

After doing this, you can create your catalog. There are two ways to do this: by using the wizard or using T-SQL.

Before you create a full-text index, you must create a full-text catalog. In the wizard, full-text catalog creation can be done alongside full-text index creation, but under the covers, the catalog is always created first.

We first discuss creating the full-text catalog using the wizard and then using the T-SQL commands.

Setting Up a Full-Text Index

There are two ways to create a full-text index:

- ▶ Using T-SQL commands
- ▶ Using the Full-Text Wizard

Using T-SQL Commands to Build Full-Text Indexes and Catalogs

In SQL 2008 full-text catalogs are “virtual.” They are just containers for full-text catalog properties like accent sensitivity or catalog rebuild or population statements. They live inside the database in SQL 2008, unlike SQL 2000 and 2005, where the catalogs and full-text indexes resided in the filesystem.

To build your full-text catalogs and indexes, you need to use the `CREATE FULLTEXT` commands.

NOTE

T-SQL commands are not case sensitive.

There are three commands for full-text index creation and maintenance:

- ▶ `CREATE FULLTEXT CATALOG`
- ▶ `CREATE FULLTEXT INDEX`
- ▶ `ALTER FULLTEXT INDEX`

Let’s look at how they work.

CREATE FULLTEXT CATALOG

To create a full-text catalog in its simplest form, you enter this command:

```
USE AdventureWorks;
Create fulltext catalog MyCatalog
```

In this command, *MyCatalog* is the name of the catalog. The `CREATE FULLTEXT CATALOG` statement has several switches:

- ▶ `ON FILEGROUP`
- ▶ `IN PATH`
- ▶ `WITH ACCENT_SENSITIVITY`
- ▶ `AS DEFAULT`
- ▶ `AUTHORIZATION`

We next cover each of these parameters.

ON FILEGROUP The ON FILEGROUP command is for backward compatibility only.

IN PATH The IN PATH command is for backwards compatibility only.

WITH ACCENT_SENSITIVITY The WITH ACCENT_SENSITIVITY option allows you to create a catalog that is sensitive (Accent_Sensitivity ON) to accents (the default) or insensitive to accents. With Accent_Sensitivity OFF, a search on *café* would match with *café* and *cafe*. Likewise, a search on *cafe* would match with *cafe* and *café*. With Accent_Sensitivity ON, a search on *café* would match only with *café* and not *cafe*. Likewise, a search on *cafe* would match only with *cafe* and not *café*.

The following is the typical syntax for using the option:

```
USE AdventureWorks;
CREATE FULLTEXT CATALOG MyCatalog ON FILEGROUP MyFileGroup
    WITH ACCENT_SENSITIVITY = OFF
```

AS DEFAULT The AS DEFAULT option allows you to create a default full-text catalog for every full-text index in a database. This option is convenient because you don't have to specify the full-text catalog for your full-text indexes. Ideally, each large table will have its own full-text catalog, so although it saves some time typing the commands, this option is not the best one to use all the time. For example, when you create a full-text index, at a minimum, you need to use the following:

```
Use AdventureWorks;
CREATE FULLTEXT INDEX ON person.Contact(Firstname)
    KEY INDEX pk_Contact_ContactID ON MyCatalog
```

With a default catalog for your database, all you have to type is this:

```
Use AdventureWorks;
CREATE FULLTEXT INDEX ON person.Contact(Firstname) KEY INDEX pk_Contact_ContactID
```

If you do not have a default catalog, you get the following error message:

```
Msg 9967, Level 16, State 1, Line 2
A default full-text catalog does not exist in database 'AdventureWorks'
or user does not have permission to perform this action.
```

Here is the syntax to create a default catalog: Create FullText Catalog AdventureWorksFT as Default

NOTE

You can have only one default catalog per database.

AUTHORIZATION The `AUTHORIZATION` option allows a user or a role to own and consequently manage a full-text catalog. The following is the typical syntax for using this option:

```
Use AdventureWorks;
CREATE FULLTEXT CATALOG MyCatalog WITH ACCENT_SENSITIVITY =OFF Authorization [dbo]
```

Now that you know how to create a catalog, let's create full-text indexes on the tables that will be stored in these catalogs.

CREATE FULLTEXT INDEX

You use the `CREATE FULLTEXT INDEX` command to create full-text indexes. Your searches query full-text indexes to return results.

The `CREATE FULLTEXT INDEX` command has several parameters:

- ▶ COLUMN NAME
- ▶ TYPE COLUMN
- ▶ LANGUAGE
- ▶ ON FULL-TEXT CATALOG
- ▶ KEY INDEX
- ▶ POPULATION TYPE

We next cover each of these parameters.

COLUMN NAME The `COLUMN NAME` parameter is the `char`, `varchar`, `nchar`, `nvarchar`, `text`, or `xml` column that you are full-text indexing. A minimal `CREATE FULLTEXT INDEX` statement would look like this:

```
Use AdventureWorks;
CREATE FULLTEXT INDEX ON Person.Contact(Firstname) KEY INDEX pk_Contact_ContactID
```

In this example, `Person.Contact` is the name of the table you are full-text indexing, and `pk_Contact_ContactID` is the Full-Text Search key. A Full-Text Search key must be a unique, non-nullable, single-column index that is not offline and has a maximum size of 900 bytes. Note that this full-text index is created on the default full-text catalog. Once again, if you do not have a default full-text catalog, you get the following message:

```
A default full-text catalog does not exist in database 'AdventureWorks'
or user does not have permission to perform this action.
```

You specify a full-text catalog by using the following command:

```
Use AdventureWorks;
CREATE FULLTEXT INDEX ON Person.Contact(Firstname, Lastname)
KEY INDEX pk_Contact_ContactID ON MyCatalog
```

In this command, *MyCatalog* is the name of the full-text catalog. Note that the second example creates a full-text index on two columns.

TYPE COLUMN You can index columns of the `char`, `varchar`, `nchar`, `nvarchar`, `text`, `ntext`, and `xml` data types. You can also index columns of the `image` and `varbinary(max)` data types if you have an ancillary column, which tells what the content is in that column. The reason for this is the Indexer needs to interpret the binary data in the `image` and `varbinary(max)` columns and will need to load an IFilter, which corresponds to the binary data stored in these columns. The Indexer will load the IFilter, which corresponds to the extension stored in this ancillary column. For example, if you store a PDF in the `image` or `varbinary(max)` column, the ancillary column would have to have the value `PDF` or `.PDF` (not case sensitive) so the PDF IFilter would be launched.

There is a relevant example in the AdventureWorks database. Consider the `Production.Document` table. If you want to search Word documents stored in this table, a `LIKE` clause search would not work because the Word documents are in binary format. Full-text indexing on the `Document` column similarly wouldn't work because the IFilter would not be able to interpret the binary stream. So you need to add a column that contains the extension the document in this row would have if it were stored in the filesystem; in this case, it's a Word document, so the extension would be `.doc`. This column is called a *document type column*. In the `Production.Document` table, this column is the `FileExtension` column. When you index binary large objects (BLOBs), there are special considerations, as discussed in the next section.

Full-Text Indexing of BLOBs and XML SQL Server 2008 can natively index content columns of the `char`, `nchar`, `varchar`, `nvarchar`, `text`, and `xml` data types. If you want to index binary large objects, you need to store them in the `image` or `varbinary(max)` column and associate with the `image` column a column that will contain the extension the document would have if it were stored in the filesystem. For example, if you were storing a Word document in the `image` or `varbinary(max)` column, the document type column would have the value `doc`. While indexing the contents of the `image` or `varbinary(max)` column, the Indexer reads the value of the document type column for that row and launches the IFilter that corresponds to that value. SQL Server 2008 ships with many IFilters. You can tell which document extensions have IFilters by querying `sys.fulltext_document_types`:

```
SELECT * FROM sys.fulltext_document_types
```

If you are indexing a document stored in the `image` or `varbinary(max)` data type for which the extension is not listed in `sys.fulltext_document_types`, the indexer is unable to index the document. To enable indexing for unsupported document types, you must do the following:

1. Download the IFilter for that document type and install it on the server running SQL Server.
2. Enable the third-party IFilters to be used in SQL Server FTS. You do this by issuing the following commands:

```
Exec Sp_fulltext_service 'load_os_resources', 1
GO
Exec Sp_fulltext_service 'verify_signature', 0
GO
```

LANGUAGE By default, the content in the columns you are full-text indexing is broken by the word breakers according to the language rules for the default full-text index language setting for your instance of SQL Server. You establish this setting by issuing the following command:

```
sp_configure 'default full-text language'
go
```

name	minimum	maximum	config_value	run_value
default full-text language	0	2147483647	1033	1033

Note the value for `run_value`. This is the locale identifier (LCID). To determine which language the LCID corresponds to, you issue the following:

```
SELECT name FROM sys.fulltext_languages WHERE lcid=1033
go
```

```
name
```

```
-----
English
```

In this example, 1033 is the value returned for `run_value` in the `sp_configure` query. Note that this returns a list of the language word breakers that ship by default with SQL Server 2008.

The preceding execution of `sp_configure` returned the default full-text value of 1033, which corresponds to English. Microsoft recognizes two types of English in all Microsoft search products: English (U.S. English) and British English (International English). There are very slight differences between the two word breakers, mainly due to differing suffixes and spellings (for example, British English recognizes *connexion* and *colour* as legitimate spellings).

By default, all columns are full-text indexed by the word breaker that corresponds to your default full-text language settings for your instance of SQL Server.

SQL Server FTS allows you to use the language tag to specify word breakers for different languages to be used to full-text index columns. For example, if you are storing Traditional Chinese content in a column you want to index, and you want it to be indexed using Traditional Chinese, you could issue the following statement to create a full-text index:

```
CREATE FULLTEXT INDEX ON Person.Contact(FirstName,
                                         LastName LANGUAGE 1028)
```

```
KEY INDEX PK_Contact_ContactID ON MyCatalog
```

This example full-text indexes two columns; one called `FirstName` is indexed using the server default full-text language, and the other, called `LastName`, is indexed using the Traditional Chinese language word breaker. This means that what ends up stored in the full-text indexes is broken according to the language rules of the word breaker. For U.S. and International English, the words are primarily broken at whitespace or word boundaries (that is, punctuation marks). For other languages, the word may be broken into constituent words or alternate words. For example, if you use the German word breaker, *wanderlust* is broken as *wanderlust*, *wandern*, and *lust*, and all three words are stored in the index; searches on *wanderlust*, *wandern*, and *lust* all return hits to rows containing *wanderlust*.

You can specify different language settings for each column you are full-text indexing, but you can assign only one language setting for each column.

If you are storing BLOBs in the columns of the `image` or `varbinary` data type and have a document-type column assigned to these columns, depending on your content, the language settings within the content themselves may override the language setting you specified to be used for your full-text index or your SQL Server default full-text language settings. For example, if you are indexing HTML or Word documents, have marked these documents as Chinese, and have specified that the documents be indexed in German, if your SQL Server default full-text language setting is French, the content is indexed as Chinese. The same holds true for XML documents stored in columns of the `xml` data type: the `xml:lang` setting determines the language in which these documents are indexed.

ON FULLTEXT CATALOG The `ON FULLTEXT CATALOG` parameter allows you to place your full-text index in a specific catalog. If you have a default full-text catalog for the database, you do not need to specify a catalog. You get better indexing and querying performance if you place larger tables in their own full-text catalogs.

KEY INDEX SQL Server FTS must be able to identify the row that it is indexing or that is returned in the query results. You specify which column is to be used as the key by using the `KEY INDEX` parameter in your full-text index creation statement. As mentioned previously, this column must be unique and non-nullable, and it must have a single-column index that is not offline and have a maximum size of 900 bytes. It can be a unique index or your primary key.

POPULATION TYPE The process in which the indexer extracts your table content and builds a full-text index is called *population*. There are three types of populations:

- ▶ Full
- ▶ Incremental
- ▶ Change tracking

No matter what population type you choose, a full population is initially done first. The full population extracts rows in batches and indexes them. It does not do any change tracking, so your catalog starts to become out-of-date as soon as the population completes.

An incremental population occurs if there is a time stamp column on the table you are full-text indexing. The incremental population extracts each row to determine which rows have been updated and re-indexes only the changed rows. It also determines which rows have been removed from the table you are full-text indexing. A row is flagged to be re-indexed if any of the columns are updated, so if you update one of the columns that is not being full-text indexed, this row is indexed again.

You should use incremental populations rather than full populations when a significant amount of your table's contents changes at any one time. If the bulk of your table changes—around 90%—a full population is faster than an incremental population.

You use the following commands to do a full population and an incremental population:

```
Use AdventureWorks;CREATE FULLTEXT INDEX ON Person.Contact(Firstname)
    KEY INDEX pk_Contact_ContactID WITH CHANGE_TRACKING OFF, NO POPULATION
```

To then start a full or incremental population, you issue the following for full and incremental populations, respectively:

```
Use AdventureWorks;
ALTER FULLTEXT INDEX ON Person.Contact START FULL POPULATION — FULL POPULATION
```

```
Use AdventureWorks;
ALTER FULLTEXT INDEX ON Person.Contact START FULL INCREMENTAL — INCREMENTAL POP
```

At all other times, you should use change tracking because it is much more efficient and offers near-real-time indexing. Change tracking indexes rows that have had the columns you are full-text indexing modified in near-real-time. Change tracking starts by doing a full population but does an incremental population if a timestamp column exists on the table. Change tracking (like other population types) causes some locking on the tables you are full-text indexing, so you have an option to schedule when the indexing of the modified rows is done.

By default, when you create a new full-text index, change tracking is enabled. In other words, a full population is done and when it completes, all rows modified during the full population and after it completes are indexed. So the following statements are equivalent:

```
Use AdventureWorks;CREATE FULLTEXT INDEX ON Person.Contact(Firstname)
    KEY INDEX pk_Contact_ContactID WITH CHANGE_TRACKING AUTO
```

```
Use AdventureWorks;CREATE FULLTEXT INDEX ON Person.Contact(Firstname)
    KEY INDEX pk_Contact_ContactID
```

Because change tracking causes some locking, you can schedule rows to be tracked in real-time but indexed only at scheduled intervals by using the following statement:

```
Use AdventureWorks;
CREATE FULLTEXT INDEX ON Person.Contact(Firstname)
    KEY INDEX pk_Contact_ContactID WITH CHANGE_TRACKING MANUAL
```

The preceding command assumes a default index. If you do not have a default catalog, you would have to specify a named one like this:

```
Use AdventureWorks;
CREATE FULLTEXT INDEX ON Person.Contact(Firstname)
    KEY INDEX pk_Contact_ContactID ON DEFAULT_FULLTEXT_CATALOG WITH
CHANGE_TRACKING MANUAL
```

To update your index, you issue the following

```
Use AdventureWorks;
ALTER FULLTEXT INDEX ON Person.Contact START UPDATE
```

ALTER FULLTEXT INDEX

As you have seen in this chapter, you can use the `ALTER FULLTEXT INDEX` command to manage populations. You can also use it for a wide variety of index maintenance tasks. Here are its parameters, which are discussed in the following sections:

- ▶ `ENABLE`
- ▶ `DISABLE`
- ▶ `SET CHANGE_TRACKING { MANUAL | AUTO | OFF }`
- ▶ `ADD`
- ▶ `DROP`
- ▶ `START`
- ▶ `STOP`

ENABLE and **DISABLE** The `ENABLE` and `DISABLE` parameters enable and disable full-text indexing on a table. When you use them, you can still conduct full-text searches on your full-text indexed tables, but the catalogs are no longer kept up-to-date.

For example, you could disable indexing with the following command:

```
Use AdventureWorks;
ALTER FULLTEXT INDEX ON Person.Contact DISABLE
```

And then you could re-enable indexing with the following:

```
Use AdventureWorks;
ALTER FULLTEXT INDEX ON Person.Contact ENABLE
```

When you re-enable a full-text index, change tracking commences to update changes that occurred while full-text indexing was disabled. If you disabled change tracking prior to disabling the full-text index, you have to run a full or incremental population to get your catalog up-to-date.

SET CHANGE_TRACKING The `SET CHANGE_TRACKING` option allows you to control change tracking. For example, you can turn it off, turn it on, or schedule it. Because change tracking does cause some locking, you might want to schedule it during a quiet time when the database is not under load to minimize the impact of the locking.

Here is an example of the use of `SET CHANGE_TRACKING`:

```
Use AdventureWorks;
ALTER FULLTEXT INDEX ON Person.Contact SET CHANGE_TRACKING AUTO
```

The options for setting change tracking are as follows:

- ▶ **AUTO**—Enables continuous real-time indexing.
- ▶ **OFF**—Disables change tracking.
- ▶ **MANUAL**—Provides continuous change tracking, but rows are indexed only when you issue the following command:

```
Use AdventureWorks;
ALTER FULLTEXT INDEX ON Person.Contact Start Update Population
```

ADD You use the `ADD` parameter to add a new column to a full-text index. For example, consider `Person.Contact`, a table in the AdventureWorks database, with three char columns on it: `Firstname`, `Lastname`, and `EmailAddress`. You have already created a full-text index on `Firstname` and `Lastname`. You could add full-text indexing to `EmailAddress` by issuing the following command:

```
Use AdventureWorks;
ALTER FULLTEXT INDEX ON Person.Contact ADD(EmailAddress)
```

As soon as you add the new column, a full population is done to index the contents of the newly added column. You can disable it with the `WITH NO POPULATION` clause, as in this example:

```
Use AdventureWorks;
ALTER FULLTEXT INDEX ON Person.Contact ADD(EmailAddress) WITH NO POPULATION
```

You may get the following message:

```
Msg 7663, Level 16, State 2, Line 2
Option 'WITH NO POPULATION' should not be used when change tracking is enabled.
```

This message indicates the change tracking is on. To prevent a population starting immediately after adding the column, you would first have to disable change tracking and then make your change as illustrated in the following example:

```
ALTER FULLTEXT INDEX ON Person.Contact
SET CHANGE_TRACKING OFF
ALTER FULLTEXT INDEX ON Person.Contact ADD(EmailAddress)
WITH NO POPULATION
```

You also have the option to specify a specific word breaker to be used or a document type column to reference whether the column you add is an `image` or `varbinary(max)` column.

DROP Like the `ADD` parameter, the `DROP` parameter allows you to drop a full-text column you are indexing. This parameter also supports the `WITH NO POPULATION` clause, which disables automatic re-indexing after you drop the full-text column. Here is an example of its use:

```
Use AdventureWorks;
ALTER FULLTEXT INDEX ON Person.Contact DROP (Firstname) WITH NO POPULATION
```

Again, you may get the following message:

```
Msg 7663, Level 16, State 2, Line 2
Option 'WITH NO POPULATION' should not be used when change tracking is enabled.
```

This message indicates the change tracking is on. To prevent a population starting immediately after adding the column, you would first have to disable change tracking and then make your change as illustrated in the following example:

```
ALTER FULLTEXT INDEX ON Person.Contact
SET CHANGE_TRACKING OFF
ALTER FULLTEXT INDEX ON Person.Contact DROP(EmailAddress)
WITH NO POPULATION
```

The `DROP` command can be used to drop all the full-text columns on a table.

START and **STOP** The `START` and `STOP` parameters can be used to start and stop full, incremental, or update populations. Following is the typical syntax:

```
Use AdventureWorks;
```

```
ALTER FULLTEXT INDEX ON Person.Contact Stop Population
```

```
Use AdventureWorks;
```

```
ALTER FULLTEXT INDEX ON Person.Contact Start Full Population
```

The update population is used in conjunction with change tracking, for example, if you set up change tracking in manual mode like this:

```
Use AdventureWorks;
```

```
ALTER FULLTEXT INDEX ON Person.Contact SET CHANGE_TRACKING Manual
```

```
Use AdventureWorks;
```

```
ALTER FULLTEXT INDEX ON Person.Contact START Update Population
```

We've completed our look at the catalog and index creation statements. Next, we look at how to manage full-text catalogs and indexes.

Managing MSFTESQL

After you create full-text catalogs and indexes, you might need to manage the full-text engine. The command used to do this is `sp_fulltext_service`, which accepts the following parameters:

- ▶ @action
- ▶ @value

Following are the acceptable values for the @action parameter:

- ▶ **load_os_resources**—Controls whether the full-text engine loads word breakers and IFilters that are not part of SQL Server but are installed in the OS. A value of 1 loads the OS word breakers and IFilters.
- ▶ **pause_indexing**—Pauses the indexing process. During this pause, you can still query the full-text catalogs.
- ▶ **resource_usage**—Is used for backward compatibility.
- ▶ **update_languages**—Updates the language cache with recently installed word breakers.
- ▶ **verify_signature**—Disables the checking of signatures for word breakers and IFilters when set to 0. When set to the default, 1, signatures are checked.
- ▶ **upgrade_option**—Controls how SQL Server processes catalogs in a database that are restored or attached to SQL Server 2008. It accepts three values: 0, which forces attached or restored databases with full-text catalogs to be rebuilt; 1, which means the full-text catalogs' metadata remains, but the catalog contents are deleted (these

catalogs are queryable, but no results are returned until you rebuild them); 2, which means the full-text indexes are imported into the database (however, the results may be inconsistent because some of the full-text indexes are generated by the SQL 2005 full-text word breakers and not the SQL Server 2008 word breakers).

Now you know how to build full-text catalogs and indexes and modify them. The next section describes how to get information on the catalogs and indexes you build.

Diagnostics

After you create catalogs and indexes, you occasionally need to get information about your catalogs, tables, and indexes. So that you can do this, Microsoft has supplied the `sp_help_fulltext_tables` and `sp_help_fulltext_columns` stored procedures and the system view `sys.fulltext_catalogs`.

These stored procedures and view allow you to examine the state of your full-text tables, columns, and catalogs. Microsoft recommends that rather than using these objects, you use the `OBJECTPROPERTY`, `COLUMNPROPERTY`, and `FULLTEXTCATALOGPROPERTY` metadata functions. Table 50.1 lists the full-text index properties for the `OBJECTPROPERTY` function.

TABLE 50.1 Full-Text Index Properties for the **OBJECTPROPERTY**

Property	Description	Values
<code>TableFullTextBackgroundUpdateIndexOn</code>	Indicates whether change	1 = true and 0 = false tracking is enabled.
<code>TableFulltextCatalogId</code>	Returns the catalog ID of the catalog the full-text index is placed on.	CatalogID or 0 (table not indexed)
<code>TableFulltextChangeTrackingOn</code>	Enables change tracking.	1 = true and 0 = false
<code>TableFulltextDocsProcessed</code>	Returns the number of rows processed since indexing started.	
<code>TableFulltextFailCount</code>	Returns the number of rows that failed to index.	
<code>TableFulltextItemCount</code>	Returns the number of rows successfully indexed.	
<code>TableFulltextKeyColumn</code>	Returns the ID of the key index used by SQL Server FTS (normally the primary key).	

TABLE 50.1 Full-Text Index Properties for the **OBJECTPROPERTY**

Property	Description	Values
TableFulltext PendingChanges	Returns the number of rows outstanding to be indexed.	
TableFulltext PopulateStatus	Returns a number indicating the state of the population.	1 = full population is in progress; 2 = incremental population is in progress; 3 = propagation of tracked changes is in progress; 4 = background update index is in progress, such as autochange tracking; and 5 = full-text indexing is throttled or paused
TableHasActive FulltextIndex	Indicates whether a table has an active full-text index on it.	1 = true and 0 = false

Table 50.2 lists the full-text index properties for the **COLUMNPROPERTY** function.

TABLE 50.2 Full-Text Index Properties for the **COLUMNPROPERTY** Function

Property	Description	Values
IsFulltextIndexed	Indicates whether a column is full-text indexed.	1 = true and 0 = false
FullTextTypeColumn	Returns the ID of the document type column.	

Table 50.3 lists the properties for the **FULLTEXTCATALOGPROPERTY** function.

TABLE 50.3 Properties for the **FULLTEXTCATALOGPROPERTY**

Property	Description	Values
AccentSensitivity	Indicates whether the catalog is accent sensitive.	1 = true and 0 = false
IndexSize	Returns the size of the full-text catalog.	
ItemCount	Returns the number of items (rows) indexed in the catalog.	

TABLE 50.3 Properties for the **FULLTEXTCATALOGPROPERTY**

Property	Description	Values
MergeStatus	Indicates whether a master merge is in progress.	1 = true and 0 = false
PopulateCompletion Age	Specifies how long ago the last population completed.	
PopulateStatus	Returns the status of the population.	0 = idle, 1 = full population in progress, 2 = paused, 3 = throttled, 4 = recovering, 5 = shut down, 6 = incremental population in progress, 7 = building index, 8 = disk is full, paused, and 9 = change tracking
UniqueKeyCount	Returns the number of unique words indexed.	
ResourceUsage	Returns a number indicating how aggressively SQL Server FTS is consolidating the catalog.	Ranges from 1 to 5 (the most aggressive); 3 is the default.
IsFulltextInstalled	Indicates whether SQL Server FTS is installed.	1 = true and 0 = false
LoadOSResources	Indicates whether third-party word breakers are loaded.	1 = true and 0 = false
VerifySignature	Determines whether signatures of word breakers and language resources are checked.	1 = true and 0 = false

The following examples show how to query metadata functions using the full-text index properties:

```
SELECT OBJECTPROPERTY(object_id('Person.Contact'),
    'TableFullTextBackgroundUpdateIndexOn')
select objectproperty(object_id('Person.Contact'),'TableFulltextChangeTrackingOn')
SELECT OBJECTPROPERTY(object_id('Person.Contact'),'TableFulltextKeyColumn')
SELECT OBJECTPROPERTY(object_id('Person.Contact'),'TableFulltextPendingChanges')
SELECT OBJECTPROPERTY(object_id('Person.Contact'),'TableFulltextPopulateStatus')
SELECT OBJECTPROPERTY(object_id('Person.Contact'),'TableHasActiveFulltextIndex')
```

```

SELECT COLUMNPROPERTY ( object_id('Person.Contact'),
                        'charcol' , 'IsFulltextIndexed' )
SELECT COLUMNPROPERTY ( object_id('Person.Contact'),
                        'VarbinaryColumn','FullTextTypeColumn' )

SELECT FULLTEXTCATALOGPROPERTY('MyCatalog','indexsize')
SELECT FULLTEXTCATALOGPROPERTY('MyCatalog','itemcount')
SELECT FULLTEXTCATALOGPROPERTY('MyCatalog','mergestatus')
SELECT FULLTEXTCATALOGPROPERTY('MyCatalog','populatecompletionage')
SELECT FULLTEXTCATALOGPROPERTY('MyCatalog','populatestatus')
SELECT FULLTEXTSERVICEPROPERTY('loadosresources')

```

Using the Full-Text Indexing Wizard to Build Full-Text Indexes and Catalogs

Although the T-SQL full-text commands provide a scriptable interface for creating full-text catalogs and indexes, sometimes it is easier to use the Full-Text Indexing Wizard to create them. To create a full-text index, follow these steps:

1. Connect to SQL Server in SQL Server Management Studio.
2. Expand the databases folder.
3. Expand the database that contains the tables you want to full-text index.
4. Expand the tables folder.
5. Right-click the table you want to full-text index (in this example, the `Production.Document` table).
6. Select Full-Text Index, as shown in Figure 50.1.

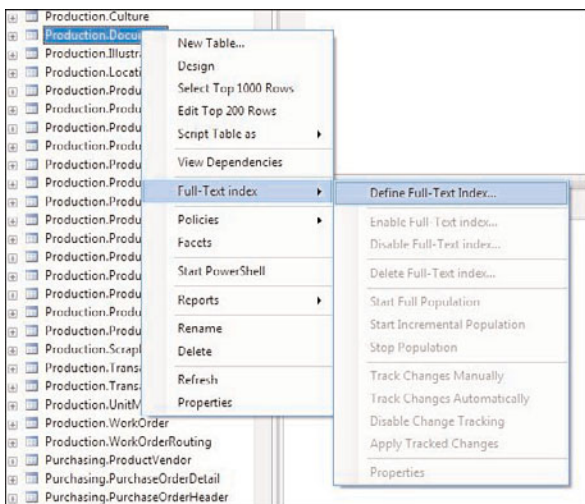

FIGURE 50.1 Selecting the Full-Text Index menu in SSMS.

You then click Define Full-Text Index to launch the Full-Text Indexing Wizard. On the Welcome to the SQL Server Full-Text Indexing Wizard splash screen, you click Next to bring up the Select an Index dialog, as shown in Figure 50.2. In the Unique Index drop-down box, you select the unique index you want to use for the full-text index. In this example, the only option is the primary key, PK_Document_DocumentID.

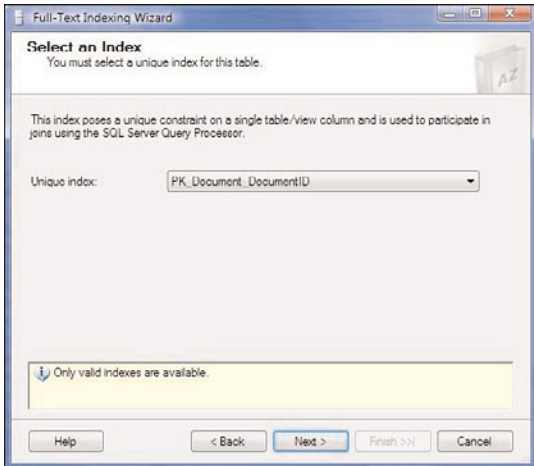

FIGURE 50.2 The Full-Text Indexing Wizard Select an Index dialog.

TIP

If there are multiple unique keys to choose from, it is recommended that you choose the smallest of the unique keys. It is also a good idea to choose a unique key; this is a static column that is unlikely to be modified.

You may get the message “A unique column must be defined on this table/view.” In this case, you have to create a unique index or primary key on the table before you can proceed. If a unique index or primary key exists, the Next button is enabled. When you click the Next button, the next dialog you see is the Select Table Columns dialog (see Figure 50.3). In this dialog, you select the columns you want to index and the word breaker you want to use to index the contents of this column.

Notice that the Select Table Columns dialog displays only the columns that can be full-text indexed. In this example, the FileName and DocumentSummary columns will be indexed by the server default full-text language. For the Document column, you select the language (English) by clicking the drop-down box that displays the available languages. The document type (in this case FileExtension) also needs to be selected. You then click Next and proceed to choose the population type from the Select Change Tracking dialog (see Figure 50.4).

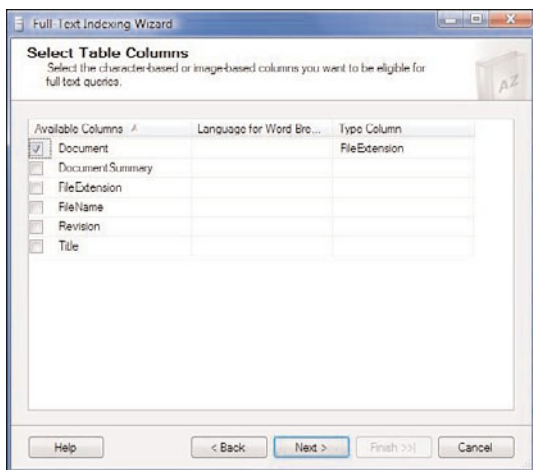

FIGURE 50.3 The Full-Text Index Wizard Select Table Columns dialog.

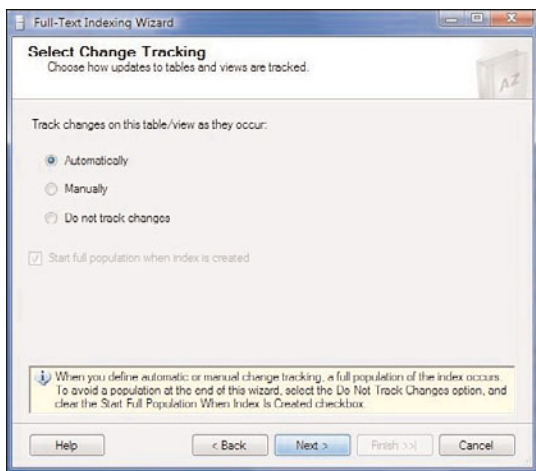

FIGURE 50.4 The Full-Text Index Wizard Select Change Tracking dialog.

There are three options in the Select Change Tracking dialog: Automatically (continuous change tracking), Manually (change tracking with scheduled or manual updates), and Do Not Track Changes. If you specify Do Not Track Changes, the Start Full Population When Index Is Created check box is enabled. You click Next to advance to the Select a Catalog dialog. This dialog allows you to select an existing catalog or create a new catalog with options to set the catalog accent sensitivity and to make it the default catalog. You click Next to set incremental table and catalog populations. You click Next to view the summary page and finish creating your full-text indexes and catalogs. You click Close to complete

the wizard. If you are running Service Pack 1, you need to right-click your table one more time, select Full-Text Index, and select Enable Full-Text Index to start change tracking.

You are now ready to start querying your full-text indexes.

Full-Text Searches

Four SQL clauses allow you to conduct full-text searches on your full-text index tables:

- ▶ **CONTAINS**—Specifies a strict exact match, with options to make the search flexible.
- ▶ **CONTAINSTABLE**—Returns a ranked rowset from SQL Server FTS implementing the Contains algorithm, which must be joined against the base table.
- ▶ **FREETEXT**—Specifies a stemmed search that returns results to all generations of the search phrase.
- ▶ **FREETEXTTABLE**—Returns a ranked rowset from SQL Server FTS implementing the FreeText algorithm, which must be joined against the base table.

CONTAINS and CONTAINSTABLE

The CONTAINS and CONTAINSTABLE predicates have the following parameters:

- ▶ Search phrase
- ▶ Generation
- ▶ Proximity
- ▶ Weighted

Search Phrase

The search phrase is the phrase or word that you are looking for in a full-text indexed table. If you are searching for more than one word, you have to wrap your search phrase in double quotation marks, as in this example:

```
SELECT * FROM Person.Contact
    WHERE CONTAINS(*, 'search phrase') — search all columns
```

In this query, you are searching all full-text indexed columns. However, you can search a single column, a list of columns, or all columns. The following example shows how:

```
SELECT * FROM Person.Contact
    WHERE CONTAINS(FirstName, 'search phrase') — searching 1 column
```

```
SELECT * FROM Person.Contact
    WHERE CONTAINS((FirstName, Lastname), 'search phrase') — searching 2 columns
```

You can also use Boolean operators in your search phrase, as in this example:

```
SELECT * FROM Person.Contact WHERE CONTAINS(*, 'Ford'
    AND NOT ('Harrison' OR 'Betty'))
```

This example searches on Ford cars, where you don't want hits to rows that contain references to *Harrison* and *Ford* or *Betty* and *Ford*.

CONTAINS supports Boolean AND, OR, and AND NOT but not OR NOT.

You can also use wildcards in your searches by adding the * to the end of a word in your search phrase. A wildcard added to one word acts as wildcard on all words in the search phrase, so a search on *Al Anon** matches with *Alcoholics Anonymous*, *Al Anon*, and *Alexander Anonuevo*.

Generation

The term *generation* refers to all forms of a word, which could be the word itself, all declensions (that is, singular or plural forms, such as *book* and *books*), conjugations of a word (such as *book*, *booked*, *booking*, and *books*), and thesaurus replacements and substitutions of a word. To search on all generations of a word, you use a FREETEXT search on the formsOf predicate. The following example shows how to use the formsOf predicate to search on declensions and conjugations of a word:

```
SELECT * FROM Person.Contact WHERE CONTAINS(*, 'formsOf(inflectional,book)')
```

Generations of a word also include its thesaurus expansions and replacements. An *expansion* is the word and other synonyms of the word (for example, *book* and *volume* or *car* and *automobile*). An expansion can also include alternate spellings, abbreviations, and nicknames. A *replacement* is a word that you want replaced in a search. For example, if you have users searching on the word *sex*, and you want *sex* interpreted as gender, you can replace the search on the term *sex* with a search on the word *gender*. To get the thesaurus option to work, you need to edit the thesaurus file for your language. By default, the thesaurus files are in C:\Program Files\Microsoft SQL Server\MSSQL.X\MSSQL\FTData, where X is the instance number. There is a thesaurus file for each full-text supported language; it is named TSXXX.XML, where XXX is a three-letter identifier for the language. There also is another thesaurus file called TSG1oba1.XML. Changes made to the TSG1oba1 thesaurus file are effective in all languages but are overridden by the language-specific thesaurus files. To make the thesaurus file effective, you have to remove the comment marks and then restart MSFTESQL (the Microsoft SQL Server Full-Text Search service). Notice that the thesaurus files have an XML element called <diacritics = true/>. Setting this element to false makes the thesaurus not sensitive to accents; otherwise, the thesaurus file is accent sensitive.

As mentioned previously, the thesaurus file has two sections: an expansion section and a replacement section. The expansion section looks like this:

```
<expansion>
<sub>Internet Explorer</sub>
<sub>IE</sub>
<sub>IE5</sub>
<sub>IE6</sub>
</expansion>.
```

The sub nodes refer to substitutes, so a search on *Internet Explorer* is substituted to additional searchers on *Internet Explorer*, *IE*, *IE5*, and *IE6*.

The replacement section looks like this:

```
<replacement>
<pat>NT5</pat>
<pat>W2K</pat><sub>Windows 2000</sub>
</replacement>
```

Here, searches on the patterns *NT5* or *W2K* are replaced by a search on *Windows 2000*, so your search will never find rows containing only the words *NT5* or *W2K*.

To use the thesaurus option, you need to use the `formsOf` predicate. Here is an example of a `formsOf` query:

```
SELECT * FROM Person.Contact WHERE CONTAINS(*, 'formsOf(thesaurus,ie)')
```

Proximity

SQL Server 2008 FTS supports the proximity predicate, which allows you to search on tokens that are close, or near, to each other. *Near* is defined as within 50 words. Words separated by more than 50 words do not show up in a `CONTAINS` or `CONTAINSTABLE` search. With a `FREETEXT` or `FREETEXT` table search, the separation distance can be up to 1,326 words. Here is an example of a proximity-based search:

```
SELECT * FROM Person.Contact WHERE CONTAINS(*, '"peanut butter" NEAR "jam"')
```

Weighted

A weighted search allows you to assign different weights to search tokens; you use the `ISABOUT` predicate to do a weighted search. If you want to search on *Gulf of Mexico* and *Oil*, and you want to place more emphasis on *Gulf of Mexico* than on *Oil*, you could query like this:

```
SELECT * FROM Person.Contact
WHERE CONTAINS(*, 'isabout("Gulf of Mexico" weight(0.7), Oil weight(0.1))')
```

You can use multiple weighted search items in a search, but doing so decreases the search speed.

LANGUAGE

Sometimes you might want to conduct a search in a different language than the default full-text language for your server. For example, say you want to conduct a German-language search on the contents of a column. To do this, you would use the language predicate like this:

```
SELECT * FROM Person.Contact WHERE CONTAINS(*, 'volkswagen', LANGUAGE 1031)
```

In this search, German language rules are applied when searching the index. In this case, the search on *Volkswagen* is expanded to a search on *Volkswagen*, *wagen*, and *volk*. If you are storing multilingual content in a single column, you should have a column that indicates the language of the content stored in the column. Otherwise, your searches might return unwanted results from content in different languages.

CONTAINSTABLE

CONTAINSTABLE supports all the predicates of the CONTAINS operator but returns a result set containing only the key and rank. The CONTAINSTABLE clause also supports all predicates of CONTAINS, but it allows you to use the TOP_*n*_BY_RANK parameter to return only the first *n* results. Because the CONTAINSTABLE predicate returns only the key value and rank, you have to join it against the base table (or another related table) to get meaningful results. Here are some examples:

```
SELECT * FROM Person.Contact JOIN
(SELECT [key], rank FROM CONTAINSTABLE(Person.Contact, *, 'test')) AS k
ON k.[key]= Person.Contact.ContactID
```

In the following example, Person.Contact is a child table of the Sales.Individual table. Sales.Individual has a foreign key relationship to the Person.Contact table's primary key, ContactID. This query illustrates how you could join the CONTAINSTABLE result set from the Person.Contact table against the Sales.Individual table (this example also illustrates the TOP_*n*_BY_RANK option):

```
SELECT * FROM Sales.Individual as s
JOIN (SELECT [key], rank FROM CONTAINSTABLE(Person.Contact, *, 'jon',100)) AS k
ON k.[key]=s.Contactid order by rank desc
```

In this query, you limit the results to the top 100 rows. The second query returns, at most, 100 rows with the highest-rank values.

Keep in mind that CONTAINS is faster than FREETEXT, but it is a strict character-by-character match, unless you use some of the word-generation searches.

FREETEXT and FREETEXTTABLE

FREETEXT and FREETEXTTABLE incorporate what Microsoft considers to be the natural way to search. For example, if you were searching on *book*, you would expect to get hits to rows containing the word *books* (the plural). If you were searching on the word *swimming*, you would expect results containing the words *swimming*, *swim*, *swims*, *swum*, and so on. The FreeText and FREETEXTTABLE queries implicitly search on all generations of a word and include a proximity-based search. However, if you wrap your search in double quotation marks, the FREETEXT and FREETEXTTABLE predicates do not do any stemming. FREETEXT and FREETEXTTABLE also include the TOP_*n*_BY_RANK parameter.

Here are some examples using FREETEXT and FREETEXTTABLE:

```
Use AdventureWorks;SELECT * from Person.Contact where Freetext(*,'Barack Obama')
Corrected! HPC
```

```
Use AdventureWorks;
```

```
SELECT * FROM Sales.Individual as s
JOIN (SELECT [key], rank FROM FREETEXTTABLE(Person.Contact, *, 'jon',100)) AS k
ON k.[key]=s.Contactid order by rank desc
```

Notice that the FREETEXTTABLE example does the functional equivalent of a CONTAINSTABLE query because the search is wrapped in double quotation marks.

Stop Lists

Stop lists are used when you want to hide words in searches or to prevent from being indexed those words that would otherwise bloat your full-text index and might cause performance problems. Stop lists (also known as noise word lists or stop word lists) are a legacy component from decades ago when disk prices were very expensive. Back then, using stop lists could save considerable disk space. However, with disk prices being relatively cheap, the use of stop lists is no longer as critical as it once was. You can create your own stop word list by expanding your database in SSMS and then right-clicking on the Full-Text Stoplists node and selecting New Full-Text Stoplist. You have an option of creating your own stop list, basing it on a system stop list, creating an empty one, or creating one based on another stop list in a different database. Each catalog can have its own stop list, which is a frequently demanded feature because some search consumers want to be able to prevent some words from being indexed in one table but want those words indexed in a different table. After you create a stop word list, you can maintain it by right-clicking on it in the Full-Text Stoplists node and selecting Properties. Figure 50.5 illustrates this option.

The options are to add a stop word, delete a stop word, delete all stop words, and clear the stop list. After selecting the option you want, you can enter a stop word and the language in which you want that stop word to be applied.

Keep in mind that the stop lists are applied at query time (while searching) and index time (while indexing). Changes made to a stop list are reflected real-time in searches but applied only to newly indexed words. The stop words remain in the catalog until you rebuild the catalog. It is a best practice to rebuild your catalog as soon as you have made changes to your stop word list. To rebuild your full-text catalog, right-click on the catalog in SSMS and select Rebuild.

Full-Text Search Maintenance

After you create full-text catalogs and indexes that you can query, you have to maintain them. The catalogs and indexes maintain themselves, but you need to focus on backing up and restoring them as well as tuning your search solution for optimal performance. In SQL Server 2008, the full-text catalogs get fragmented from time to time, especially if you are using the Automatic (Track Changes Automatically) setting. You can check the level of fragmentation by using the following command:

```
SELECT table_id, status FROM sys.fulltext_index_fragments WHERE status=4 OR
status=6;
```

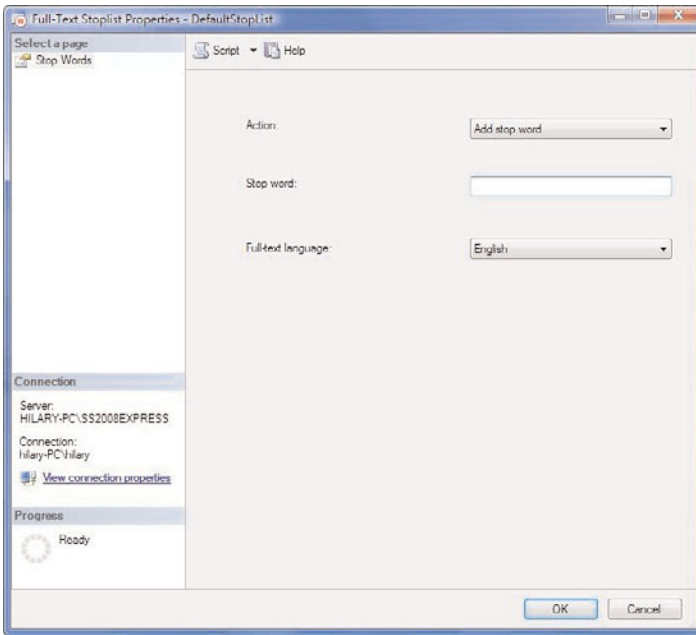

FIGURE 50.5 Maintaining a full-text stop list.

If you notice that your tables are highly fragmented you will optimize your full-text indexes. Here is the command you would use to do this:

```
ALTER FULLTEXT CATALOG AdventureWorks2008 REORGANIZE;
```

Full-Text Search Performance

SQL Server FTS performance is most sensitive to the number of rows in the result set and number of search terms in the query. You should limit your result set to a practical number; most searchers are conditioned to look only at the first page of results for what they are looking for, and if they don't see what they need there, they refine the search and search again. A good practical limit for the number of rows to return is 200. You should try, if at all possible, to use simple queries because they perform better than more complex ones. As a rule, you should use `CONTAINS` rather than `FREETEXT` because it offers better performance, and you should use `CONTAINSTABLE` rather than `FREETEXTTABLE` for the same reason.

Several factors are involved in delivering an optimal Full-Text Search solution. Consider the following:

- ▶ Avoid indexing binary content. Convert it to text, if possible. Most `IFilters` do not perform as well as the text `IFilter`.
- ▶ Use integer columns on the base table that comprises your unique index.

- ▶ Partition large tables into smaller tables. There seems to be a sweet spot around 50 million rows, but your results may vary. Ensure that for large tables, each table has its own catalog. Place this catalog on a RAID 10 array, preferably on its own controller.
- ▶ SQL Full-Text Search benefits from multiple processors, preferably four or more. A sweet spot exists on eight-way machines or better. You will find 64-bit hardware also offers substantial performance benefits over 32-bit.
- ▶ Dedicate at least 512MB to 1GB of RAM to `MSFTESQL` by setting the maximum server memory to 1GB less than the installed memory. Set resource usage to run at 5 to give a performance boost to the indexing process (that is, `sp_fulltext_service 'resource_usage',5`), set `ft crawl bandwidth (max)` and `ft notify bandwidth (max)` to 0, and set `max full-text crawl range` to the number of CPUs on your system. Use `sp_configure` to make these changes.

Full-Text Search Troubleshooting

The first question you should ask yourself when you have a problem with SQL Full-Text Search is this: “Is the problem with searching or with indexing?” To help you make this determination, Microsoft has included three DMVs in SQL Server 2008:

- ▶ `sys.dm_fts_index_keywords`
- ▶ `sys.dm_fts_index_keywords_by_document`
- ▶ `sys.dm_fts_parser`

The first two DMVs displays the contents of your full-text index. The first DMV returns the following columns:

- ▶ **Keyword**—Each keyword in varbinary form.
- ▶ **Display_term**—The keyword as indexed; all the accents are removed from the word.
- ▶ **Column_ID**—The column ID where the word exists.
- ▶ **Document_Count**—The number of times the word exists in that column.

The second DMV breaks down the keywords by document. Like the first DMV, it contains the `Keyword`, `Display_term`, and `Column_ID` columns, but in addition it contains the following two columns:

- ▶ **Document_ID**—The row in which the keyword occurs.
- ▶ **Occurrence_count**—The number of times the word occurs in the cell (a cell is also known as a tuple; it is a row-column combination—for example, the contents of the third column in the fifth row).

The first DMV, `sys.dm_fts_index_keywords`, is used primarily to determine candidate noise wordsit can be used to diagnose indexing problems. The second DMV, `sys.dm_fts_index_keywords_by_document`, is used to determine what is stored in your index for a particular cell.

Here are some examples of their usage:

```
select * From sys.dm_fts_index_keywords(DB_ID(),Object_id('MyTable'))
select * From sys.dm_fts_index_keywords_by_document(DB_ID(),Object_id('MyTable'))
```

These two DMVs are used to determine what occurs at index time. The third DMV, `sys.dm_fts_parser`, is used primarily to determine what happens at search time—in other words, how SQL Server Full-Text Search interprets your search phrase. Here is an example of its usage.

```
select * from sys.dm_fts_parser(@queryString, @LCID, @StopListID, @AccentSensitive)
@QueryString is your search word or phrase, @LCID is the LoCale ID for your language
(determinable by querying sys.fulltext_languages), @StopListID is your stoplist
file (determinable by querying sys.fulltext_stoplists), @AccentSensitive allows you
to set accent sensitivity (0 not sensitive, 1 sensitive to accents) . Here is an
example of how this works:
select * from sys.dm_fts_parser('café', 1033, 0, 1)
select * from sys.dm_fts_parser('café', 1033, 0, 0)
```

In the second example, you will notice that the `Display_term` is *cafe* and not *café*. These queries return the following columns:

- ▶ **Keyword**—This is a varbinary representation of your keyword.
- ▶ **Group_id**—The query parser builds a parse tree of the search phrase. If you have any Boolean searches, it assigns different group IDs to each part of the search term. For example in the search phrase "Hillary Clinton" OR "Barack Obama", *Hillary* and *Clinton* belong to Group ID 1 and *Barack* and *Obama* belong to Group ID 2.
- ▶ **Phrase_id**—Some words are indexed in multiple forms; for example, data-base is indexed as data, base, and database. In this case, data and base have the same phrase ID, and database has another phrase ID.
- ▶ **Occurrence_count**—This is how frequently the word appears in the search string.
- ▶ **Special_term**—This column refers to any delimiters that the parser finds in the search phrase. Possible values are Exact Match, End of Sentence, End of Paragraph, and End of Chapter.
- ▶ **Display_term**—This is how the term would be stored in the index.
- ▶ **Expansion_type**—This is the type of expansion, whether it is a thesaurus expansion (4), an inflectional expansion (2), or not expanded (0). For example, the following query shows the stemmed variants of the word *run*.

```
select * from sys.dm_fts_parser('FORMSOF( INFLECTIONAL, run)', 1033, 0, 0)
```

- ▶ **Source_Term**—This is the source term as it appears in your query.

When troubleshooting indexing problems, you should consult the full-text error log, which can be found in C:\Program Files\Microsoft SQL

Server\MSSQL10.MSSQLSERVER\MSSQL\LOG and starts with the prefix SQLFT followed by the database ID (padded with leading zeros), the catalog ID (query `sys.fulltext_catalogs` for this value), and then the extension `.log`. You may find many versions of the log each with a numerical extension, such as `SQLFT0001800005.LOG.4`; this is the fourth version of this log. These full-text indexing logs can be read by any text editor.

You might find entries in this log that indicate documents were retried or documents failed indexing in addition to error messages returned from the iFilters.

Summary

SQL Server 2008 Full-Text Search offers extremely fast and powerful querying of textual content stored in tables. In SQL Server 2008, the full-text index creation statements are highly symmetrical, with the table index creation statements making SQL Server FTS much more intuitive to use than previous versions of SQL Server FTS. Also new is the tremendous increase in indexing and querying speeds. These features make SQL Server Full-Text Search a very attractive component of SQL Server 2008.

CHAPTER 51

SQL Server 2008 Analysis Services

IN THIS CHAPTER

- ▶ What's New in SSAS
- ▶ Understanding SSAS and OLAP
- ▶ Understanding the SSAS Environment Wizards
- ▶ An Analytics Design Methodology
- ▶ An OLAP Requirements Example: CompSales International

SQL Server 2008 Analysis Services (SSAS) continues to expand with numerous data warehousing, data mining, and online analytical processing (OLAP)-rich tools and technologies. Microsoft continues to attack the data warehousing/business intelligence (BI) market by pouring millions and millions of dollars into this area. Microsoft knows that the world is hungry for analytics and is betting the farm on it. As a part of its internal project named “Madison,” Microsoft has been acquiring other complementary BI technologies to accelerate its plans (such as acquiring the MPP data warehousing appliance company DATAlegro and rolling it under its BI offering). Other more traditional (and much more expensive) OLAP and BI platforms such as Cognos, Hyperion, Business Objects, and Micro Strategies are being challenged, if not completely replaced, by this new version of SSAS.

A chief data architect from a prominent Silicon Valley company said recently, “I can now build [using SSAS] sound, extremely usable, highly scalable, OLAP cubes myself, faster and smarter than the entire data warehouse team could do only a few years ago.” This is what Microsoft has been trying to bring to the forefront for years—“BI for the masses.”

What's New in SSAS

SQL Server 2005 was the big jump into completely re-deploying Analysis Services—from the architecture, to the development environment, to the multidimensional languages supported, and even to the wizard-driven deployments. SQL Server 2008 R2 raises this core work up a few

more notches with enhancements at almost every part of SSAS and with the addition of major scaleout capabilities. Following are some of the top new features and enhancements:

- ▶ Microsoft has improved and streamlined the Cube Designer.
- ▶ Several subtle enhancements have been made around the Dimension and Aggregation Designers.
- ▶ You can now create attribute relationships with the new Attribute Relationship Designer.
- ▶ You can use subspace computations to optimize performance for your Multidimensional Expressions (MDX) queries.
- ▶ Multidimensional OLAP (MOLAP) enables write-back capabilities that support high-performance “what if” scenarios.
- ▶ A shared read-only Analysis Services database between several Analysis Services servers enables you to “scale out” easily and efficiently.
- ▶ You are able to use localized analytical data in native languages, including translation capabilities and automatic currency conversions.
- ▶ A highly compressed and optimized data cache is maintained automatically.
- ▶ Backup performance is optimized.
- ▶ SQL Server PowerPivot for Excel is a new feature.
- ▶ The master data hub in SQL Server 2008 R2 helps manage your master data services more efficiently.

And, last, but not least,

- ▶ SQL Server 2008 R2 Parallel Data Warehouse is a highly scalable data warehouse appliance-based massively parallel processing (MPP) solution that knows no bounds.

Understanding SSAS and OLAP

Because OLAP is at the heart of SSAS, you need to understand what it is and how it solves the requirements of decision makers in a business. As you might already know, data warehousing requirements typically include all the capability needed to report on a business’s transactional history, such as sales history. This transactional history is often organized into subject areas and tiers of aggregated information that can support some online querying and usually much more batch reporting. Data warehouses and data marts typically extract data from online transaction processing (OLTP) systems and serve data up to these business users and reporting systems. In general, these are all called decision support systems (DSS), or BI systems, and the latency of this data is determined by the business requirements it must support. Typically, this latency is daily or weekly, depending on the business needs, but more and more, we are seeing more real-time (or near-real-time) reporting requirements.

OLAP falls squarely into the realm of BI. The purpose of OLAP is to provide for a mostly online reporting environment that can support various end user reporting requirements. Typically, OLAP representations are of OLAP cubes. A *cube* is a multidimensional representation of basic business facts that can be accessed easily and quickly to provide you with the specific information you need to make a critical decision. It is useful to note that a cube can be composed of from 1 to N dimensions. However, remember that the business facts represented in a cube must exist for all the dimensions being defined for the fact. In other words, all dimensional values (that is, intersections) have to be present for a fact value to be stored in the cube.

Figure 51.1 illustrates the Sales_Units historical business fact, which is the intersection of time, product, and geography dimensional data. For a particular point in time (February 2010), for a particular product (IBM laptop model 451D), and in a particular country (France), the sales units were 996 units. With an OLAP cube, you can easily see how many of these laptop computers were sold in France in February 2010.

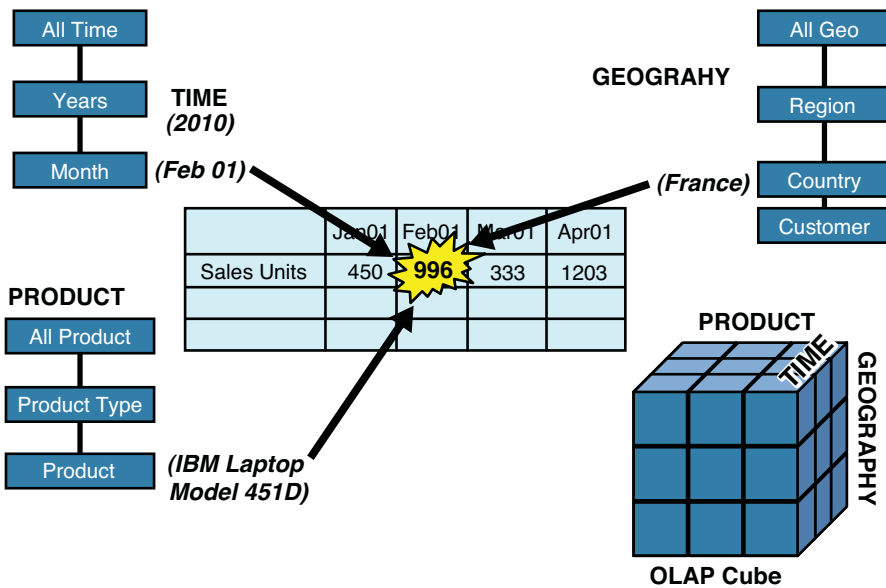

FIGURE 51.1 Multidimensional representation of business facts.

Basically, cubes enable you to look at business facts via well-defined and organized dimensions (time, product, and geography dimensions, in this example). Note that each of these dimensions is further organized into hierarchical representations that correspond to the way data is looked at from the business point of view. This provides for the capability to drill down into the next level from a higher, broader level (like drilling down into a specific country’s data within a geographic region, such as France’s data within the European geographic region).

SSAS directly supports this and other data warehousing capabilities. In addition, SSAS allows a designer to implement OLAP cubes using a variety of physical storage techniques that are directly tied to data aggregation requirements and other performance considerations. You can easily access any OLAP cube built with SSAS via the Pivot Table Service, you can write custom client applications by using MDX with OLE DB for OLAP or ActiveX Data Objects Multidimensional (ADO MD), and you can use a number of third-party “OLE DB for OLAP” compliant tools.

Microsoft utilizes something called the Unified Dimensional Model (UDM) to conceptualize all multidimensional representations in SSAS. It is also worth noting that many of the leading OLAP and statistical analysis software vendors have joined the Microsoft Data Warehousing Alliance and are building front-end analysis and presentation tools for SSAS. The data mining capabilities that are part of SSAS provide a new avenue for organized data discovery. This includes using SQL Server DMX.

This chapter takes you through the major components of SSAS, discusses a mini-methodology for OLAP cube design, and leads you through creating and managing robust OLAP cube that can easily be used to meet a company’s BI needs.

Understanding the SSAS Environment Wizards

Welcome to the “land of wizards.” This implementation of SSAS, as with older versions of SSAS, is heavily wizard oriented. SSAS has a Cube Wizard, a Dimension Wizard, a Partition Wizard, a Storage Design Wizard, a Usage Analysis Wizard, a Usage-Based Optimization Wizard, an Aggregation Wizard, a Calculated Cells Wizard, a Mining Model Wizard, and a few other wizards. All of them are useful, and many of their capabilities are also available through editors and designers. Using a wizard is helpful for those who need to have a little structure in the definition process and who want to rely on defaults for much of what they need. The wizards are also plug-and-play oriented and have been made available in all SQL Server and .NET development environments. In other words, you can access these wizards from wherever you need to, when you need to. All the wizard-based capabilities can also be coded in MDX, DMX, and ASSL.

Figure 51.2 shows how SSAS fits into the overall scheme of the SQL Server 2008 environment. SSAS has become completely integrated into the SQL Server platform. Utilizing many different mechanisms, such as SSIS and direct data source access capabilities, a vast amount of data can be funneled into the SSAS environment. Most of the cubes you build will likely be read-only because they will be for BI. However, a write-enabled capability (WriteBack) is available in SSAS for situations that meet certain data updatability requirements.

As you can also see in Figure 51.2, the basic components in SSAS are all focused on building and managing data cubes. SSAS consists of the analysis server, processing services, integration services, and a number of data providers. SSAS has both server-based and client-/local-based SSAS capabilities. This essentially provides a complete platform for OLAP.

You create cubes by preprocessing aggregations (that is, precalculated summary data) that reflect the desired levels within dimensions and support the type of querying that will be done. These aggregations provide the mechanism for rapid and uniform response times to

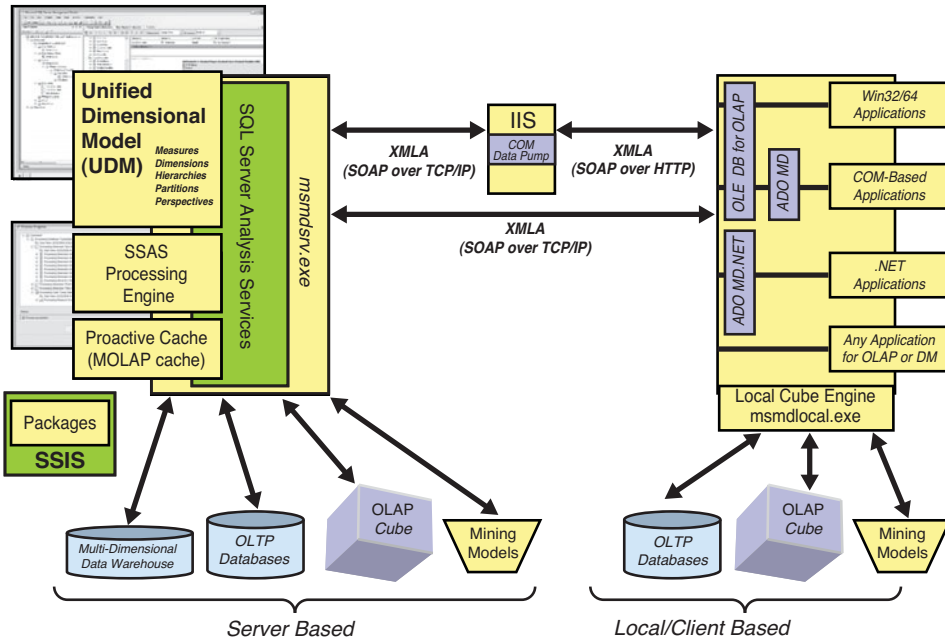

FIGURE 51.2 SSAS as part of the overall SQL Server 2008 environment.

queries. You create them *before* the user uses the cube. All queries utilize either these aggregations, the cube’s source data, a copy of this data in a client cube, data in cache, or a combination of these sources. A single Analysis Server can manage many cubes. You can have multiple SSAS instances on a single machine.

By orienting around UDM, SSAS allows for the definition of a cube that contains data measures and dimensions. Each cube dimension can contain a hierarchy of levels to specify the natural categorical breakdown that users need to drill down into for more details. Look back at Figure 51.1, and you can see a product hierarchy, time hierarchy, and geography hierarchy representation.

The data values within a cube are represented by measures (the facts). Each measure of data might utilize different aggregation options, depending on the type of data. Unit data might require the SUM (summarization) function, Date of Receipt data might require the MAX function, and so on. Members of a dimension are the actual level values, such as the particular product number, the particular month, and the particular country. Microsoft has solved most of the limitations within SSAS. SSAS addresses up to 2,147,483,647 of most anything within its environment (for example, dimensions in a database, attributes in a dimension, databases in an instance, levels in a hierarchy, cubes in a database, measures in a cube). In reality, you will probably not have more than a handful of dimensions. Remember that dimensions are the paths to the interesting facts. Dimension members should be textual and are used as criteria for queries and as row and column headers in query results.

Every cube has a schema from which the cube draws its source data. The central table in a schema is the fact table that yields the cube's data measures. The other tables in the schema are the dimension tables that are the source of the cube dimensions. A classic star-schema data warehouse design has this central fact table along with multiple dimension tables. This is a great starting point for OLAP cube creation, as you can see in Figure 51.3. Here, we show you a high-tech company's computer sales star-schema data warehouse that can be used as the source of building up an OLAP cube within SSAS.

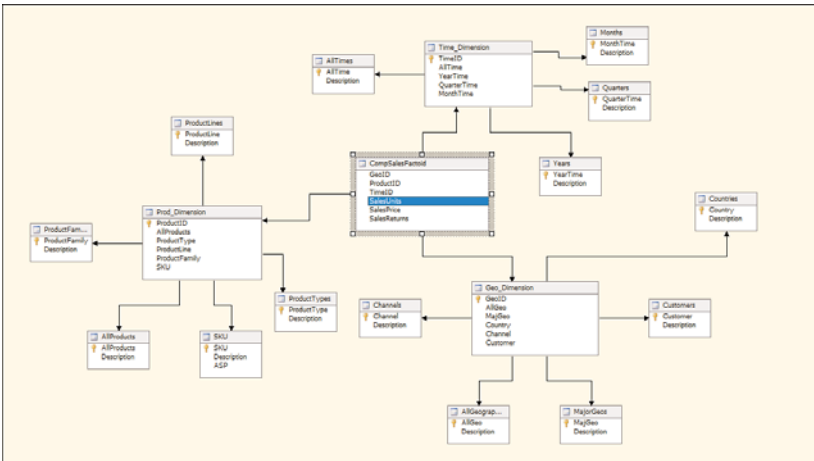

FIGURE 51.3 A star-schema data warehouse design with a central fact table and multiple dimensions of these facts as the source for an OLAP cube in SSAS.

SSAS allows you to build dimensions and cubes from heterogeneous data sources. It can access relational OLTP databases, multidimensional data databases, text data, and any other source that has an OLE DB provider available. You don't have to move all your data first; you just connect to its source. In SSAS, you can also design OLAP cubes from scratch. Then you can have SSAS create the relational schema of tables in SQL Server that you want to populate with the transactional data that will drive the OLAP cube.

Essentially, cubes can be regular or local cubes. Regular cubes are based on real tables as the data source, have aggregations, and occupy physical storage space of some kind. If a data source that contributes to this cube changes, the cube must be reprocessed. Figure 51.4 shows this cube representation and that it consists of something called *partitions*.

Local cubes are entirely contained in portable SSAS files (that is, tables) and can be browsed without a connection to an SSAS instance. This is really like being in “disconnected” mode.

Write-enabled dimensions within a cube enable updates (that is, writes) of data that can be shared back (that is, written back) with the data sources.

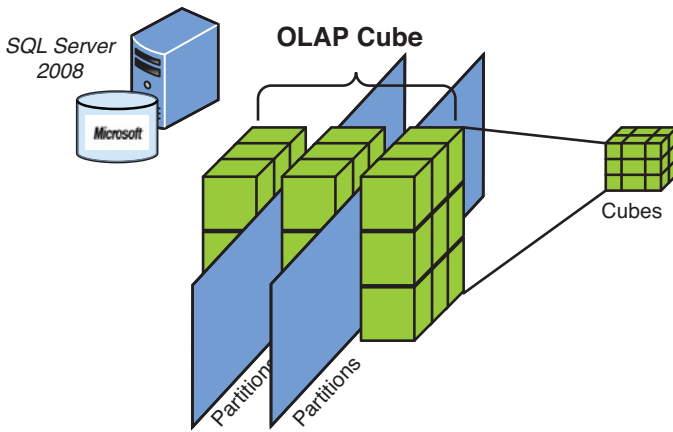

FIGURE 51.4 The SSAS cube representations: regular OLAP cubes and partitions.

Following is a quick summary of all the essential cube terms in SSAS:

- ▶ **Database**—A database is a logical container of one or more cubes. Cubes are defined within Analysis Server databases.
- ▶ **Cube**—A cube is a multidimensional representation of the business facts. Types of cubes are regular and local.
- ▶ **Data source**—The data source is the origin of a cube's data.
- ▶ **Measure group**—This group is a collection (or grouping) of one or more measures into some type of logical unit for business purposes. A measure group does not occupy any physical space. It is metadata only.
- ▶ **Measure**—A measure is a data fact representation. A measure is typically a data value fact, such as price, unit, or quantity.
- ▶ **Cell**—A cell is the part of a data measure that is at the intersection of the dimensions. The cell contains the data value. If an intersection (that is, cell) has no value yet, it does not physically exist until it is populated.
- ▶ **Dimension**—A cube's dimension is defined by the aggregation levels of the data that are needed to support the data requirements. A dimension can be shared with other cubes, or it can be private to a cube. The structure of a dimension is directly related to the dimension table columns, member properties, or structure of OLAP data mining models. This structure becomes the hierarchy and should be organized accordingly. You can also have strict parent/child dimensions in which two columns are identified as being parent and child and the dimension is organized according to them. In a regular dimension, each column in the dimension contributes a hierarchy level.

- ▶ **Level**—A level includes the nodes of the hierarchy or data mining model. Each level contains the members. Millions of members are possible for each level.
- ▶ **Partition**—One or more partitions comprise a cube. Using a partition is a way to physically separate parts of a cube. This separation essentially lets you deal with individual slices of a data cube separately, querying only the relevant data sources. If you partition by dimension, you can perform incremental updates to change that dimension independently of the rest of the cube. Consequently, you have to reprocess only the aggregations that are affected by those changes. This is an excellent feature for scalability.
- ▶ **Hierarchy**—A hierarchy is a set of members in a dimension and their position relative to each other. Hierarchies can either be balanced or unbalanced. Being balanced simply means that all branches of the hierarchy descend to the same level. An unbalanced hierarchy allows for branches to descend to different levels. It is also possible to define more than one hierarchy for a single dimension. A great example of this is “fiscal calendar time” and “Gregorian calendar time” being defined in one dimension—a Time dimension that contains both `time.gregorian` and `time.fiscal`.

As mentioned previously, SSAS has many wizards. Which wizards you use depends on what you need to create. The “Creating an OLAP Database” section, later in this chapter, outlines the order and path through this maze of wizards.

OLAP Versus OLTP

One of the primary goals of OLAP is to increase data retrieval speed for business-related queries that are critical to decisions. Very often, there is a need to broaden the scope of a business query or to drill down into more granular details of the query. OLAP was created to facilitate this type of capability. A multidimensional schema is not a typical normalized relational database; redundant data is stored to facilitate quick retrieval. The data in a multidimensional database should be relatively static; in fact, data is not useful for decision support if it changes constantly. The information in a data warehouse is built out of carefully chosen snapshots of business data from OLTP systems. If you capture data at the right times for transfer to the data warehouse, you can quickly make accurate comparisons of important business activities over time.

In an OLTP system, transaction speed is paramount. Data modification operations must be quick, deal with concurrency (locking/holding of resources), and provide transactional consistency. An OLTP system is constantly changing; snapshots of the OLTP system, even if taken only a few seconds apart, are all different. Although historical information is certainly available in an OLTP system, using it for BI-type analysis might be impractical. Storing old data in an OLTP system becomes expensive, and you might need to reconstruct history dynamically from a series of transactions. In addition, OLTP designs and indexes usually don’t support large-scale decision support querying.

SSAS supports three OLAP storage methods—MOLAP, ROLAP, and HOLAP—providing flexibility to the data warehousing solution and enabling powerful partitioning and aggregation optimization capabilities.

Figure 51.5 shows the MOLAP, HOLAP, and ROLAP storage continuum. MOLAP stores all data locally (to SSAS), and ROLAP is the opposite (storing all data in the relational database). MOLAP is by far the most often used storage approach. The following sections take a closer look at them.

FIGURE 51.5 MOLAP, HOLAP, and ROLAP storage continuum.

MOLAP

Multidimensional OLAP (MOLAP) is an approach in which cubes are built directly from OLTP data sources or from dimensional databases and downloaded to a persistent store.

In SSAS, data is downloaded to the server, and the details and aggregations are stored in a native Microsoft OLAP format. No zero-activity records are stored.

The dimension keys in the fact tables are compressed, and bitmap indexing is used. A high-speed MOLAP query processor retrieves the data.

ROLAP

Relational OLAP (ROLAP) uses fact data in summary tables in the OLTP data source to make data much more current (real-time). The summary tables are populated by processes in the OLTP system and are not downloaded to SSAS. The summary tables are known as materialized views and contain various levels of aggregation, depending on the options you select when building data cubes with SSAS. SSAS builds the summary tables with a column for each dimension and each measure. It indexes each dimension column and creates an additional index on all the dimension columns.

HOLAP

SSAS implements a combination of MOLAP and ROLAP called hybrid OLAP (HOLAP). Here, the facts are left in the OLTP data source, and aggregations are stored in the SSAS server. You use SSAS to boost query performance. This approach helps avoid data duplication, but performance suffers a bit when you query fact data in the OLTP summary tables. The amount of performance degradation depends on the level of aggregation selected.

ROLAP and HOLAP are useful in situations in which an organization wants to leverage its investment in relational database technology and existing infrastructure. The summary tables of facts are also accessible in the OLTP system via normal data access methods. However, when you are using SSAS, both ROLAP and HOLAP require more storage space because they don't use the storage optimizations of the pure MOLAP-compressed implementation.

An Analytics Design Methodology

A data warehouse can be built from the top down or from the bottom up. To build a top-down warehouse, you need to form a complete picture or logical data model for the entire organization (or all the subsystems within the scope of the project, such as all financial systems). In contrast, building a warehouse from the bottom up takes a much more departmental or specific business-area focus (for example, a sales order system only). This breaks the task of modeling the data into more manageable chunks. Such a departmental approach produces data marts that are potentially subsets of the overall data warehouse. The bottom-up approach can simplify implementation. It helps get departmental or business-area information to the people who need it, makes it easier to protect sensitive data, and results in better query response times because data marts deal with less data than a voluminous transactional system. The potential risk in the data mart approach is that disparity in data mart implementation can result in a logically disjointed enterprise data warehouse if efforts aren't carefully coordinated across the organization.

Before you embark on an OLAP database creation effort, the time you spend understanding the underlying requirements is the best time you can give your effort. If scope is set correctly, you will be able to achieve an industrial-strength OLAP design without much difficulty. First, you need to take care of some groundwork:

1. Carefully assess the scope of what you want to represent in the BI environment. Start small, as the bottom-up approach suggests. For instance, just tackle the sales data facts.
2. Coordinate your efforts with other related BI efforts. Let people know that you are carving out a specific subject area or departmental data and, when you finish, publish your design to everyone.
3. Seek out any shared dimensions that might have already been created for other cubes. You want to leverage these as much as possible for the sake of data consistency and nonredundant processing.
4. Understand your data sources. The OLAP cube you create will be only as good as the data you put into it. It's best to understand the dirty data issues of what you are about to touch long before you try to build an OLAP cube with it.

An Analytics Mini-Methodology

To successfully build OLAP solutions, you are advised to carefully assess the requirements of your end users in as detailed fashion as is possible. A mini-methodology that focuses on the essential usages and characteristics of an Analytic solution can prove invaluable. The following sections outline a solid approach to nailing down your BI requirements and yielding optimal OLAP designs that solve your end users' needs.

Assumption: You are building a business area-focused OLAP cube.

Requirements Phase

1. Identify the processing requirements for this DSS. What analysis do you need to do? Are trend reporting, forecasting, and so on necessary? These can often be represented in use case form (via UML).
 - a. Ask each user what business decision questions he or she needs to have answered.
 - b. Ask each user how often he or she needs these questions answered and exactly when the questions must be answered.
 - c. Ask each user how current the data must be to get accurate answers. (This speaks to data latency.)
2. Identify the data needed to fulfill these requirements. What data must be touched to provide answers? The best way to capture this type of information is a logical data model. Even a rough model is better than none at all. This is the point where you focus on the facts that need to be analyzed.
3. Identify all possible hierarchies and level representations (that is, aggregations). This is how the data is used. Most users are likely to tell you that they want to see product data in the product hierarchy structure that has already been set up (for example, product family, product groups).
4. Identify the time hierarchies that the users need. Because time is usually implicit, it just needs to be clarified in terms of levels of aggregation (for example, years, quarters, months, weeks, days) and whether it needs to be fiscal versus Gregorian calendar, both, or something else.
5. Understand the data that each user can view from a security point of view.

Design Phase

1. Analyze which data sources are needed to fulfill the requirements. See whether dimensions or OLAP cubes that already exist can be shared.
2. Understand what data transformations need to be done to the source data to provide it to the OLAP world. This might include pre-aggregation, reformatting, data integrity verifications, and so on.
3. Translate these requirements into an OLAP model design:
 - a. Translate to MOLAP if your data sources are not going to be leveraged at all and you will be taking full advantage of OLAP storage.
 - b. Translate to ROLAP if you are going to leverage an existing relational design and storage.
 - c. Translate to HOLAP if you are going to partially utilize the source data storage and partially utilize OLAP storage. This is the most frequently used approach.

Construction Phase

1. Implement data extraction, transformation, and loading (ETL) logic (via T-SQL, SSIS, or other methods).

2. Create the data sources to be used.
3. Create the dimensions.
4. Create the cube.
5. Select data measures (that is, the data facts) for the cube.
6. Design the storage and aggregations.
7. Process the cube. This brings the data into the OLAP environment.
8. Verify data integrity.

Implementation Phase

1. Define the security roles in the cube.
2. Train the user to use the system.
3. Process the data into the OLAP environment (from production data sources).
4. Verify data integrity.
5. Allow users to use the OLAP cube.

Maintenance Phase

1. Evaluate access optimization in the OLAP cube via usage analysis.
2. Do data mining discovery, if desired.
3. Make schema changes/enhancements, as necessary.

An OLAP Requirements Example: CompSales International

Following is an abbreviated requirement that reflects an actual implementation that was done for a large Silicon Valley company. We follow the mini-methodology as closely as possible to implement this requirement in SSAS, pointing out which facilities of SSAS should be used for which purpose along the way.

CompSales International Requirements

A large computer manufacturer named CompSales International needs to do basic analytical processing of its product data in a new BI environment. The main business issues at hand are related to minimizing channel inventory and better understanding market demand for the company's most popular products. The detailed data processing requirements are as follows:

1. You want to view sales unit actuals and sales returns for system and nonsystem products for the past two years via the product hierarchy (All Products, Product Types, Product Lines, Product Families, SKUs), geography hierarchy (All Geos, Major Geos, Countries, Channels, Customers), and different time levels (All Time, Years, Quarters, Months).
2. You want to view data primarily at the yearly and monthly levels, although the finance department also uses it a little bit at quarterly levels.

3. You want to view net sales (sales minus returns) at all levels of the hierarchy.
4. The fiscal and Gregorian calendar are the same for CompSales International.
5. One day past month-end processing, all “actuals” data from the prior month is available (sales units and returns).

You need to implement some general design decisions using SSAS, including the following:

- ▶ **Hierarchies (dimensions)**—This includes product, geography, and time.
- ▶ **Facts (measures)**—This includes sales units, sales returns, and net sales (units minus returns) calculated.
- ▶ **OLAP storage**—This will be MOLAP or HOLAP (if you want to use the star-schema data mart that already contains most of what you are after).
- ▶ **Physical tables that exist**—This includes Geo_Dimension, Prod_Dimension, Time_Dimension, and CompSalesFactoid (the fact table that will become your measures in the OLAP cube). This data is updated weekly. Each of these tables uses an artificial key into the main facts table for performance reasons (GeoID, ProductID, TimeID). In addition, several member/value description tables are associated with each dimension table. Basically, there is one table for each level in a dimension. These description tables can be leveraged to make the result rows from OLAP queries much more user friendly (look back at Figure 51.3 and you can see all tables included in CompSales and how they are related via primary/foreign key references).

Figure 51.6 illustrates the desired hierarchies and facts for CompSales International’s requirements.

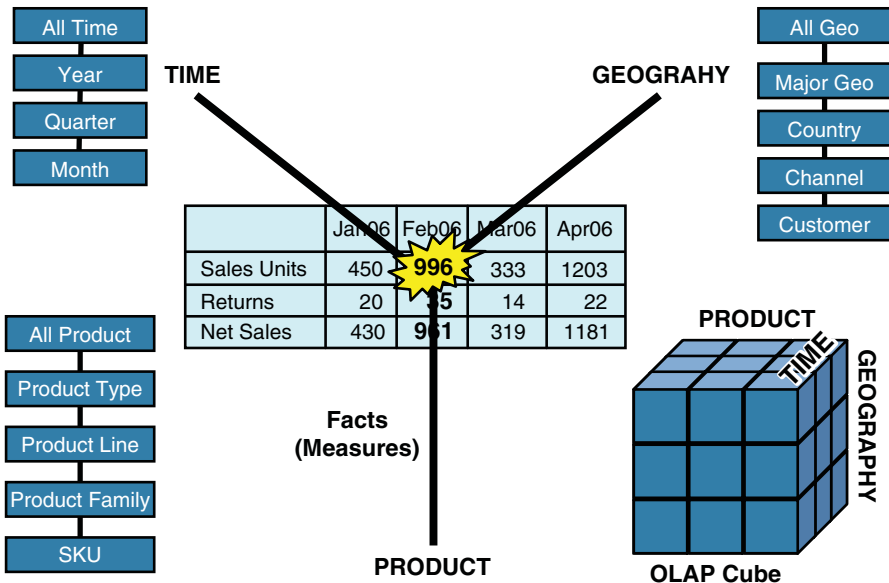

FIGURE 51.6 CompSales International’s multidimensional OLAP requirements.

OLAP Cube Creation

A star-schema data mart/warehouse named `CompSales2008` is used as the basis of creating the OLAP cube example in this chapter. You can download this data mart, `CompsSales2008.zip`, from the Sams Publishing website for this book title at www.sampublishing.com, and it is also on this book's CD. You can easily unzip and attach this database to any SQL Server 2008 database instance. This is not an SSAS database; it is a SQL Server database of a star-schema data warehouse/mart. We use this SQL Server database as the source for the exercises in this chapter. You will build the SSAS OLAP cube yourself (by following the steps outlined here).

You'll spend most of the construction phase using SQL Server Business Intelligence Development Studio (BIDS; also known as Visual Studio) and Microsoft SQL Server Management Studio (SSMS). All wizards and editors are invoked from either BIDS or SSMS. As mentioned earlier, Microsoft has moved to a project orientation. For this reason, you need to start out in the BIDS (which actually invokes Visual Studio with the BI plug-ins). You must have already installed SSAS. In general, here's what you'll be doing in this example:

1. Create a BI project.
2. Identify data sources and data source views that you want to use for a new cube.
3. Define the basic dimensions for the cube (Time, Geography, Product).
4. Define the hierarchies.
5. Process the dimensions.
6. Create a cube structure.
7. Define the measure groups/measures.
8. Process the cube.
9. Deploy the solution.
10. Use the cube.

Using SQL Server BIDS

The SQL Server BIDS (a.k.a. Visual Studio with the BI plug-ins) is launched from the SQL Server 2008 Program group on the Start menu or from the Visual Studio 2008 Program group on the Start menu. We will assume you have installed Visual Studio and SQL Server Analysis Services. When this is open, you choose File, New Project, Business Intelligence Projects. Figure 51.7 shows the New Project dialog from which you should highlight the Analysis Services Project template option and specify a project name, project location, and solution name for this new BI project. In this case, the solution name is `CompSalesUnleashed`.

NOTE

You can also start a new project by leveraging any other existing SSAS database project. You can easily clone an existing project and tweak it a bit to fit your new needs. To do this, you use the Import Analysis Services Database option.

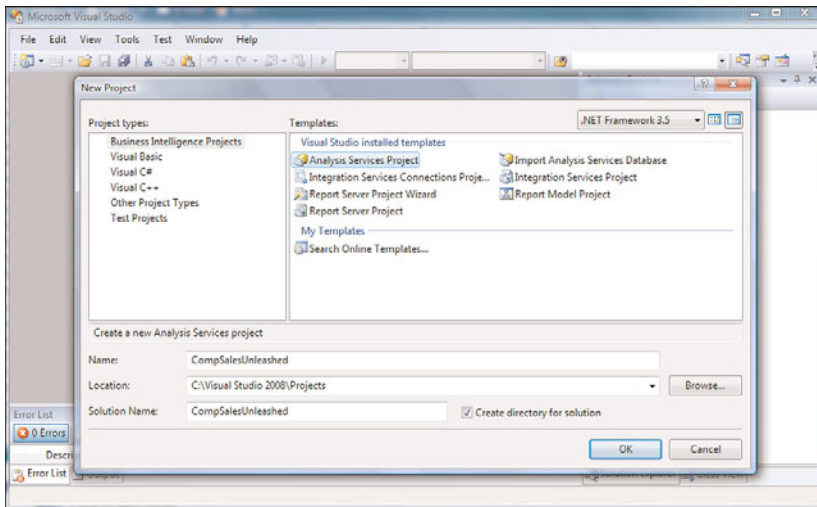

FIGURE 51.7 The SQL Server BIDS New Project dialog.

After you create a new project, a set of objects is presented to you in the upper-right pane, which is the Solution Explorer. Figure 51.8 shows the Solution Explorer for the new project. All OLAP project objects reside here, including data sources, dimensions, cubes, mining structures, and roles.

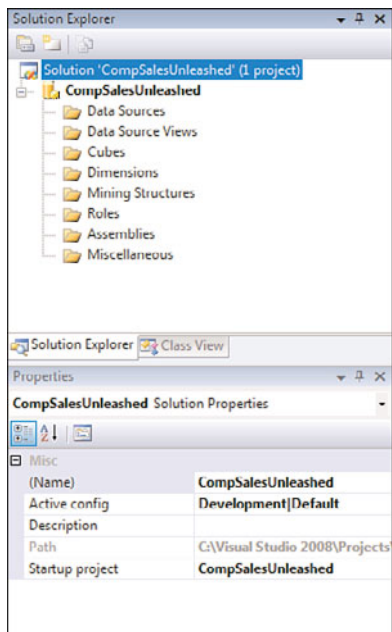

FIGURE 51.8 The Solution Explorer view for the new CompSalesUnleashed project.

Creating an OLAP Database

Remember that an OLAP database is made up of data sources, dimensions, and cubes. A data source is simply a pointer to data somewhere, such as via a Jet OLE DB provider, an OLE DB provider, SQL Native Client, Microsoft Directory Services, or even SSIS packages. You populate the data in your cube from the data source. Dimensions are constructed of columns from tables that you select to be used to build and filter data cubes. Cubes are combinations of dimensions whose intersections contain strategically significant measures of business performance, such as quantities, units, amounts, and so on. You need to identify the data sources from which your OLAP cube is to be based.

Adding a Data Source

To add data sources for a new database, you simply right-click the Data Sources object in the Solution Explorer or select Project, New Data Source in Visual Studio. The Data Source Wizard is then initiated. As mentioned earlier, much of SSAS administration is wizard based. The Data Source Wizard starts with a prompt for you to select how to define the connection to a data source. You can use any existing connections or create new ones from this dialog. Figure 51.9 shows these two options, along with the data connection properties. If you have attached the `CompSales` database (or any other database) already, you can easily create a new connection to this database for use in this example.

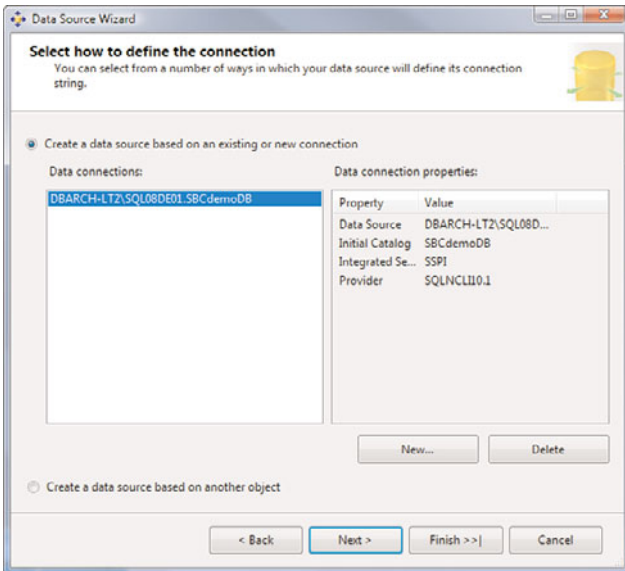

FIGURE 51.9 Defining a data source connection in the Data Source Wizard.

Figure 51.10 shows the Connection Manager dialog, where you specify the provider to use (for example, Native OLE DB\SQL Native Client 10.0), the name of the database to connect to, and the authentication method to use for the connection. You should go

ahead and establish a connection to the CompSales database you just attached and click the Test Connection button in the lower-left corner to verify that it is valid. If you have referenced the CompSales2008 database from Visual Studio before, it may already appear in the Data Connections list.

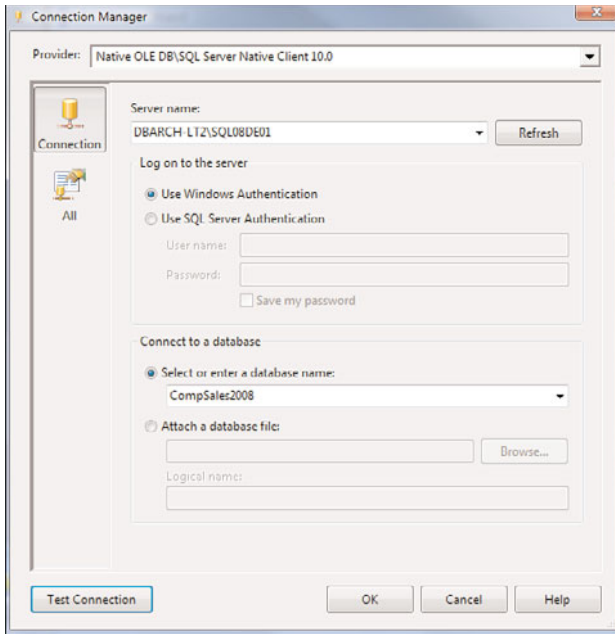

FIGURE 51.10 Connection Manager specification for a new data source.

As part of this connection specification wizard sequence, you must specify the impersonation information. That is, you must define what credentials SSAS should use to connect to the data source. You can specify a specific username and password, use the service account, use the credentials of the current user, or use default authentication. You can also create a specialized domain account to use for all SSAS connections. We recommend using the service account approach, which is easily leveraged for most cube administration.

To finish, you must name the data source `Comp Sales2008` and then click the Finish button. Your data source then appears in the Solution Explorer, under Data Sources. As part of this process, an XML file is created, from which you can easily manage all connection properties for this data source (`Comp Sales2008.ds` in this example). Remember that you have just established connection information only—nothing more. If you right-click the `Comp Sales2008.ds` entry under the Data Sources object, you can view the complete XML code of this entry by selecting the View Code option.

The following XML code represents this data source connection:

```
<DataSource xmlns:xsd="http://www.w3.org/2001/XMLSchema"
  xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance"
  xmlns:ddl2="http://schemas.microsoft.com/
  analysisservices/2003/engine/2"
  xmlns:ddl2_2="http://schemas.microsoft.com/
  analysisservices/2003/engine/2/2" xmlns:ddl100_100="http://schemas.microsoft.com/
  analysisservices/2008/engine/100/100" xmlns:ddl200_200="
  http://schemas.microsoft.com/
  analysisservices/2010/engine/200/200" xmlns:dwd="http://schemas.microsoft.com/
  DataWarehouse/Designer/1.0"
  xsi:type="RelationalDataSource"
  dwd:design-time-name="59d9b6d8-4394-40a9-b793-13fd819b892f"
  xmlns="http://schemas.microsoft.com/
  analysisservices/2003/engine">
  <ID>Comp Sales2008</ID>
  <Name>Comp Sales2008</Name>
  <CreatedTimestamp>0001-01-01T00:00:00Z</CreatedTimestamp>
  <LastSchemaUpdate>0001-01-01T00:00:00Z</LastSchemaUpdate>
  <ConnectionString>Provider=SQLNCLI10.1;
    Data Source=DBARCH-LT2\SQL08DE01;
    Integrated Security=SSPI;Initial Catalog=CompSales2008
</ConnectionString>
  <ConnectionStringSecurity>Unchanged</ConnectionStringSecurity>
  <ImpersonationInfo>
    <ImpersonationMode>ImpersonateAccount</ImpersonationMode>
    <Account>DBARCH-LT2\DBARCH</Account>
    <ImpersonationInfoSecurity>PasswordRemoved</ImpersonationInfoSecurity>
  </ImpersonationInfo>
  <Timeout>PT0S</Timeout>
</DataSource>
```

You can also choose the View Designer option on this data source entry, which allows you to view and modify the properties of the data source entry.

Creating Data Source Views

Because you will be basing your cube on a data warehouse/data mart star schema you already have available, you need to further define exactly what you need to have access to within that data source. Creating a data source view essentially allows you to look more deeply into the metadata of the data source and add additional relationships, create things like calculations, and set logical keys on the metadata of the data source. You start by right-clicking the Data Source View object in the Solution Explorer and selecting New Data Source View (or choosing Project, New Data Source View). This starts the Data Source View Wizard, which you use to define what view of data to use for the cube. The first dialog box allows you to select a data source to use as the basis of the data source view.

Figure 51.11 shows the data source `Comp Sales2008` that you defined earlier. Chose it and click Next.

FIGURE 51.11 Identifying which data source to use for the view in the Data Source View Wizard.

If you need to limit the data source to a particular schema within the database, you can click the Advanced button and specify a schema (or schemas) to be restricted to and retrieve any foreign key and primary key relationships that may exist.

If your schema doesn't include foreign key specifications, you can use this wizard to try to discover foreign key relationships, using a few different types of column name matching. Figure 51.12 shows an example of using a simple primary key column name matching technique to identify any foreign key relationships with other tables in your schema. If you have used some type of common naming convention on your source tables, you can easily leverage this name-matching dialog.

You essentially can identify the following:

- ▶ Matches based on the exact column name match (as compared to the primary key column):
Order.CustomerID (foreign key) → Customer.CustomerID (primary key)
- ▶ Matches based on the column name being the primary key table name:
Order.Customer → Customer.CustomerID (primary key)

- Matches based on similar column name by comparing the table name concatenated with its primary key column name and then loosely comparing it to other column names of other tables:

Order.CustomerID → CustomerID (concatenated to Customer+ID=CustomerID)

Order.Customer ID → CustomerID

Or Order.Customer_ID → CustomerID

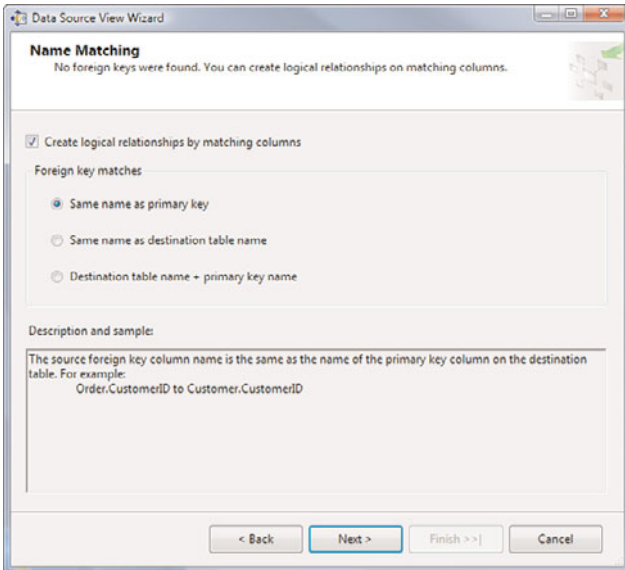

FIGURE 51.12 Logical relationship discovery, using column-naming matching in the Data Source View Wizard.

In this example, we used some good naming conventions for columns, so you can simply specify the first option (match based on exact column match). This is the lead-in to select the tables (and/or views) you need to be included from your data source. As you can see in Figure 51.13, you can choose from any number of objects. You must select the base tables you need in your data source views. These are the `CompSalesFactoid`, `Geo_Dimension`, `Prod_Dimension`, and `Time_Dimension` tables. However, you should also click the `Add Related Tables` button to add all related tables, based on the matching technique you specified earlier. We've seen a little inconsistency of the wizard not adding all related tables properly. Please double check the list of tables with our figures list (Figure 51.13). This completes the set of tables that comprise the data source views for your cube.

You now complete this wizard by naming the data source views (`Comp Sales2008 DSV`) and clicking `Finish`.

When you exit the wizard, you end up in the designer view in Visual Studio, with a graphical representation of the data source views that will be the basis of the cube you are

building (see Figure 51.14). This figure highlights the primary fact table (CompSalesFactoid), the primary dimension tables (Time_Dimension, Prod_Dimension, Geo_Dimension), and all tables related to these dimensions (that contain the values/descriptions of the member entries for the hierarchies of the dimensions).

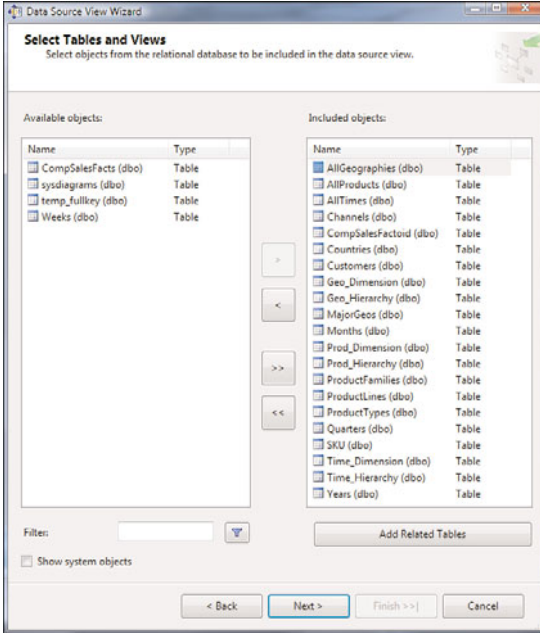

FIGURE 51.13 Available and included objects for your data source views in the Data Source View Wizard.

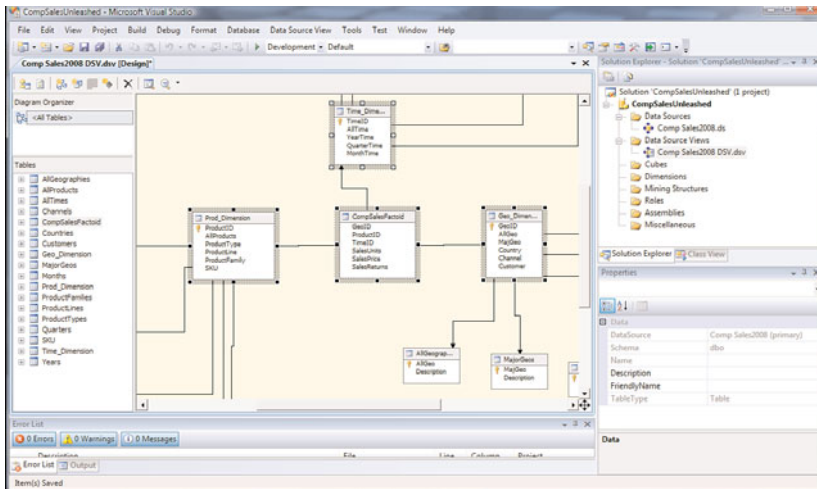

FIGURE 51.14 A designer graphical representation of the data source views.

Now, because you have fully specified data source views, you can easily define a cube via the Cube Wizard. Or you can start defining your cube's dimensions and then use these dimensions in the Cube Wizard later. Because you know your source database well, you should go ahead and create your dimensions and hierarchies first.

Defining Dimensions and Hierarchies

You are now ready to start defining dimensions and hierarchies to your database. Dimensions are the building blocks for cubes in SSAS. You start by right-clicking the Dimension object in the Solution Explorer (or choosing Project, New Dimension). You can create a new (standard) dimension or define a dimension that is linked to another SSAS cube or database.

For this example, you will be creating three new cube dimensions, based on the dimension tables you have in your data source views (`Time_Dimension`, `Prod_Dimension`, `Geo_Dimension`). When you choose the New Dimension option, you are welcomed to the Dimension Wizard. You need to build the new dimensions by using your data source views. As you can see in Figure 51.15, the first wizard dialog prompts you to specify whether you will be using a data source to create a dimension. This is the wizard build method. If you haven't defined any data sources (and perhaps don't have them yet), you can use a template approach to define dimensions. This is the bottom-most option on this dialog. If you want a time dimension but do not have a previously defined set of tables that represent your time dimension (in your data source), you can choose the second or third options to generate a well-formed time representation via this wizard. We discuss this option later. You do have a valid data source to use, so you will use the first option to create your first dimension (which is a Time Dimension based on the `Comp Sales 2008` data warehouse/mart `Time_Dimension` table).

When you choose the first option (Use an Existing Table), you are prompted to identify the data source view you want to use to provide data to the new dimension. Because you have already defined the data source view in a previous step (the `Comp Sales2008 DSV` data source view), it should be available for you to use. Figure 51.16 shows the `Comp Sales2008 DSV` data source views and all the tables available for your use. You should highlight this data source view along with the main table the dimension will be based on (`Time_Dimension` table in this case). As you can see in Figure 51.17, the key columns show up automatically. The fact table's time is keyed by a pseudo-key called `TimeID`, with no other key columns needed. You have a chance to identify any other columns you might also want to include in this dimension (do not do so in this example though) and click Next.

You have probably noticed that the time dimension table has all the other levels of the time dimension hierarchy as separate columns in it. A few related tables to this time dimension table hold the member value descriptions that correspond to each level in the hierarchy. It is really nice to have the member-level descriptions available in the cube for ease of use by the end user. It is pretty easy to include these related tables in the next step of generating this dimension. Figure 51.18 shows the list of related tables identified earlier in the data source views. You need to check all the related tables for inclusion in the time dimension and click Next (they are likely already checked automatically).

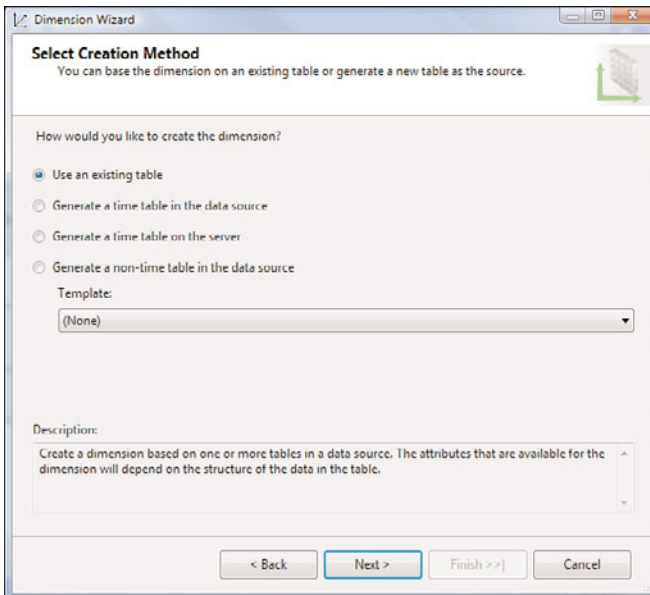

FIGURE 51.15 Creating a dimension by using a data source in the Dimension Wizard.

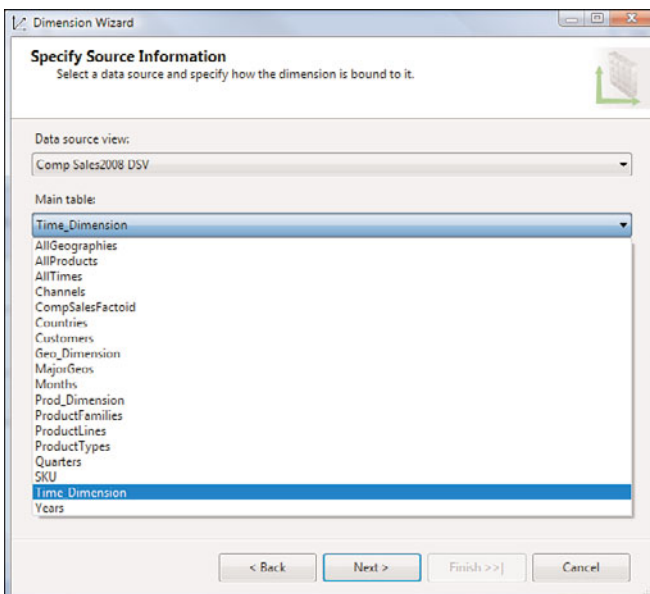

FIGURE 51.16 Identifying which data source views to use for a dimension in the Dimension Wizard.

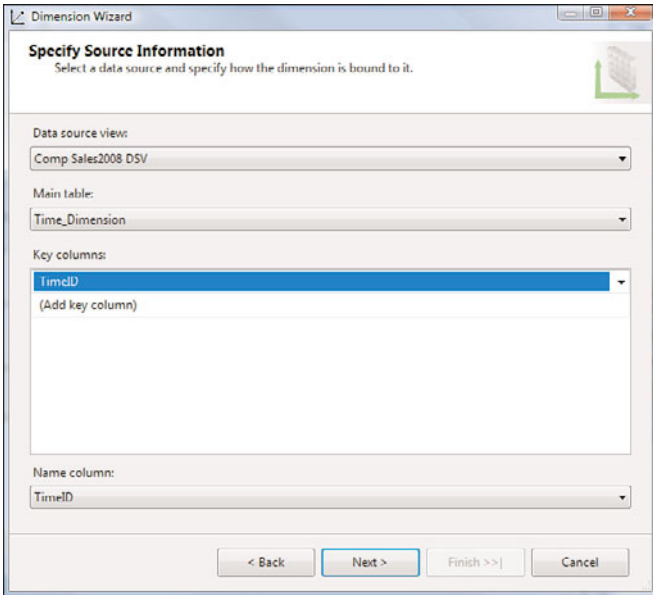

FIGURE 51.17 The key column of the table the dimension is based on.

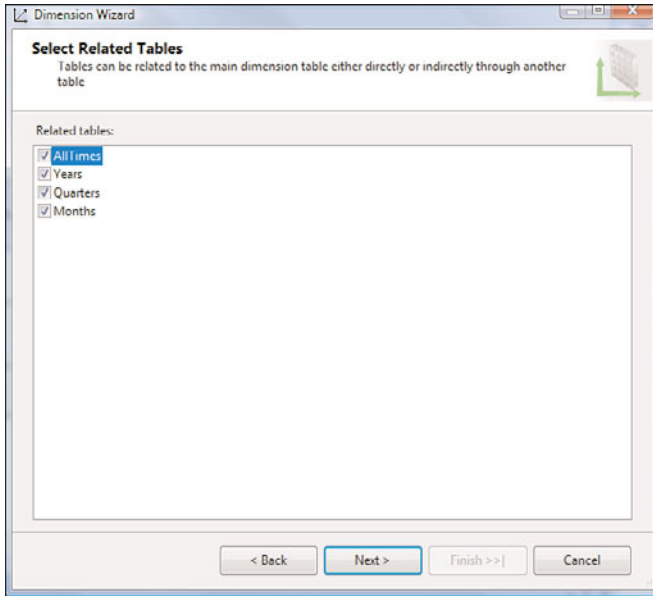

FIGURE 51.18 Including the related member description tables in the dimension in the Dimension Wizard.

It is now time to select the attributes you want to include in the dimension. As shown in Figure 51.19, the Dimension Wizard presents a Dimension Attributes list, along with the

attribute key column and attribute name column correspondences. You need to identify the correct key column value from your data source views for Attribute Key Column. You also should enable these attributes for browsing for your dimension; this essentially makes them available (surfaces them) in your dimension hierarchy. Notice also that you identify the types of attribute characteristics. The default is the Regular attribute for general use. Several other attribute types correspond to the anticipated behavior or characteristics of the attribute itself. They might follow date-based behavior, currency type behavior, or other variations such as slowly changing attributes (and hence slowly changing dimensions). For this example, you check the check box for each dimension attribute you need: All Time, Year Time, Quarter Time, and Month Time, along with the dimension key itself (TimeID). Then, for the selected dimension attributes, you specify the attribute type Regular, check the box for enabling these attributes for browsing, and click Next.

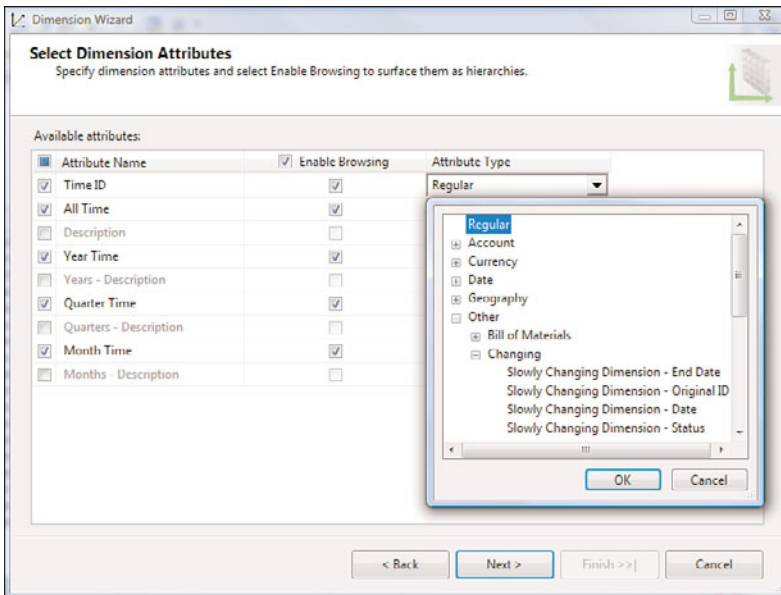

FIGURE 51.19 Selecting dimension attributes and attribute types for the dimension in the Dimension Wizard.

As you can see in Figure 51.20, the last step of the dimension generation process shows you the summary of what you have defined and prompts you to name the dimension you are about to create (Time_Dimension in this case).

After you click Next, you are placed in the dimension designer for the dimension you just created. In addition, a dimension entry is added to the Solution Explorer, and now you can easily create the hierarchical view for this dimension. This task is quite easy because all the attributes that represent a level in a hierarchy are visible (because you enabled them), and you can simply drag them into a hierarchy from within this designer. As you

can see in Figure 51.21, you can click and drag any attribute listed in this dimension from the Attributes pane (on the far left) to the Hierarchies pane. A new hierarchy is created automatically when you pull your first attribute into this work area. Your goal is to create the following hierarchy for the time dimension (in this order, from top to bottom):

1. All Time
2. Year Time
3. Quarter Time
4. Month Time

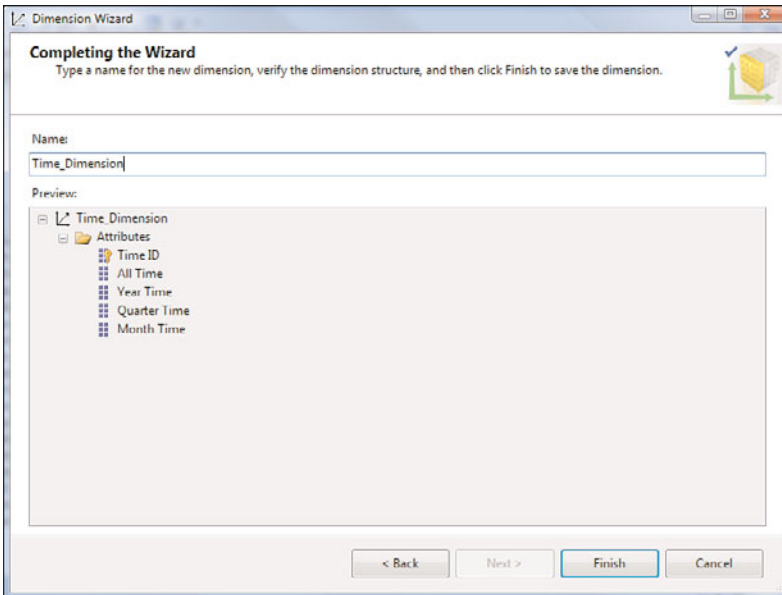

FIGURE 51.20 Finishing the generation of the time dimension.

In addition, from this designer, you can click on the Attribute Relationships tab to see how the dimension key relates to any of the other attributes you have defined in the dimension. Usually, there is a correspondence of the key attribute to each of the hierarchy levels (which show how they can be used). Figure 51.22 shows what was generated by the Dimension Wizard. If you need to specify other attribute relationships, you can easily do so here.

If you want to browse the data that will make up your dimension that is coming from the data source, you must first process your dimension (populate the values that represent the dimension and hierarchy). A process icon (the second icon) in the upper-left corner of the dimension structure designer takes you through a two-step process sequence. Step one is to deploy the definitions and see whether any errors might exist. Step two is to populate the values (run the processing). If you like, you can do this now. When this sequence is

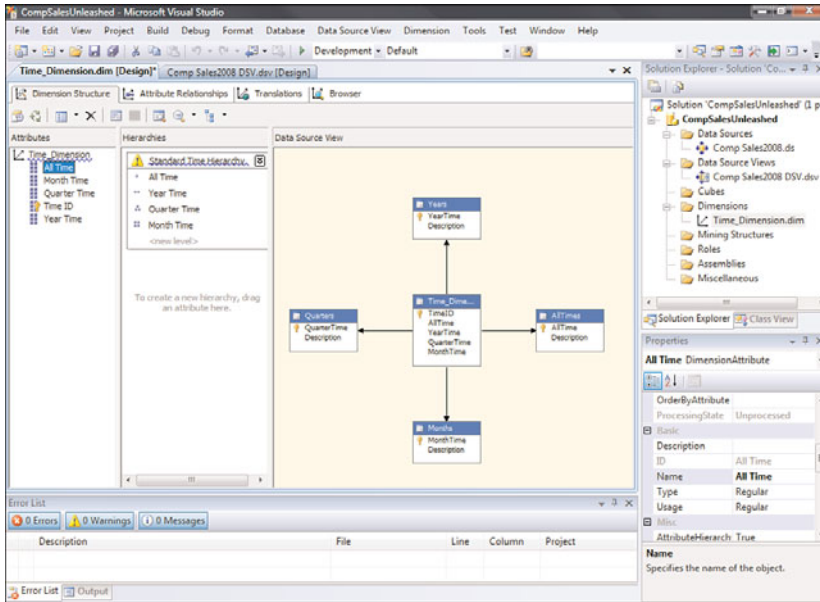

FIGURE 51.21 Creating the time hierarchy in the dimension designer.

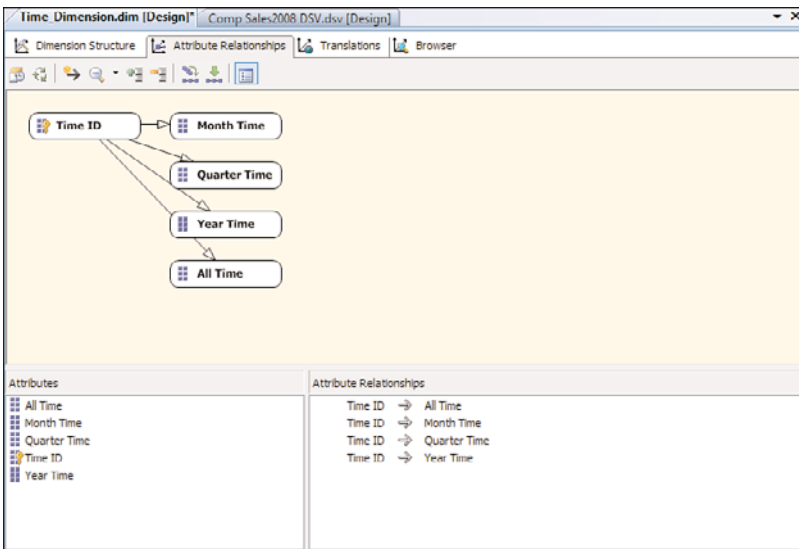

FIGURE 51.22 Attribute relationships in your dimension.

done, you should be able to open the Dimension Browser and navigate around in your fully populated dimension hierarchy (as shown in Figure 51.23).

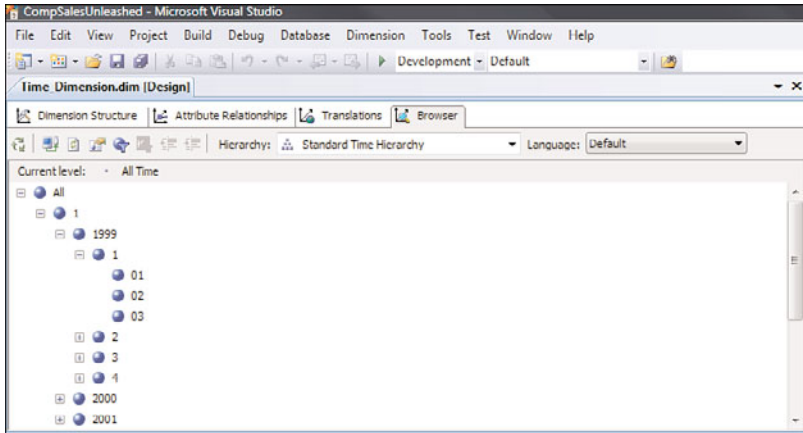

FIGURE 51.23 Browsing the time dimension hierarchy.

You will probably notice that the data values being displayed in the time hierarchy are numeric. These are the key values of each level in the hierarchy. If you want to see the full description of the hierarchy values instead of just the key values, you can easily modify the properties of each hierarchy level column's `NameColumn` and `ValueColumn` properties to have them pull the descriptive (more natural) values from the related table entries. You simply browse down into the property window of any level of the hierarchy and update the values with the corresponding column names of the related table's description column name. The window at the top of Figure 51.24 shows the top-level column (All Times) column properties with nothing identified in its `NameColumn` or `ValueColumn` properties (actually (none) is the default). The window at the bottom of Figure 51.24 shows the same properties updated with the corresponding description columns from the corresponding reference table.

You can now update each level in the hierarchy in the same way (with the corresponding description column for each time hierarchy level) and then reprocess the dimension. When you reload the dimension in the Dimension Browser, you see the full description values displayed, as shown in Figure 51.25.

That's it! You have just generated your first usable dimension for the cube!

If you didn't have such a well-defined data source set of tables to base your time dimension on, you could use either of the other two kinds of time dimension options within this wizard. As you can see in Figure 51.26, you need to specify the date periods that will be used when generating the hierarchies, along with the corresponding attributes (time table columns). Setting these attributes is relatively standard.

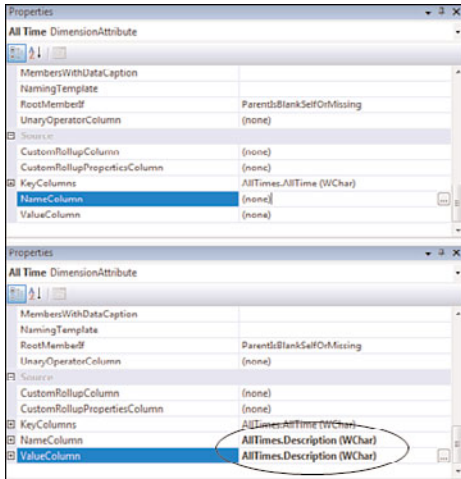

FIGURE 51.24 Updating the **NameColumn** and **ValueColumn** properties of a dimension hierarchy.

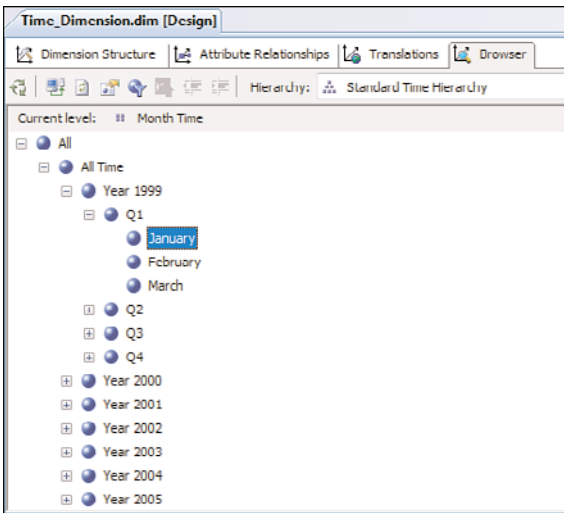

FIGURE 51.25 Full descriptions of hierarchy levels.

Figure 51.27 shows the different server time dimension options that Microsoft provides for your convenience. Microsoft has tried to cover the primary variations of time dimensions and calendars in the market: Fiscal, Reporting (for example, for Marketing, which also includes week-by-month patterns such as 4-4-5 calendars), Manufacturing, and even ISO 8601 calendars. The process is to first identify a time period and then select the calendar type to use. The wizard then creates a server time dimension that meets your needs.

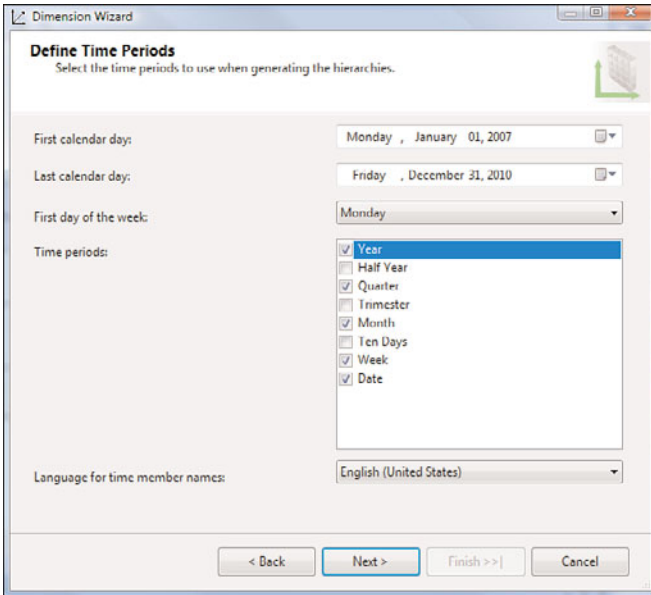

FIGURE 51.26 Specifying the time period and hierarchy attributes when not using a data source table.

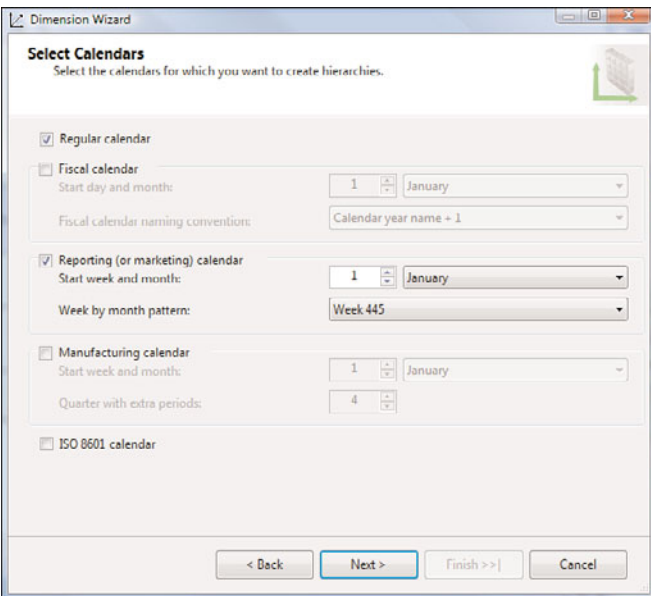

FIGURE 51.27 Calendaring options for server time dimensions in the Dimension Wizard.

NOTE

You might want to have multiple time dimensions in your cube to fulfill multiple business unit group needs. You can create as many as you need and then provide perspectives of the cube for each group that include only each group's specific time dimension for its needs.

Creating the Other Dimensions

Now you essentially need to go through the whole process of creating a dimension and a hierarchy for the other dimensions (Product and Geography). The process is as follows:

1. Invoke the Dimension Wizard (by right-clicking the Dimensions object in the Solution Explorer).
2. Choose the creation method for the dimension to use the existing table from a data source approach.
3. Specify the `Comp_Sales2008` DSV data source view.
4. Select the main dimension table to use (`Prod_Dimension` for the Product dimension and `Geo_Dimension` for the Geography dimension).
5. Identify the key column of each new dimension (`ProductID` for the Product dimension and `GeoID` for the Geography dimension).
6. Select the related tables.
7. Specify the dimension attributes and the attribute types (regular).
8. Name the dimension (`Product_Dimension` and `Geography_Dimension`) and finish the Dimension Wizard (which places you in the dimension designer).
9. Drag the dimension attributes to the Hierarchies pane to create the dimension hierarchy view:
 - ▶ Use the following product hierarchy, in this order (see Figure 51.28):
 1. All Products
 2. Product Type
 3. Product Line
 4. Product Family
 5. SKU
 - ▶ Use the following geography hierarchy, in this order (see Figure 51.29):
 1. All Geo
 2. Maj Geo
 3. Country
 4. Channel
 5. Customer

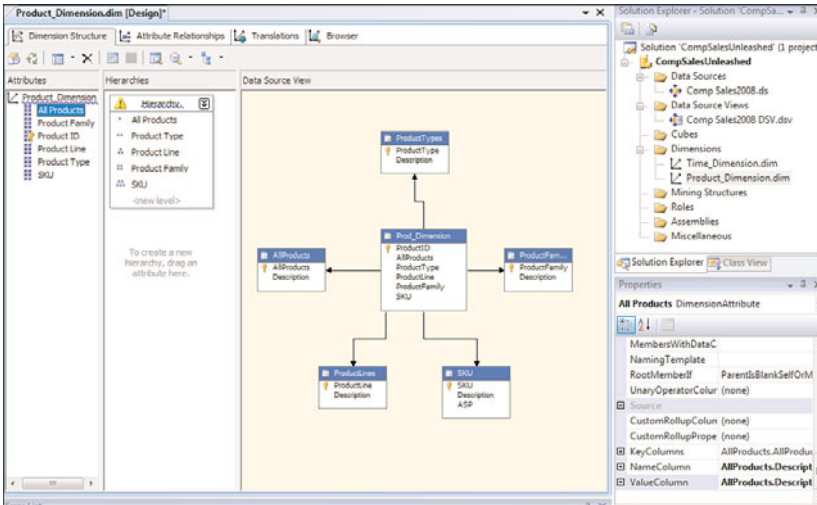

FIGURE 51.28 Creating the product hierarchy in the dimension designer.

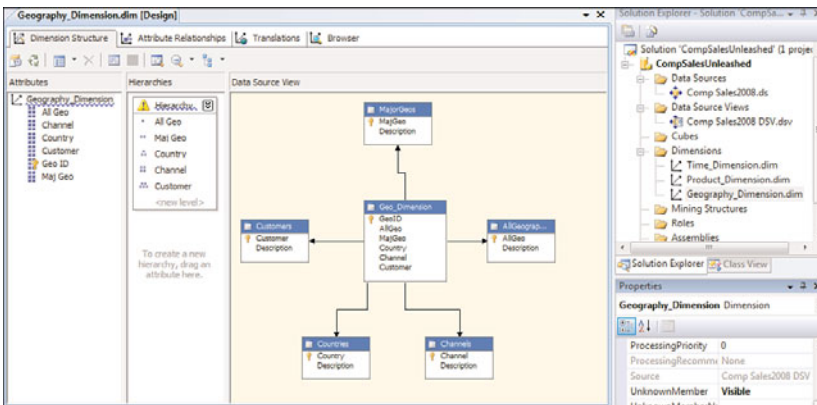

FIGURE 51.29 Creating the geography hierarchy in the dimension designer.

10. Update the NameColumn and ValueColumn properties of each dimension hierarchy level.
11. Process the dimension and browse the dimension.

Creating the Cube

Most of the hard work in the CompSales International example is done. All that is left to do now is to create a cube that is based on your fact tables in your data source, use the dimensions and hierarchies you just defined, and then process it (that is, populate the cube with data). In the Solution Explorer, you right-click the Cubes object and select New Cube. This invokes the Cube Wizard, as shown in Figure 51.30.

Next, you identify the measure group tables from the data source view that will be used to provide data to the cube. Available data source views are listed in this dialog. Because you

have already defined a data source view (Comp Sales2008 DSV), you simply highlight it and check the primary fact table (use CompSalesFactoid as your Measure group table) that will provide your data, as shown in Figure 51.31, and click Next.

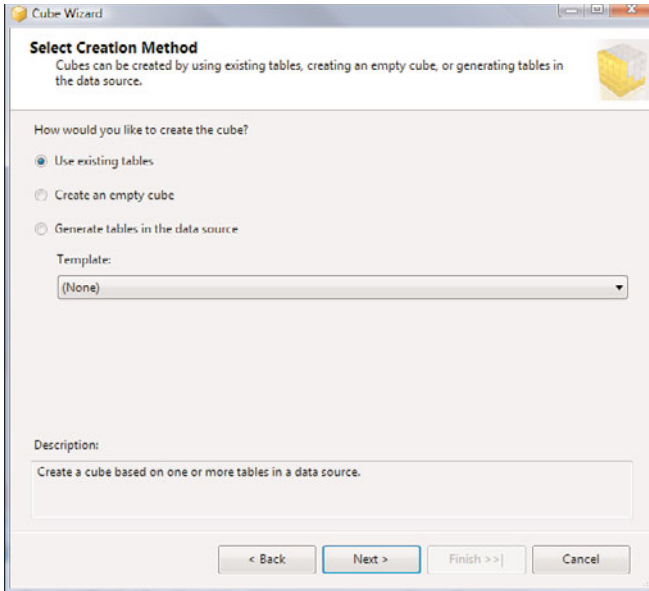

FIGURE 51.30 Selecting the build method for the cube in the Cube Wizard.

The wizard detects the possible data measures (facts) from the measure group table you just identified. In this measure group table, there are Sales Units, Sales Prices, Sales Returns, and a Count measure to choose from. Select all of them, as shown in Figure 51.32.

If you have dimensions defined already (as you chose to do earlier), you want the new cube to use these definitions. The next wizard dialog lists any shared dimensions that have been created already. Your dimensions are listed there, and you need to check all the ones to be used for your cube (Time_Dimension, Product_Dimension, and Geography_Dimension), as shown in Figure 51.33. Then you click Next.

As you can see in Figure 51.34, the last dialog in this wizard shows a preview of your complete cube definition and provides a place to name the cube (for this example, name it Comp Sales). Now you click Finish.

You are now put in the cube designer, which shows the completed cube design for Comp Sales. The cube designer provides all related cube information within the single IDE (Visual Studio). Figure 51.35 shows the cube designer and all related tabs that can be invoked from here (Dimension Usage, Calculations, KPIs, Actions, Partitions, Aggregations, Perspectives, Translations, and the Cube Data Browser).

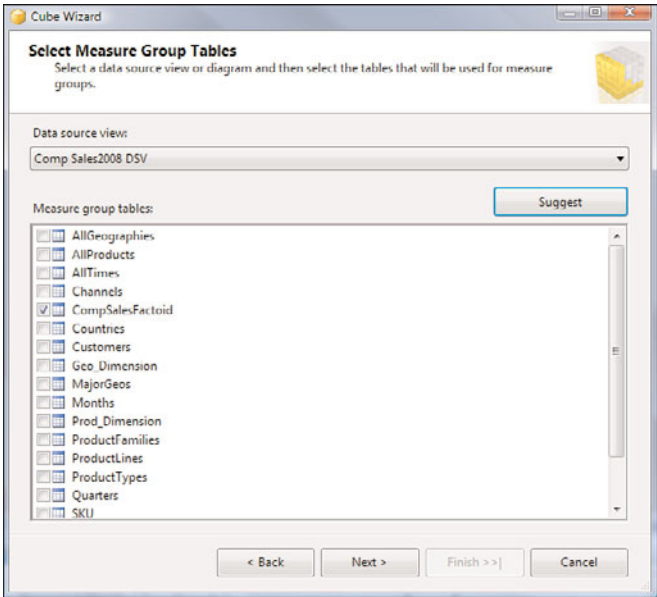

FIGURE 51.31 Selecting the data source view and measure group table to use for the cube.

FIGURE 51.32 Selecting the measures (facts) that will be in the cube.

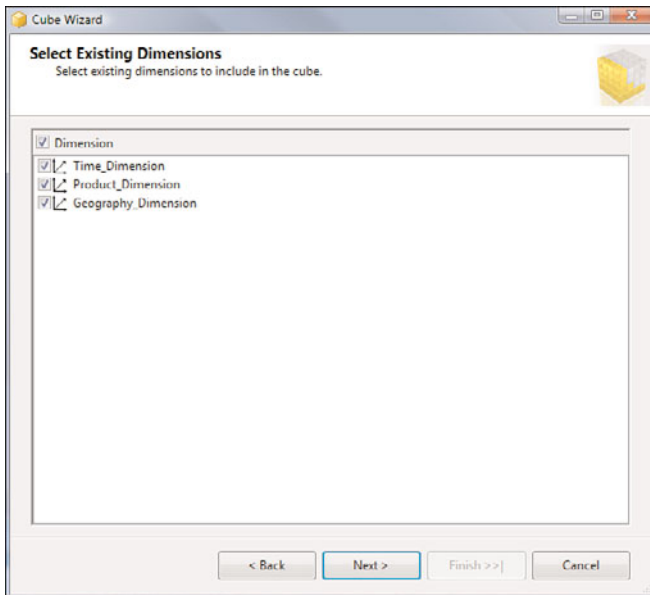

FIGURE 51.33 Selecting the existing dimensions for your cube.

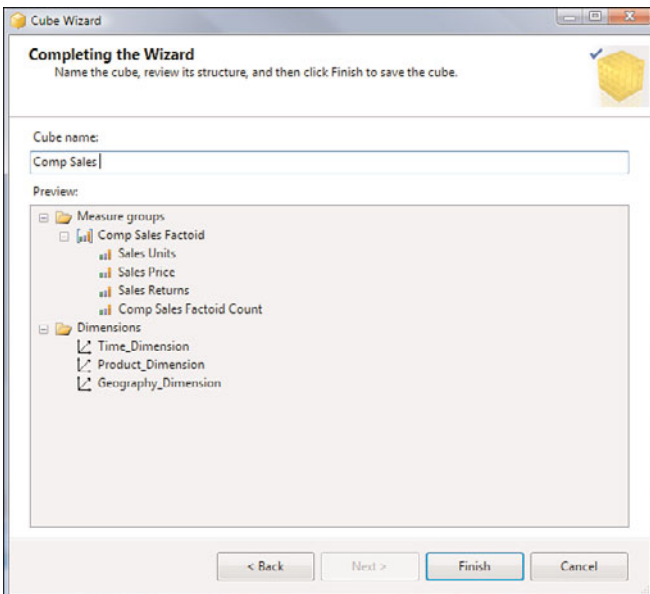

FIGURE 51.34 Naming the cube and previewing the cube definition in the Cube Wizard.

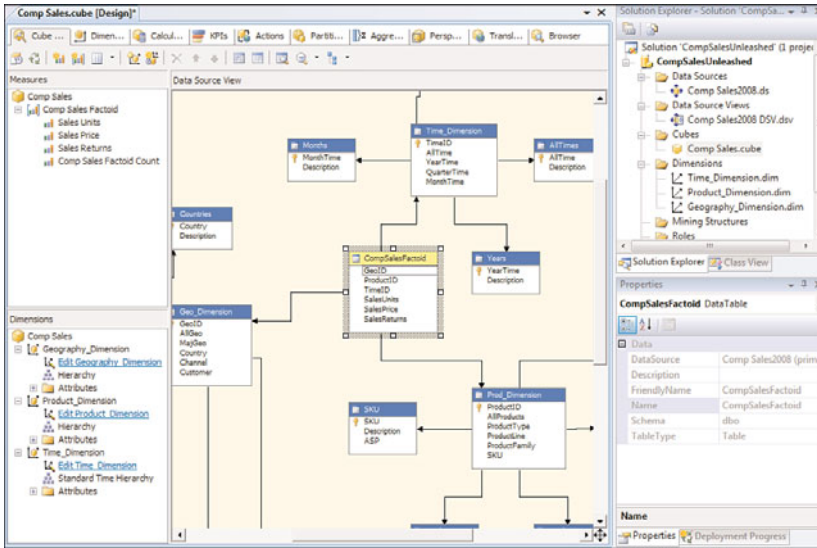

FIGURE 51.35 The Comp Sales cube definition in the cube designer.

Building and Deploying the Cube

You basically have a cube definition now, but it is just an empty shell. You need to process it and then deploy it so that it is instantiated and populated with data (via the data source view). Remember that this cube definition is a solution project, just like a C# code project. It must be deployed before it can be used. First, you need to verify that the properties of the cube you are building are set correctly. You must have these properties correct before the cube can be processed. (*Process*, in this case, means build the cube structure and populate the measures and their associated dimensions.) You can assume that the properties will not be set correctly, so you should take a quick look and update them accordingly. You start by going to the Project menu item in Visual Studio and locating the Properties item entry (see Figure 51.36).

After you select this option, you navigate to the Deployment entry (the configuration property on the bottom). You need to focus on the Target (the target of the deployment) properties. As you can see in Figure 51.37, the Server property should be pointing to the location where you want this cube to be deployed. The Database property is simply the name under which you will deploy the database. For this example, you should make sure to specify a valid Server value; the default is (localhost). The default in this property usually is not what you want to happen and usually results in an error during the deployment step. Therefore, you should specify this value explicitly (such as DBARCH-LT2\SQL08DE01, which is the Analysis Services server, and CompSalesUnleashed as the Database entry). After the cube is deployed, you will be able to connect to this server (SSAS engine) with SSMS and administer the cube accordingly.

After you apply these property changes, you are ready to first do a build and then deploy your SSAS cube. You start by making sure you have a successful build by using the Build menu item on the toolbar or using the specific build option for the current SSAS solution: Build CompSalesUnleashed. They both do the same thing. If you have no errors (and you have received a Build Succeeded message in the lower-left message bar of Visual Studio), you can deploy this SSAS solution.

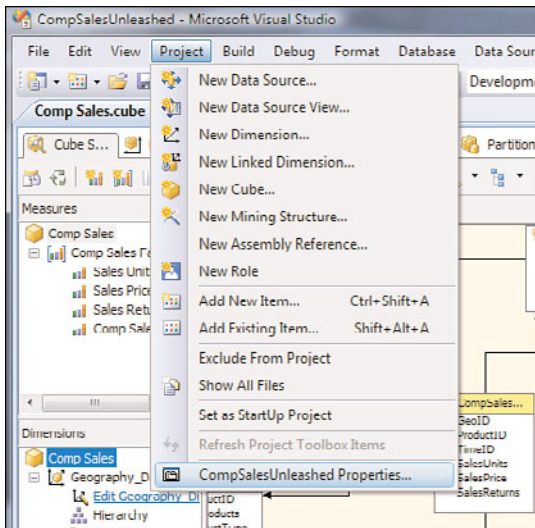

FIGURE 51.36 Selecting the cube properties for Comp Sales from the Project menu.

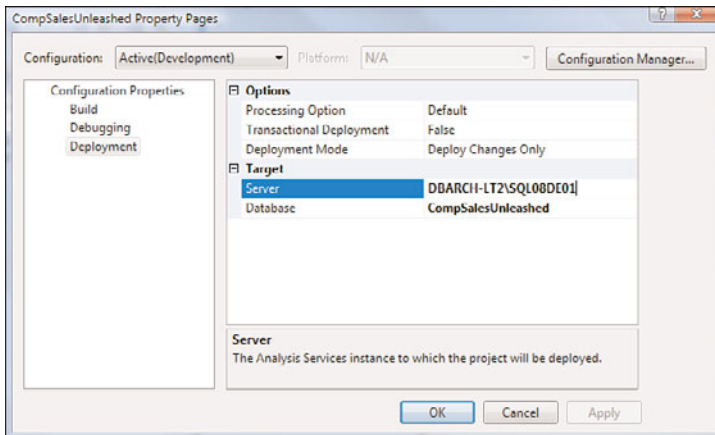

FIGURE 51.37 Deployment properties for the Comp Sales cube.

Again, you should choose the Build menu item in the toolbar and click the Deploy Solution option to deploy this cube. Immediately, a Deployment Progress dialog box appears in the lower-right corner of Visual Studio. When the deployment has progressed, you receive a Deployment Completed Successfully message.

Populating the Cube with Data

Now you can process actual data into your cube from the data source view. To do so, you right-click the Comp Sales cube entry in the Solution Explorer and choose the Process item or choose the Process icon for the cube in the cube designer (second icon from the left in the cube designer). A Process Cube dialog appears, with the object list of available

cubes to process. You select the Comp Sales cube (by highlighting it) and then click the Run button to start the processing of data (see Figure 51.38). You can also see in Figure 51.38 that the Process Option defaults to Process Full. Other options here vary depending on what part of the cube needs to be reprocessed (such as when you have structure changes, data refreshes, incremental data changes, so on).

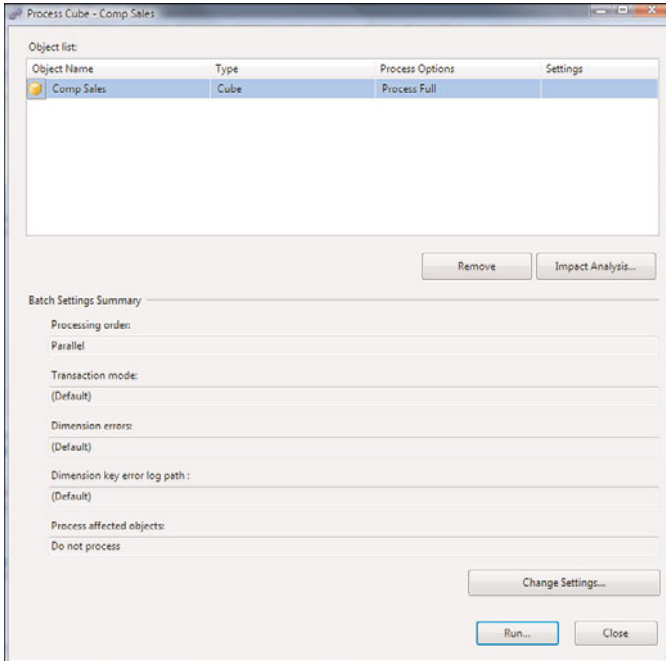

FIGURE 51.38 Process Cube dialog for Comp Sales.

A Process Progress dialog appears as the processing begins. Remember that this data is the dimension member values and the measure data values and has not been aggregated up through a complete cube representation (at all levels in the hierarchies). That will be done shortly, via the Aggregation Design Wizard. You can actually use your cube right now, but browsing would be challenging from a performance point of view.

Aggregating Data Within the Cube

The last step of creating your OLAP cube is running through the Aggregation Design Wizard and determining how best to represent and aggregate the data for your users. This is point at which you must determine the optimal aggregation levels and storage method for these aggregations (MOLAP, HOLAP, or ROLAP) for the optimal performance of queries against the cube.

You double-click the cube entry in the Solution Explorer (Comp Sales.cube) to bring up the cube designer for your newly created cube. Then you click the Partitions tab to see the current partition for Comp Sales. Figure 51.39 shows the default storage mode is MOLAP

and that there is no Aggregation Design for this cube yet. Just to the lower right of this tab is the Storage Settings option, which shows the different storage options possible for your partition, as shown in Figure 51.40.

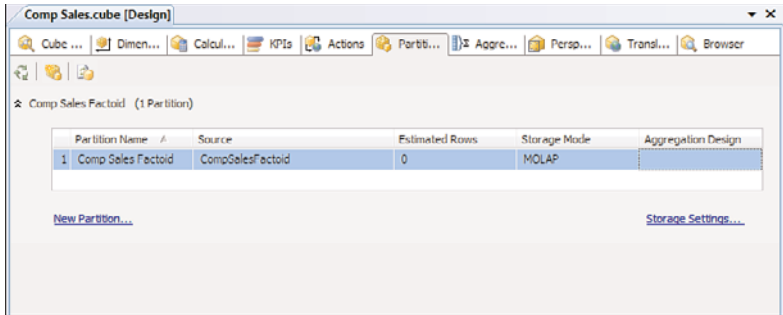

FIGURE 51.39 The Partitions for the Comp Sales cube.

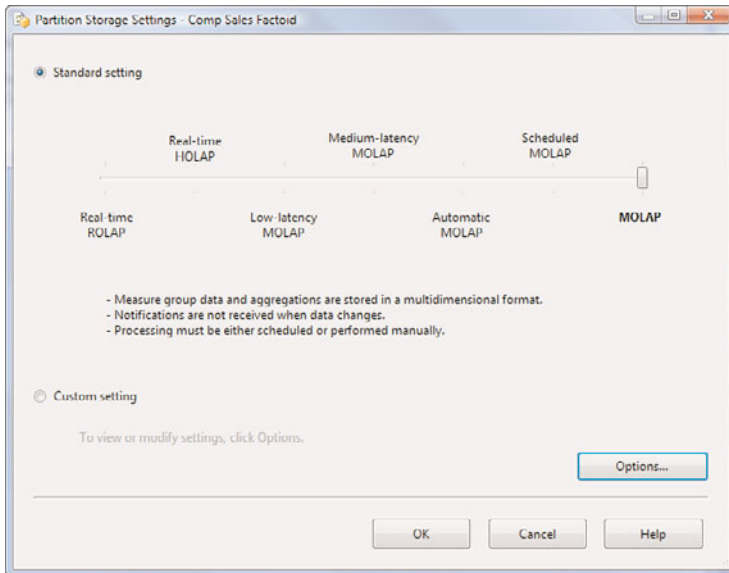

FIGURE 51.40 Specifying MOLAP storage mode for your cube in the Storage Settings dialog.

You need to indicate what type of storage mode and caching options you want for the partition that will contain your aggregations (these storage modes are discussed earlier in this chapter). You want to optimize performance and don't need real-time refreshes of the data. For these reasons, you specify the MOLAP (native SSAS storage) mode. Figure 51.40

shows this MOLAP specification in the Storage Settings dialog. This dialog works as a sliding scale. You just need to make sure the slider is positioned at the MOLAP storage option.

You also want to take advantage of the proactive caching capabilities that come with SSAS. You can activate this feature by clicking the Options button of this dialog and then checking the Enable Proactive Caching check box at the top of the Storage Options dialog that appears (see Figure 51.41). In addition, you use the option Update the Cache When Data Changes, as indicated in Figure 51.41 along with interval times for these refreshes.

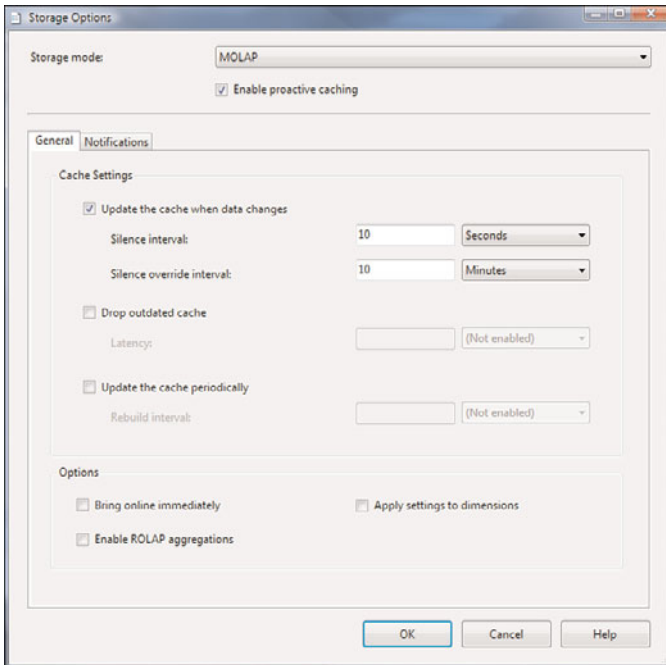

FIGURE 51.41 Enabling proactive caching for the cube.

A good rule of thumb is to refresh the cache interval based on response requirements and the volatility of the data from the data source views and whether the changes will have a dramatic effect on the BI query results.

Now you can run through the Aggregation Design Wizard to see whether you can optimize your partition for querying. You simply go to the Aggregation Design tab for this cube (from the cube designer) and choose the Design Aggregations option (click the first icon in the Design Aggregations tab or right-click within the Aggregation Design tab and choose Design Aggregations). This launches the Design Aggregation Wizard.

First up is the dialog that allows you to specify object counts of the total population of facts and the number of values at each hierarchical level within each dimension. If you know what the full extent of counts will be for your cube, you can manually supply these count values in the Estimated Count column (see Figure 51.42). You typically do this when you have been able to load only a partial amount of data or the data will grow quite rapidly over time. If you are building a statically sized cube and have populated the data already, you just click the Count button to tell the wizard to use the actual data as the basis of the aggregation.

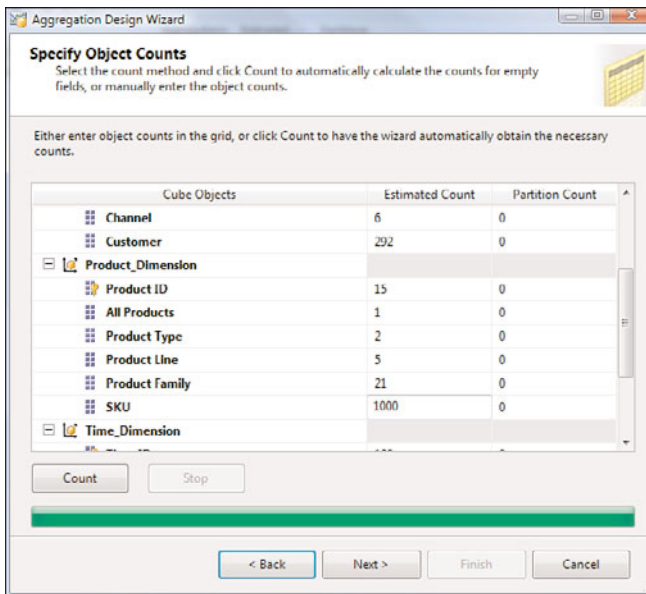

FIGURE 51.42 Specifying cube object counts for aggregation in the Aggregation Design Wizard.

The next dialog optimizes the storage, based on the level of aggregation. You can specify a maximum storage approach (you create optimized storage based on the amount of disk space you can allocate to the cube), tell the wizard to simply optimize to achieve a certain percentage of performance gain (for example, 50%, 80%), specify to start the aggregation design process dynamically, and stop when you feel the cube is optimized enough, or do no design aggregation at all. You really want to see the design aggregation process happen. Remember that the higher the performance you want, the more storage it will require (and the longer it will take to reprocess the aggregations). As you can see in Figure 51.43, you should select the I Click Stop option and stop the design aggregation when the optimization level starts to level off (somewhere between 75% to 88% optimization level). Any further optimization would really just waste storage space.

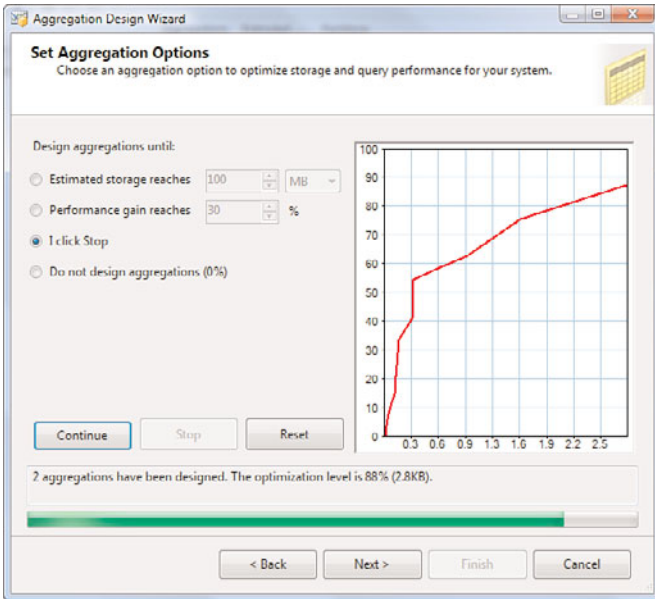

FIGURE 51.43 Setting the optimal storage and query performance level in the Aggregation Design Wizard.

When you are satisfied with the aggregation design, you simply click NEXT and name this design (the sample is named `AggregationDesignPrimary`, as you can see in Figure 51.44). You then assign this design aggregation to the partition to use in the Partition tab.

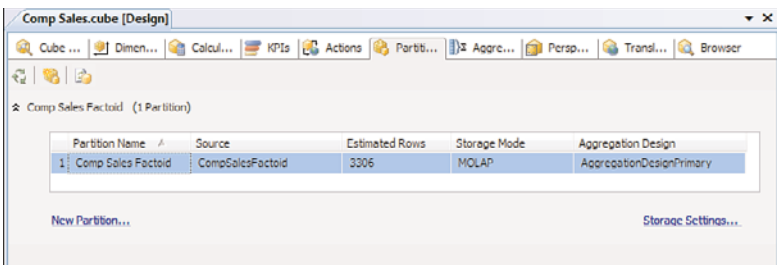

FIGURE 51.44 Resulting aggregation design to be assigned to the Comp Sales Factoid partition.

If your company has sales transaction data for the past five years and 250 stores that sell an average of 1,000 items per day, the fact table will have 456,500,000 rows. This is obviously a challenge in terms of disk space by itself, without aggregation tables to go along with it. The control that SSAS provides here is important in balancing storage and retrieval speed (that is, performance versus size). Aggregations are built to optimize rollup opera-

tions so that higher levels of aggregation are easily derived from the existing aggregations to satisfy broader queries. If a high degree of query optimization weren't possible due to limitations in storage space, SSAS might choose to build aggregates of monthly or quarterly data only. If a user queried the cube for yearly or multiyear data, those aggregations would be created dynamically from the highest level of pre-aggregated data. With disk storage becoming more and more inexpensive and servers becoming more powerful, the tendency is to opt for meeting performance gains. A recommended approach is to specify between an 80% and 90% performance gain here.

You are now ready to complete the Aggregation Design Wizard. The final step is to either process this aggregation or save your results and process it later. You should choose to process this aggregation now and then click Finish (see Figure 51.45). The Process Progress dialog appears immediately, and you get to watch the full extent of the cube's aggregation partitions being built (that is, populated). Aggregation SQL queries are actually created under the covers to populate all these aggregation levels (which are implementing your design levels). It's nice to have Microsoft dynamically create these complex queries for this critical performance optimization step so you don't have to worry about it yourself.

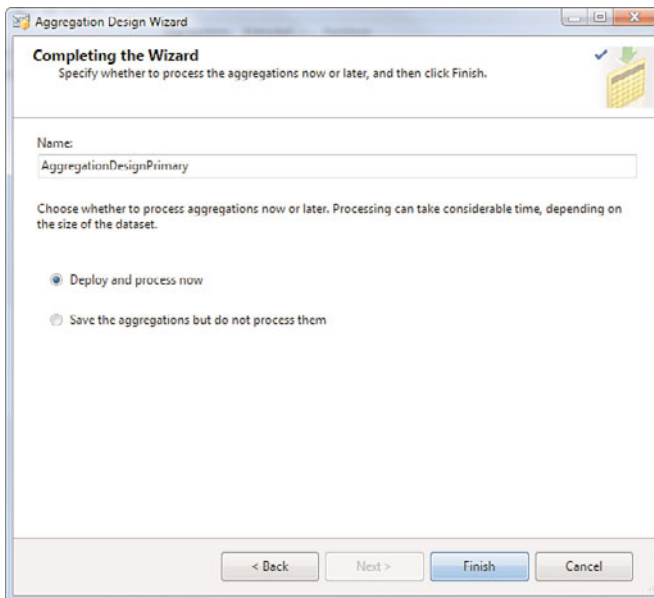

FIGURE 51.45 Deploy and process the aggregation now to complete your cube.

When this step completes, you have a fully optimized cube that is ready for data browsing. Congratulations!

Browsing Data in the Cube

You're ready to browse some cube data now. There are several ways to view data in a multidimensional cube. OLE DB for OLAP and ADO MD expose interfaces to do this kind

of data browsing, and many leading vendors have used these interfaces to build front-end analysis tools and ActiveX controls. These tools should prove useful for developers of user interfaces in data warehousing and data mart projects. You can also easily browse a cube's data from either Visual Studio or SSMS or via any tool or facility that uses the multidimensional extensions of SQL (that is, SQL with DMX and MDX extensions).

To browse your newly created cube from SSMS, you fire up SSMS and connect to the SSAS server (Analysis Services server type) on which you deployed your cube. You should not connect to the SQL Server Database Engine. These are two completely different servers. When you are connected, you expand the Databases tree on the left until you can see the cube you created (Comp Sales, in this example).

NOTE

In Visual Studio, you can simply click the Browse tab when you are in the cube designer. All browse functionality uses the same plug-ins, whether you are in Visual Studio or SSMS. In either Visual Studio or SSMS, you can browse the cube (the entire cube with all dimensions) or just a dimension (using the dimension browser).

In SSMS, you just right-click the Comp Sales cube entry and choose the Browse option. As you can see in Figure 51.46, a multipaned, drag-and-drop interface is your view into the data in your cube.

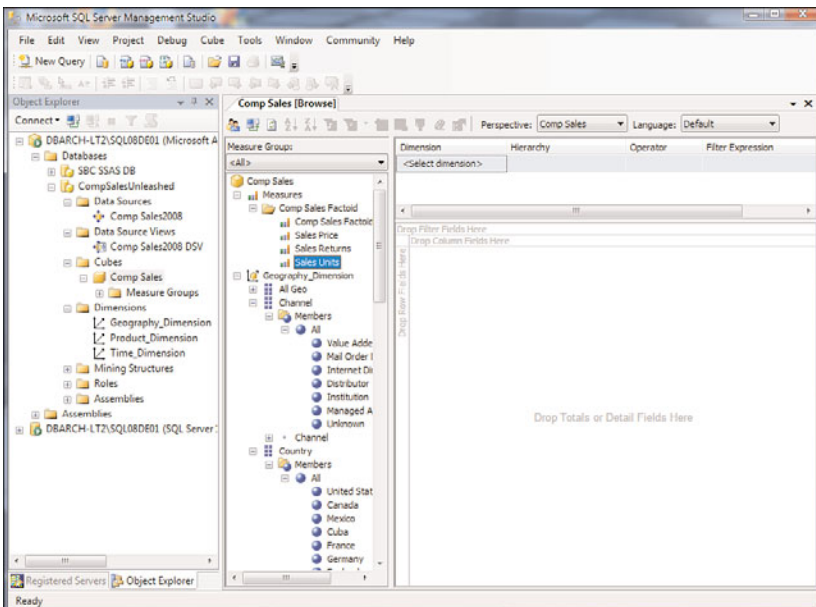

FIGURE 51.46 Browsing data in your cube in the SMSS data browser.

The middle pane lists all cube objects that you can drag into the data browsing pane (on the right). The data browser uses the Pivot Table Service to access and display your cube's data. You can expand any of the cube hierarchy objects and see the actual member entries that are in your cube for each level. This capability is helpful when you want to further filter data in the browser (for example, focus on a particular SKU value or a particular geography, such as United States or France).

The data browsing pane is easy to use. For example, say that you simply want to see all product sales and product returns for SKUs across all geographies, for each year in the cube. To do this, you expand the measures object until you see all the measures in the Comp Sales cube. Then you drag Sales Units to the center of the lower portion of the data browsing pane (into the Drop Totals or Detail Fields Here section in the lower right). You do the same for the Sales Returns measure. Data values (totals) for these measures are already displayed immediately. These are the total (aggregated) values for sales returns and sales units across all products, all geographies, and all times. To see the product breakdown of these data measures, you drag the SKU object within the product dimension object to the Drop Column Fields Here section (just above where the data measures were dropped). You immediately see the data measure values being broken out by each product SKU value. Now, you drag the Year Time object within the time dimension to the Drop Row Fields Here section (just to the left of where the data measures were dropped). You now see the data broken out by the years along the left side (rows) in the cube that contains sales and return data for products, as shown in Figure 51.47.

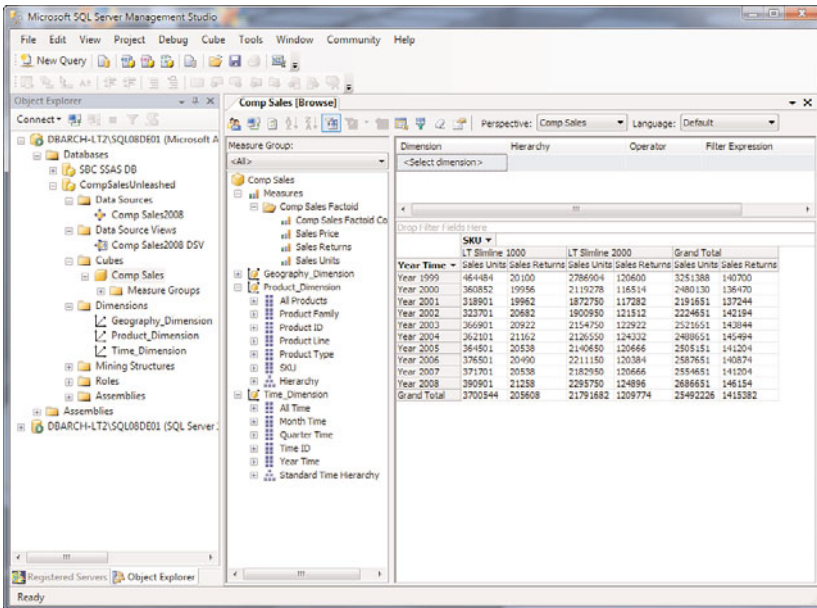

FIGURE 51.47 Sales units and sales returns for all SKUs by years in the SMSS data browser.

If you want much more drill-up and drill-down visibility into your data, you could build up a much more complicated representation in the data browser. Say that you want to see sales units and sales returns but across the full product dimension breakouts and full time dimension breakouts for the United States geographic region only. You also want to see all dimension levels, totals by levels, and grand totals by dimension. You start the same way as you did earlier and expand out the measures object until you see all the detail measures in the Comp Sales cube. If you still have the previous example in your data browser, you can simply locate the Clear Results icon in the data browser tab and clear the data browser pane. Then you drag Sales Units to the center of the lower portion of the data browsing pane (into the Drop Totals or Detail Fields Here section in the lower right). You do the same for the Sales Returns measure. Then you drag the geography dimension to the upper section called Select Dimensions or just highlight Select Dimensions and choose the geography dimension. This is the dimension-level filtering capability within the data browser. You now just select (via the drop-downs of each section within a filter specification) the level and type of filtering you want to do for the dimension you are working with. You can specify any number of filters within any number of dimensions. To just filter on countries within the geography dimension, you select Countries within the hierarchies list of the geography dimension, and the operator you want is Equal, and the filter expression is the data value that you want to filter on (the United States country value, in this case). These are all drop-down lists that you can easily select by either clicking the entry or indicating which ones to use via a check box entry. Figure 51.48 shows the fully specified Geo Dimension filter specified.

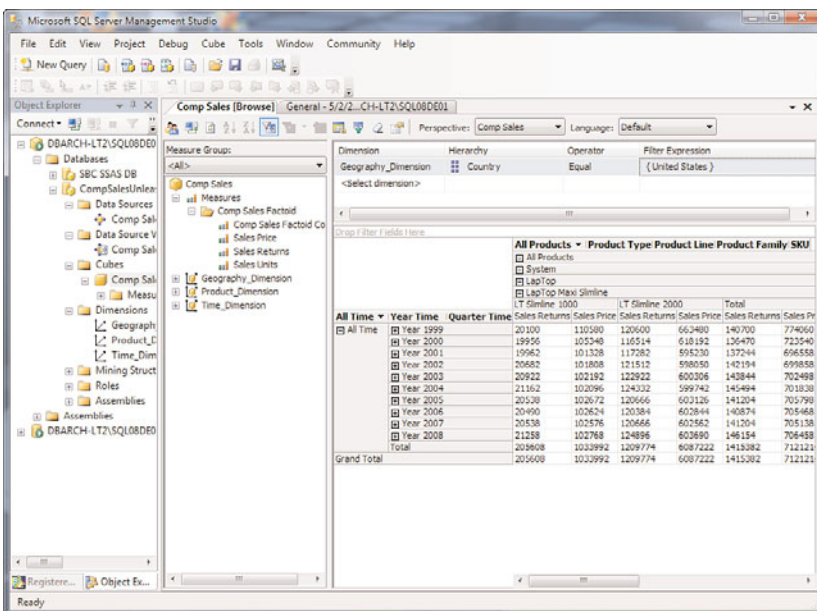

FIGURE 51.48 Complex data browsing with full dimensions and filtering in the SSMS data browser.

The data values you now see are only those of the United States. You now drag the product dimension object to the Drop Column Fields Here section (just above where the data measures were dropped). You immediately see the data measure values being broken out by the entire product dimension (you expand the plus sign of the product hierarchy all the way out to the SKU level). Then you drag the time dimension object to the Drop Row Fields Here section (just to the left of where the data measures were dropped). You can choose to view the data at any level within either the time or product hierarchies, and you can filter on any other dimension values. You can also just add a dimension or dimension level to the filter portion within the data browser or just drag off dimensions, measures, or filters from the data browser if you don't want to use them anymore. This is very easy indeed. The cube browser shows you what your cube has in it and also illustrates the utility of a dimensional database. Users can easily analyze data in meaningful ways.

SSAS allows you to browse individual dimension member data. You just right-click any dimension in the left pane of SSMS (for example, the time dimension) and choose Browse. As you can see in Figure 51.49, the dimension browser opens with All as the top node in the dimension. You simply expand the levels to see the actual member values within this cube dimension. Expanding each level gets you to more detailed information as you move down the dimension hierarchy.

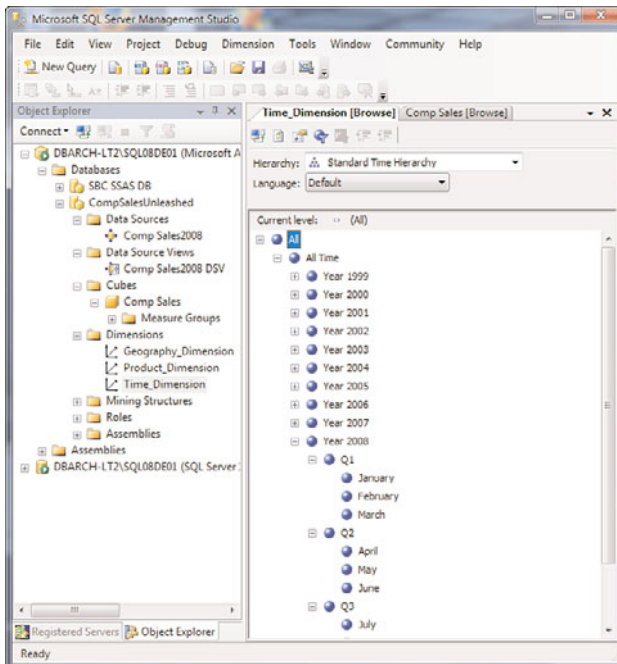

FIGURE 51.49 Browsing the Time dimension using SSMS.

Delivering Data to Users

SSAS provides a great deal of flexibility for building scalable OLAP solutions, but how do you present the data to users? The client-side components deliver much of the functionality of SSAS, using the same code base for the dimensional calculation engine, caching, and query processing. You can use the Pivot Table Service to manage client/server connections, and this is the layer for user interfaces to access SSAS cubes through the OLE DB for OLAP interface. ADO MD provides an application-level programming interface for development of OLAP applications. Third-party tools and future versions of Microsoft Excel (like 2007 and 2010) and other Microsoft Office products will use the Pivot Table Service to access cubes.

The underlying Pivot Table Service shares metadata with SSAS, so a request for data on the client causes data and metadata to be downloaded to the client. The Pivot Table Service determines whether requests need to be sent to the server or can be satisfied at the client with downloaded data. If a user requests sales information for the first quarter of 2008 and then later decides to query that data for the first quarter of 2007 for comparison, only the request for 2007 data has to go to the server to get more data. The 2008 data is cached on the client.

Slices of data that are retrieved to the client computer can also be saved locally for analysis when the client computer is disconnected from the network. Users can download the data in which they are interested and analyze it offline. The Pivot Table Service can also create simple OLAP databases by accessing OLE DB-compliant data sources.

With the ADO MD interface, developers will be able to access and manipulate objects in an SSAS database, enabling web-based OLAP application development.

Many independent software vendors, such as Brio, Cognos, Business Objects, Micro Strategies, and Hyperion, are working with Microsoft to leverage the rich features of these OLAP services. They offer robust user interfaces that can access SSAS's cubes. Versions of Microsoft Office include the Pivot Table Service to enable built-in analysis in tools such as Excel. It is getting easier and easier to bring OLAP to the masses.

Multidimensional Expressions

The OLE DB for OLAP specification contains MDX syntax that is used to build datasets from cubes and is used to define cubes themselves. Developers of OLE DB OLAP providers can map MDX syntax to SQL statements or native query languages of other OLAP servers, depending on the storage techniques.

MDX statements build datasets by using information about cubes from which the data will be read. This includes the number of axes to include, the dimensions on each axis and the level of nesting, the members or member tuples and sort order of each dimension, and the dimension members used to filter, or slice, the data. (*Tuples* are combinations of dimensions such as time and product time that present multidimensional data in a two-dimensional dataset.)

An MDX statement has four basic parts:

- ▶ Member scope information, using the `WITH MEMBER` clause

- ▶ Dimension, measure, and axis information in the SELECT clause
- ▶ The source cube in the FROM clause
- ▶ Dimension slicing in the WHERE clause

Expressions in an MDX statement operate on numbers, strings, members, tuples, and sets. *Numbers* and *strings* mean the same thing here as they do in other programming contexts. *Members* are the values in a dimension, and *levels* are groups of members. *Sets* are collections of tuple elements to further combine facts. If the dimension were time, a particular year, quarter, or month would be a member, and month values would belong to the month level. You use the dimension browser in SSAS to view members of a dimension.

The following example shows an MDX SQL expression:

```
WITH MEMBER [Measures].[Total Sales Units]
    AS 'Sum([Measures].[Sales Units])'
SELECT
    {[Measures].[Total Sales Units]} ON COLUMNS,
    {Topcount([Product_Dimension].[SKU].members,100,
        [Measures].[Total Sales Units])}
    ON ROWS
FROM [Comp Sales]
WHERE ([Time_Dimension].[All Time])
```

You can download this simple query against the Comp Sales cube from Sams Publishing at www.sampublishing.com, and it is on the CD for this book as well. This query returns the sums of the sales units for products for all time periods. Figure 51.50 shows the full execution of this query within a query window of SSMS. Notice that the metadata for the cube is also made available in the center pane of SSMS, along with an MDX Functions tab that provides all the MDX functions that can be used. This feature is very helpful for building valid MDS queries within this environment. Also notice that the result set display area is very specialized in order to display multidimensional results.

This simple MDX statement shows the basic parts of a working query. In this case, measures are displayed in columns, and the product dimension members make up the axes of this multidimensional query and are displayed in rows. The display of multiple dimensions in rows like this is how the term *tuple* is used in the context of SSAS.

Much more could be said about MDX syntax, and a complete discussion of MDX could fill its own chapter. For more information, see the *OLE DB for OLAP Programmers Reference*, which is available on the Microsoft website at <http://msdn2.microsoft.com/en-us/library/ms145506.aspx>. It contains detailed information about MDX expressions and grammar.

ADO MD

ADO MD is an easy-to-use access method for dimensional data via an OLE DB for OLAP provider. You can use ADO MD in Visual Basic, Visual C++, and Visual J++. Like ADO, ADO MD offers a rich application development environment that can be used for multi-tier client/server and web application development.

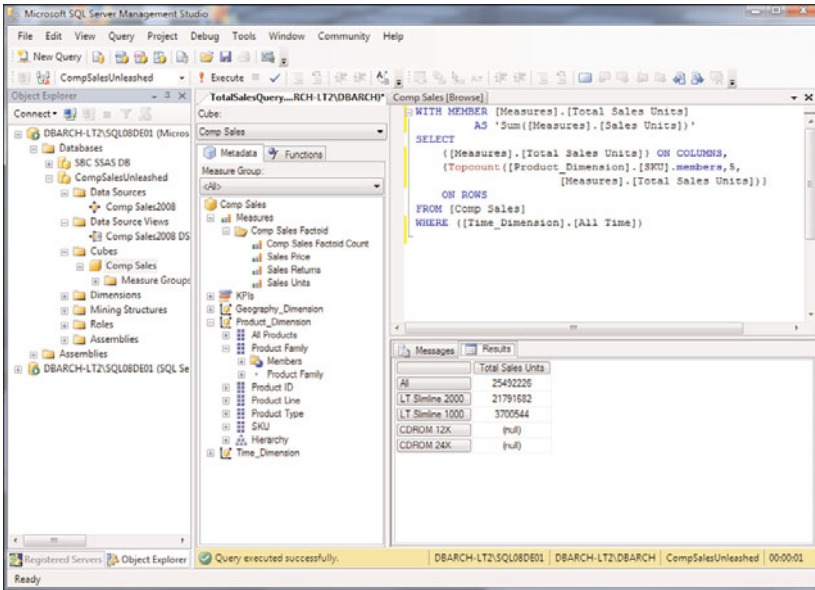

FIGURE 51.50 Comp Sales MDX query execution in SSMS.

You can retrieve information about a cube, or metadata, and execute MDX statements by using ADO MD to create cellsets to return interesting data to a user. ADO MD is another subject too broad to cover in detail in this chapter. Specifications for OLE DB for OLAP and ADO MD are available on the Microsoft website at <http://msdn2.microsoft.com/en-us/library/ms126037.aspx>.

Calculated Members (Calculations)

Remember from the Comp Sales requirements that there was an additional user need to see the difference between sales units and sales returns (sales units minus sales returns) to yield net sales. One approach is to use the SSAS calculated members (calculations) capability. This creates an expression against existing measures that will be treated the same as a measure. Basically, you need to complete the requirements for the Comp Sales cube by adding a calculation measure to this cube for net sales units.

To create a calculation, you go back to Visual Studio and the cube designer. Then you click the Calculations tab and create a new calculation measure called Sales Units NET with the calculation expression of (Sales Units - Sales Returns), as shown in Figure 51.51. Many functions are available for use that should meet your individual calculation needs.

This calculation fulfills the data measure requirements of Comp Sales. All that is left to do is to process the cube so others can use it. The following sample MDX query uses the newly created calculation measure:

```
WITH MEMBER [Measures].[Total Sales Units NET]
AS 'Sum([Measures].[Sales Units NET])'
```

```

SELECT
    {[Measures].[Total Sales Units NET]} ON COLUMNS,
    {Topcount([Product_Dimension].[SKU].members,100,
        [Measures].[Total Sales Units NET])}
    ON ROWS
FROM [Comp Sales]
WHERE ([Time_Dimension].[All Time])

```

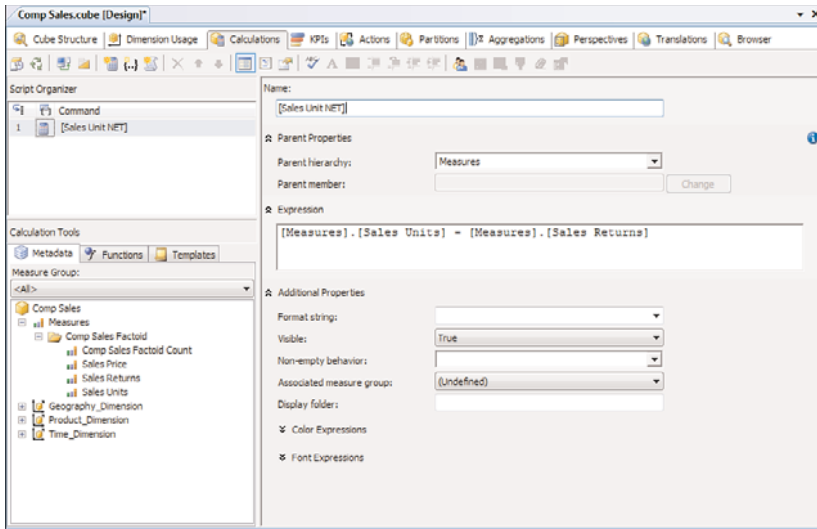

FIGURE 51.51 A new calculation measure of Sales Units NET in the Visual Studio cube designer.

Figure 51.52 shows this new calculation measure listed in the cube's metadata pane. You can see how easy it is to use in the cube data browser. You might want to check the math, however, to make sure the calculation is correct.

Query Analysis and Optimization

In SSAS, you can look at query utilization and performance in a cube. You can look at queries by user, frequency, and execution time to determine how to better optimize aggregations. If a slow-running query is used frequently by many users, or by the CEO, it might be a good candidate for individual tuning. A usage-based analysis capability can be used to change aggregations based on actual live queries that the cube must service. This adjusts aggregations based on a query to reduce response time. You start this wizard by right-clicking the cube's partition. Figure 51.53 shows the Usage-Based Optimization Wizard splash page.

The Usage-Based Optimization Wizard allows you to filter queries by user, frequency of execution, time frame, and execution time. You see a record for each query you have run since the date you began, the number of times it was executed, and the average execution time, in seconds. This is like a SQL trace analysis of your OLAP queries.

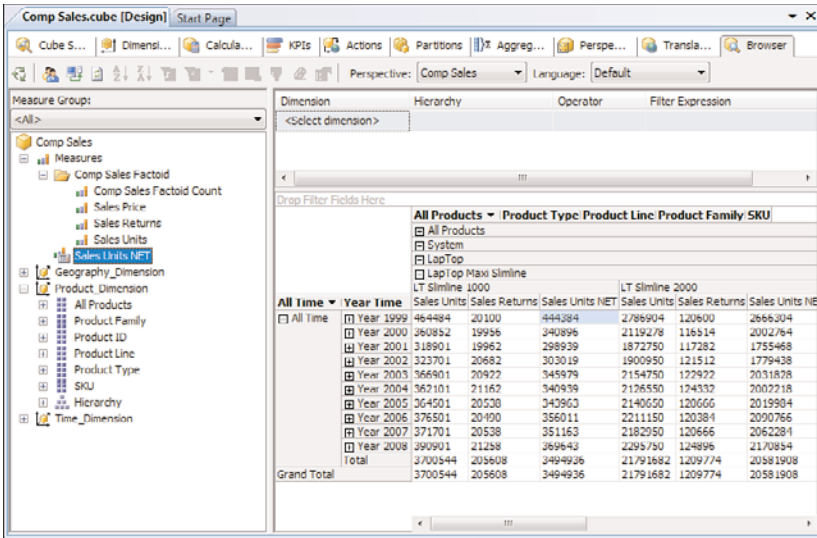

FIGURE 51.52 Data browsing using the Sales Units NET calculation in the Visual Studio cube designer data browser.

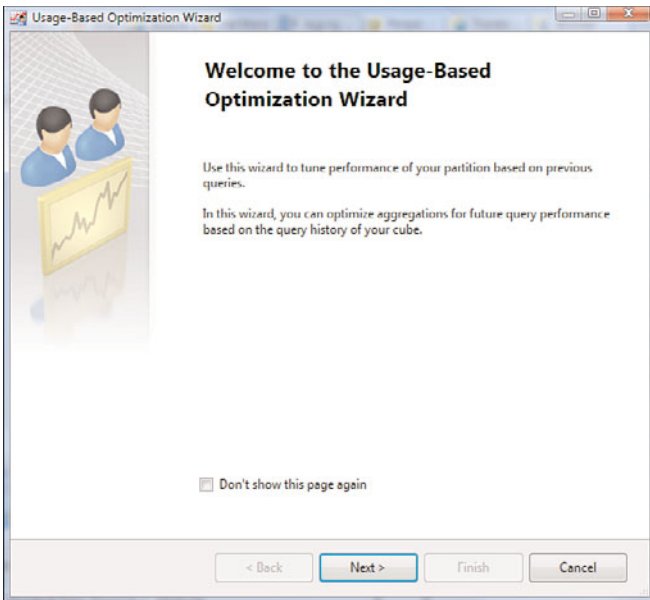

FIGURE 51.53 The Usage-Based Optimization Wizard.

Because aggregations already exist, the wizard asks whether you want to replace them or add new ones. If you replace the existing aggregations, the cube is reprocessed with this particular query in mind.

Generating a Relational Database

The examples you have worked with up to this point have been from a dimensional database that uses a star or snowflake schema (the CompSales database). Very often, however, you create cubes based on requirements only and do not have an existing data source (or sources) to draw on at design time. After you complete your cube design, you can choose to generate a relational schema that can be used to retain (that is, stage) the cube's source data or that can be a data warehouse/data mart unto itself. Figure 51.54 shows the start of the Schema Generation Wizard for building a data warehouse/staging database from the top down.

FIGURE 51.54 Generating a relational schema from the cube and dimension definitions.

NOTE

Designing dimensional databases is an art form and requires not only sound dimensional modeling knowledge, but also knowledge of the business processes with which you are dealing. Data warehousing has several design approaches. Regardless of which approach you take, having a good understanding of the approach's design techniques is critical to the success of a data warehouse project. Although Microsoft provides a powerful set of tools to implement data marts, astute execution of design methods is critical to getting the correct data—the truly business-significant business data—to the end users.

Limitations of a Relational Database

Even using a tool such as SSAS, you face limitations when dealing with a normalized database. Using a view can often solve (or mask) these issues. In some cases, however, more complicated facts and dimensions might require denormalized tables or a dimensional database in the storage component of the data warehouse to bring information together. Data cleansing and transformation are also major considerations before you attempt to present decision makers with data from OLTP systems.

Cube Perspectives

A new feature in SSAS is cube perspectives. This is essentially a way to create working views of a complex cube that is focused on just what a particular user or group of users need. They don't need all the dimensions, calculations, levels, and key performance indicators (KPIs) that would otherwise be visible as part of a complex SSAS cube. Therefore, you need a method to tailor or limit a larger cube environment to be just what the users need and nothing more—hence, the cube perspective. Figure 51.55 shows the Perspectives tab in the cube designer. It allows you to easily customize a view (perspective), which is what will be deployed or referenced to a target user group. In this example, you are creating a new perspective called *Comp Sales wo Sales Price*, which excludes the extremely sensitive Sales Price data measure from any user given access to this perspective.

You can have any number of perspectives on a cube. Figure 51.56 shows what a cube user sees when trying to browse (or access) cube data via a perspective.

Using perspectives is a great way to simplify the user's life in an already-complicated OLAP world.

KPIs

Figure 51.57 shows another new capability in SSAS: creating embedded KPIs. Just like calculations, KPIs allow you to define thresholds, goals, status indications, and trend expressions that become part of an OLAP cube. Each can then be graphically displayed in a variety of ways (for example, gauges, thermometers, traffic lights, trend indications such as up arrows, smiling faces). This is perfect for an executive dashboard or portal implementation that has its basis in an SSAS cube. You can easily access KPIs via the cube

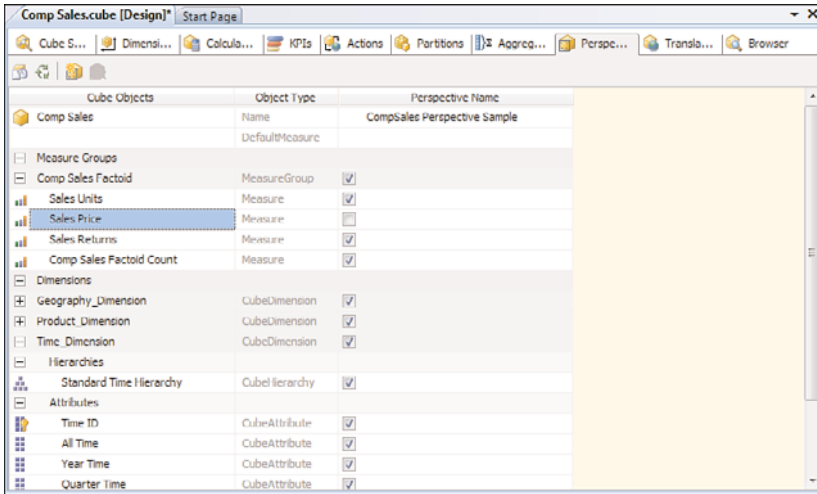

FIGURE 51.55 Creating cube perspectives within SSAS in the cube designer.

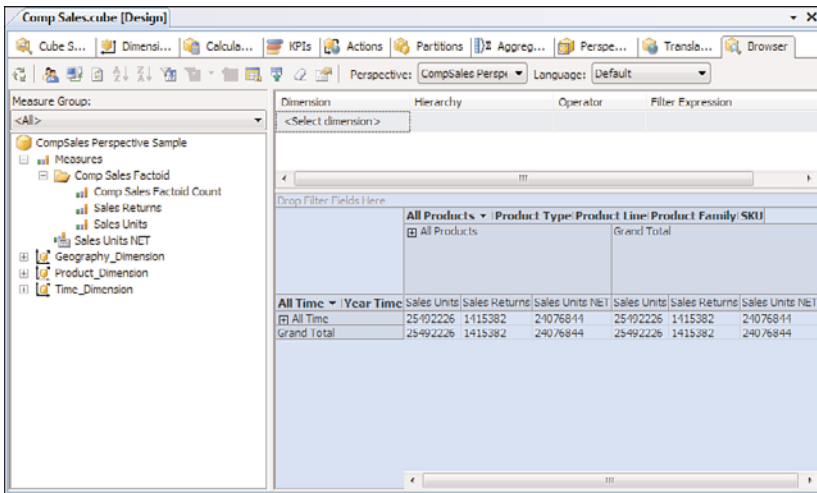

FIGURE 51.56 Browsing cube data via a perspective in the cube designer.

designer's KPIs tab. What are you waiting for? It is pretty easy to create powerful KPIs with this simple yet rich interface.

Data Mining

With SSAS, a much more robust selection of capabilities for data mining is available..

Data mining is the process of understanding potentially undiscovered characteristics or distributions of data. Data mining can be extremely useful for OLAP database design in that patterns or values might define different hierarchy levels or dimensions that were not

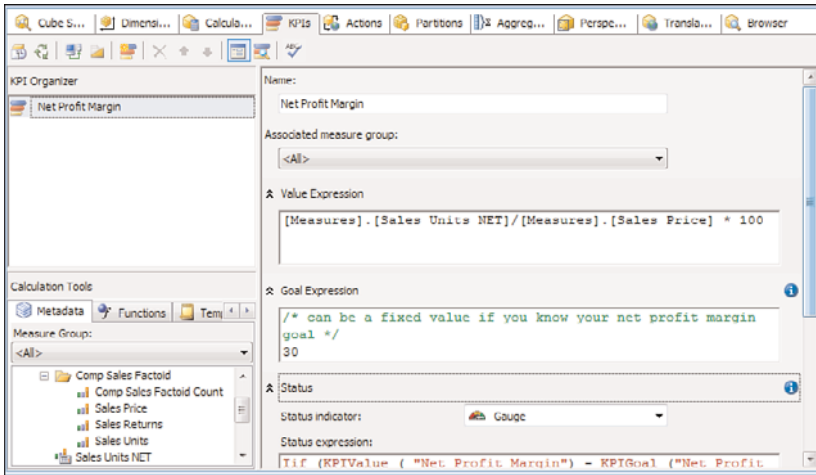

FIGURE 51.57 Creating KPIs in the cube designer.

previously known. As you create dimensions, you can even choose a data mining model as the basis for a dimension.

Basically, a data mining model is a reference structure that represents the grouping and predictive analysis of relational or multidimensional data. It is composed of rules, patterns, and other statistical information of the data that it was analyzing. These are called *cases*. A *case set* is simply a means for viewing the physical data. Different case sets can be constructed from the same physical data. Basically, a case is defined from a particular point of view. If the algorithm you are using supports the view, you can use mining models to make predictions based on these findings.

Another aspect of a data mining model is using training data. This process determines the relative importance of each attribute in a data mining model. It does this by recursively partitioning data into smaller groups until no more splitting can occur. During this partitioning process, information is gathered from the attributes used to determine the split. Probability can be established for each categorization of data in these splits. This type of data can be used to help determine factors about other data utilizing these probabilities. This training data, in the form of dimensions, levels, member properties and measures, is used to process the OLAP data mining model and further define the data mining column structure for the case set.

In SSAS, Microsoft provides several data mining algorithms (or techniques):

- ▶ **Association Rules**—This algorithm builds rules that describe which items are most likely to appear together in a transaction. The rules help predict when the presence of one item is likely with another item (which has appeared in the same type of transaction before).
- ▶ **Clustering**—This algorithm uses iterative techniques to group records from a dataset into clusters that contain similar characteristics. This is one of the best algorithms, and it can be used to find general groupings in data.

- ▶ **Sequence Clustering**—This algorithm is a combination of sequence analysis and clustering, and it identifies clusters of similarly ordered events in a sequence. The clusters can be used to predict the likely ordering of events in a sequence, based on known characteristics.
- ▶ **Decision Trees**—This classification algorithm works well for predictive modeling. It supports the prediction of both discrete and continuous attributes.
- ▶ **Linear Regression**—This regression algorithm works well for regression modeling. It is a configuration variation of the Decision Trees algorithm, obtained by disabling splits. (The whole regression formula is built in a single root node.) The algorithm supports the prediction of continuous attributes.
- ▶ **Logistic Regression**—This regression algorithm works well for regression modeling. It is a configuration variation of the Neural Network algorithm, obtained by eliminating the hidden layer. This algorithm supports the prediction of both discrete and continuous attributes.
- ▶ **Naïve Bayes**—This classification algorithm is quick to build, and it works well for predictive modeling. It supports only discrete attributes, and it considers all the input attributes to be independent, given the predictable attribute.
- ▶ **Neural Network**—This algorithm uses a gradient method to optimize parameters of multilayer networks to predict multiple attributes. It can be used for classification of discrete attributes as well as regression of continuous attributes.
- ▶ **Time Series**—This algorithm uses a linear regression decision tree approach to analyze time-related data, such as monthly sales data or yearly profits. The patterns it discovers can be used to predict values for future time steps across a time horizon.

To create an OLAP data mining model, SSAS uses either an existing source OLAP cube or an existing relational database/data warehouse, a particular data mining technique/algorithm, case dimension and level, predicted entity, or, optionally, training data. The source OLAP cube provides the information needed to create a case set for the data mining model. You then select the data mining technique (decision tree, clustering, or one of the others). It uses the dimension and level that you choose to establish key columns for the case sets. The case dimension and level provide a certain orientation for the data mining model into the cube for creating a case set. The predicted entity can be either a measure from the source OLAP cube, a member property of the case dimension and level, or any member of another dimension in the source OLAP cube.

NOTE

The Data Mining Wizard can also create a new dimension for a source cube and enables users to query the data mining data model data just as they would query OLAP data (using the SQL DMX extension or the mining structures browser).

In Visual Studio, you simply initiate the Data Mining Wizard by right-clicking the Mining Structures entry in the Solution Explorer. You cannot create new mining structures from

SSMS. When you are past the wizard's splash screen, you have the option of creating your mining model from either an existing relational database (or data warehouse) or an existing OLAP cube (as shown in Figure 51.58).

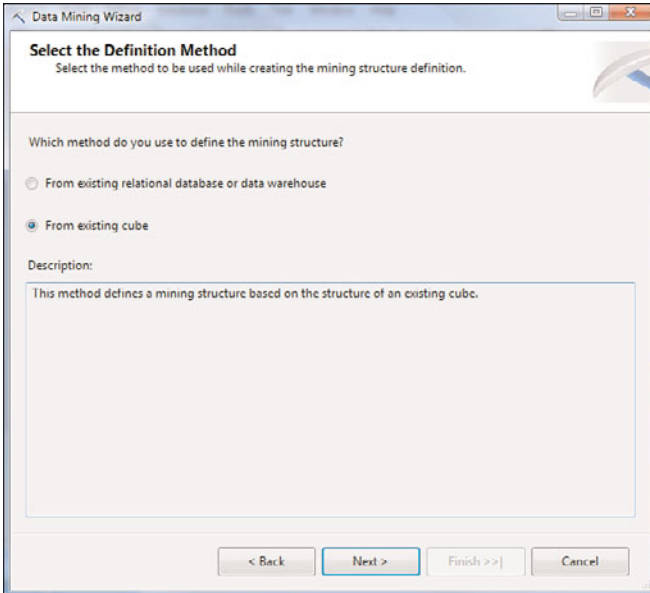

FIGURE 51.58 Selecting the definition method to used for the mining structure in the Data Mining Wizard.

You want to define a data mining model that can shed light on product (SKU) sales characteristics and that will be based on the data and structure you have created so far in your Comp Sales Unleashed cube. For this example, you choose to use the existing OLAP cube you already have (from the existing cube method).

You must now select the data mining technique you think will help you find value in your cube's data. Clustering is probably the best one to start from because it finds natural groupings of data in a multidimensional space. It is useful when you want to see general groupings in your data, such as hot spots. You are trying to find just such things with sales of products (for example, things that sell together or belong together). Figure 51.59 shows the data mining technique Microsoft Clustering being selected.

Now you have to identify the source cube dimension to use to build the mining structure. As you can see in Figure 51.60, you choose Product Dimension to fit the mining intentions stated earlier.

You then select the case key or point of view for the mining analysis. Figure 51.61 illustrates the case to be based on the product dimension and at the SKU level (that is, the individual product level).

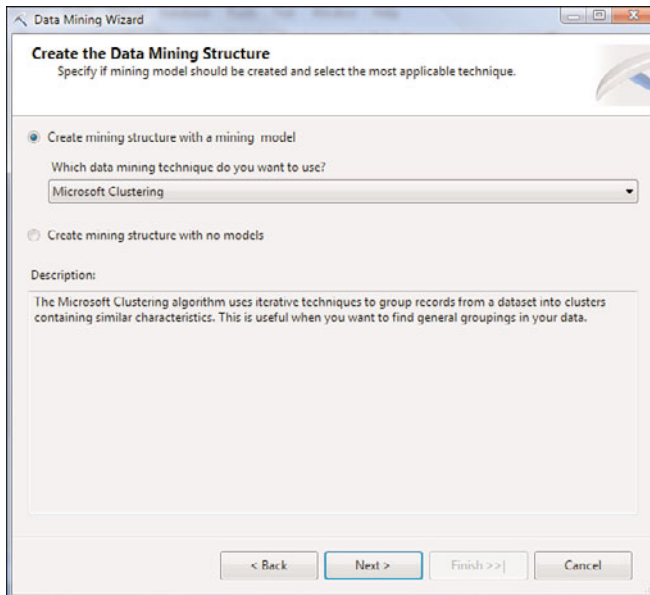

FIGURE 51.59 Using clustering to identify natural groups in the Data Mining Wizard.

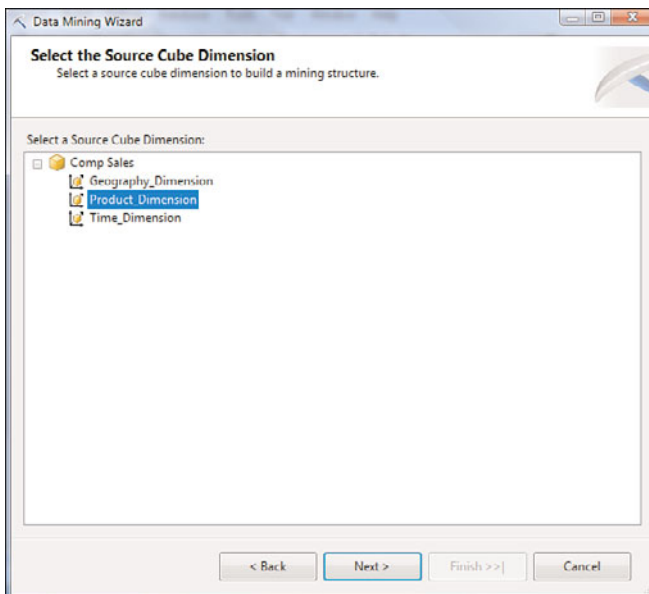

FIGURE 51.60 Identifying the product dimension as the basis for the mining structure in the Data Mining Wizard.

FIGURE 51.61 Identifying the basic unit of analysis for the mining model in the Data Mining Wizard.

You now specify the attributes and measures as case-level columns of the new mining structure. Figure 51.62 shows the possible selections. You can simply choose all the data measures for this mining structure. Then you click the Next button.

As you can see in Figure 51.63, the next few wizard dialogs allow you to specify the mining structure column's content and data types (use the defaults that were detected for most items unless we specifically describe something different), identify a filtered slice to use for the model training (you don't need to use this now because you want the whole cube), and finally identify the number of cases to be reserved for model testing (use a percentage of data for testing to be about 33%).

The mining model is now specified and must be named and processed. Figure 51.64 shows what you have named the mining structure (Product Dimension MS) and the mining model name itself (Product Dimension MM). Also, you select the Allow Drill Through option so you can look further into the data in the mining model after it is processed. Then you click the Finish button.

When the Data Mining Wizard is complete, the mining structure viewer pops up, with your mining structure case-level column's specification (on the center left) and its correlation to your cube (see Figure 51.65).

You must now process the mining structure to see what you come up with. You do this by selecting the Mining Model toolbar option and selecting the Process option. You then see the usual Process dialog, and you have to choose to run this (process the mining structure). After the mining structure processing completes, a quick click on the Cluster

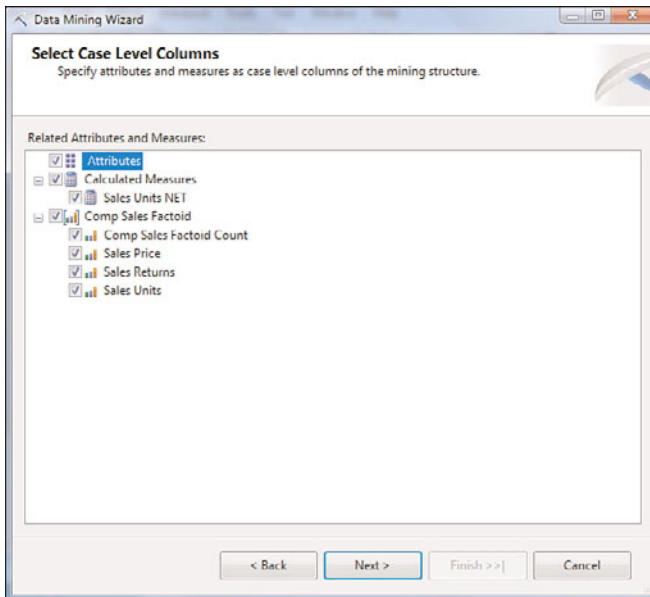

FIGURE 51.62 Specifying the measure for the mining model in the Data Mining Wizard.

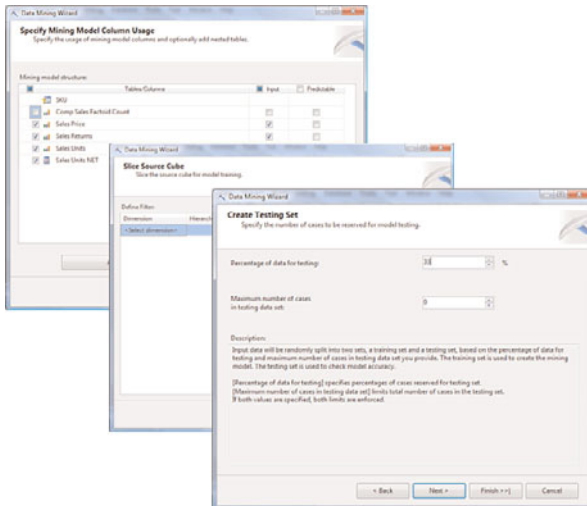

FIGURE 51.63 Specifying a column's content, slice filters, and model data training percentages.

Diagram tab shows the results of the clustering analysis (see Figure 51.66). Notice that because you selected to allow drill through, you can simply right-click any of the clusters identified and see the data that is part of the cluster (and choose Drill Through). This viewer clearly shows that there is some clustering of SKU values that might indicate products that sell together or belong together.

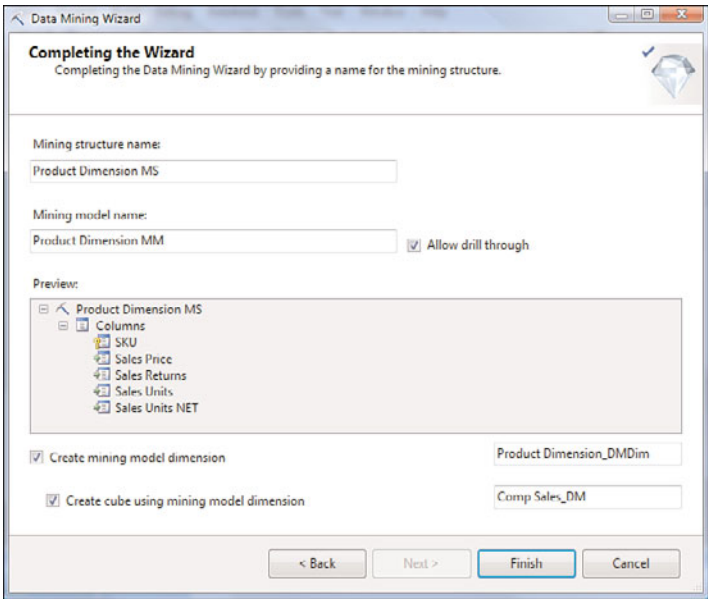

FIGURE 51.64 Naming the mining model and completing the Data Mining Wizard.

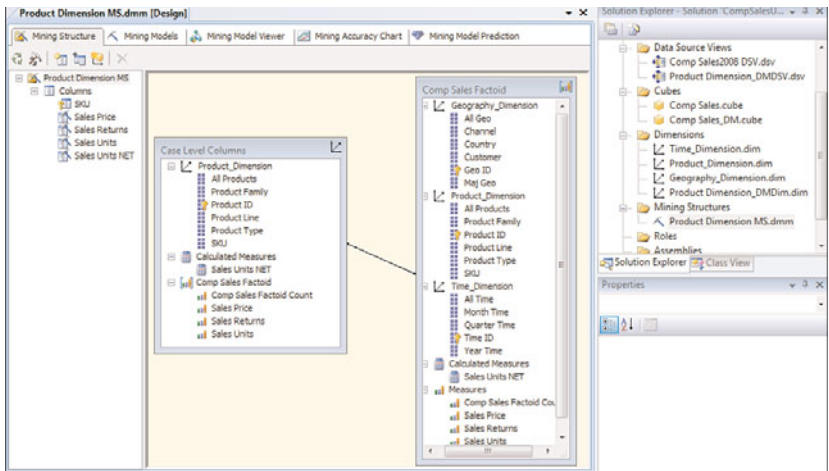

FIGURE 51.65 Your new mining structure in the mining structure viewer.

If you click the Cluster Profiles tab of this viewer, you see the data value profile characteristics that were processed (see Figure 51.67).

Figure 51.68 shows the clusters of data values of each data measure in the data mining model. This characteristic information gives you a good idea of what the actual data values are and how they cluster together.

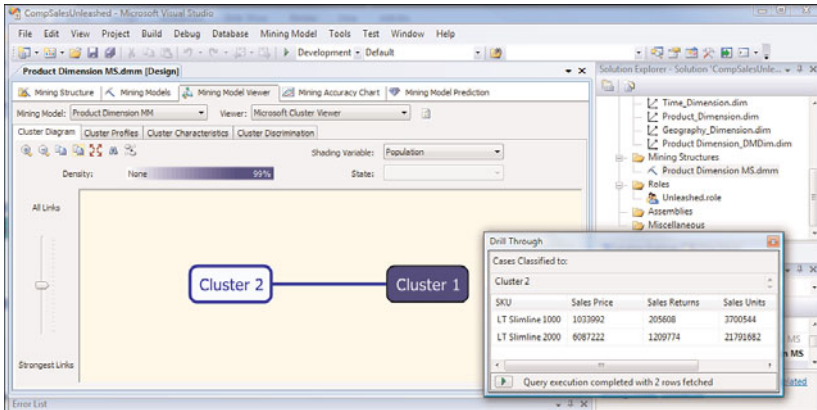

FIGURE 51.66 Clustering results and drilling through to the data in the mining model viewer.

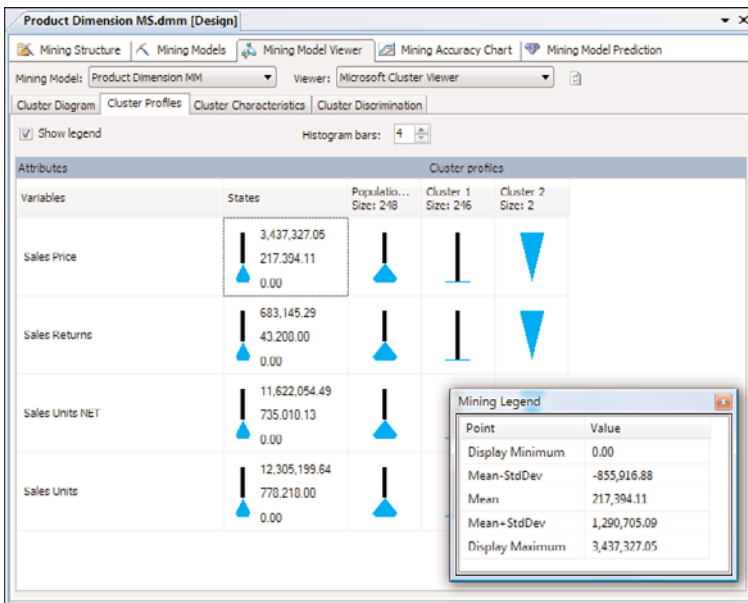

FIGURE 51.67 Cluster data profiles in the mining model viewer.

Finally, you can see the cluster node contents at the detail level by changing the mining model viewer type to Microsoft Generic Content Tree Viewer, which is just below the Mining Model Viewer tab at top. Figure 51.69 shows the detail contents of each model node and its technical specification of a report format.

If you want, you can now build new cube dimensions that can help you do predictive modeling based on the findings of the data mining structures you just processed. In this way, you could predict sales units of one SKU and the number of naturally clustered SKUs quite easily (based on the past data mining analysis). This type of predictive modeling is very powerful.

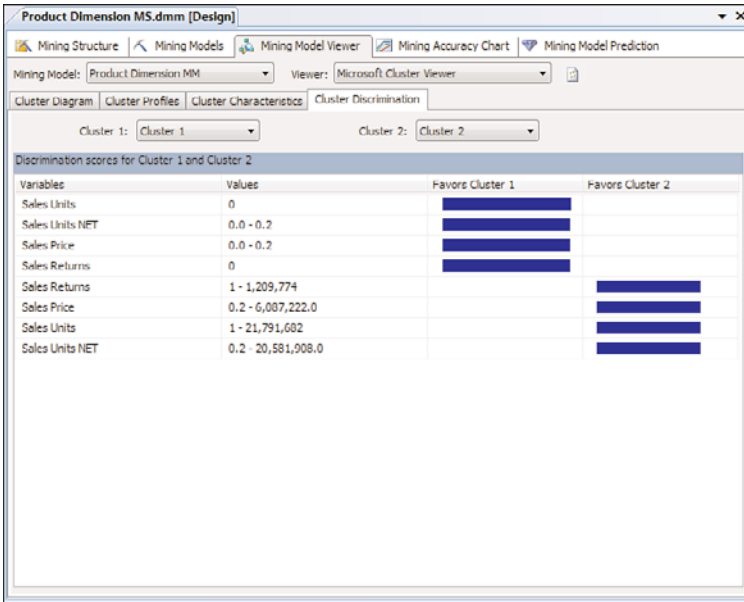

FIGURE 51.68 Cluster characteristics of the data values for each measure in the mining model viewer.

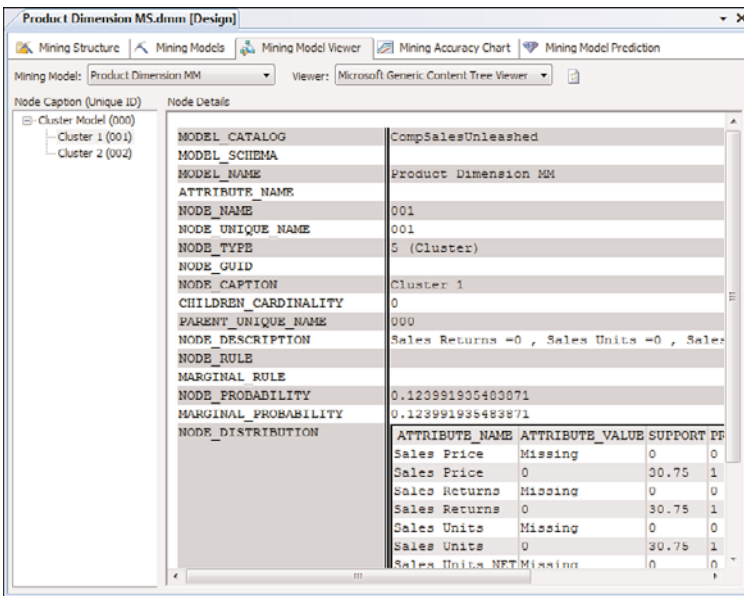

FIGURE 51.69 The Microsoft Generic Content Tree Viewer of the cluster nodes in the mining model viewer.

SSIS

SSIS provides a robust means to move data between sources and targets. Data can be exported, validated, cleaned up, consolidated, transformed, and then imported into a destination of any kind. With any OLAP/SSAS implementation, you will undoubtedly have to transform, clean, or preprocess data in some way. You can now tap into SSIS capabilities from within the SSAS platform.

You can combine multiple column values into a single calculated destination column or divide column values from a single source column into multiple destination columns. You might need to translate values in operational systems. For example, many OLTP systems use product codes stored as numeric data. Few people are willing to memorize an entire collection of product codes. An entry of 100235 for a type of shampoo in a product dimension table is useless to a vice president of marketing who is interested in how much of that shampoo was sold in California in the past quarter.

Cleanup and validation of data are critical to the data's value in the data warehouse. The old saying "garbage in, garbage out" applies. If data is missing, redundant, or inconsistent, high-level aggregations can be inaccurate, so you should at least know that these conditions exist. Perhaps data should be rejected for use in the warehouse until the source data can be reconciled. If the shampoo of interest to the vice president is called Shamp in one database and Shampoo in another, aggregations on either value would not produce complete information about the product.

The SSIS packages define the steps in a transformation workflow. You can execute the steps serially and in combinations of serially, in parallel, or conditionally. For more information on SSIS, refer to Chapter 46, "SQLCLR: Developing SQL Server Objects in .NET."

OLAP Performance

Performance is a big emphasis of SSAS. Usage-based aggregation is at the heart of much of what you can do to help in this area. In addition, the proactive caching mechanism in SSAS has allowed much of what was previously a bottleneck (and a slowdown) to be circumvented.

When designing cubes for deployment, you should consider the data scope of all the data accesses (that is, all the OLAP queries that will ever touch the cube). You should only build a cube that is big enough to handle these known data scopes. If you don't have requirements for something, you shouldn't build it. This helps keep things a smaller, more manageable size (that is, smaller cubes), which translates into faster overall performance for those who use the cube.

You can also take caching to the extreme by relocating the OLAP physical storage components on a solid-state disk device (that is, a persistent memory device). This can give you tenfold performance gains. The price of this type of technology has been dramatically

reduced within the past year or so, and the ease of transparently applying this type of solution to OLAP is a natural fit. It affects both the OLAP data population process and the day-to-day what-if usage by the end users. You should keep these types of surgical incisions in mind when you face OLAP performance issues in this platform. They are easy to apply, the gains are huge, and you quickly get a return on your investment.

MPP Data Warehouse Option from Microsoft

A few years ago, Microsoft acquired DATAlegro’s massively parallel data warehouse appliance company. This basically lifted any limitations for data warehousing that SSAS or SQL Server 2008 R2 itself had. *Massively parallel* means to scale horizontally on CPU and storage to grow with your size and processing needs. There is no practical limit here. The underlying architecture relies on standards-based technologies. Essentially, there is a separation of storage and compute nodes that allows you to spread out your data across vast storage (EMC storage) so that it is very shallow (easy to get to quickly across all data storage). The compute power is also horizontally scalable and allows any query to process data access in parallel to surface data needed by any query (and assemble it for delivery). Figure 51.70 shows the high-level architecture of Microsoft’s DATAlegro v3 offering.

FIGURE 51.70 The DATAlegro v3 MPP architecture.

Not only is the DATAlegro v3 architecture massively parallel and fast, but the multinode architecture also makes it highly available. If any node fails, hot spares kick in to pick up the load. Any failed node can easily be replaced and brought online with zero processing interruption. Moreover, multiple appliances can be combined on a common InfiniBand backbone to create large-scale and extremely powerful multitier or hub-and-spoke data warehouses with rapid, parallel data movement between the various appliances. Believe it or not, there is an Ingres SQL engine at the heart of the database portion of this appliance.

Master Data Services

Completing the business intelligence picture is a new focus on the data quality that is needed at all tiers of data information delivery. Microsoft has been pouring an enormous amount of effort (and money) into creating and embedding master data services throughout its BI and transactional platforms. By using Microsoft's Master Data Services, organizations can align operational and analytical data across the enterprise and across lines of business systems with a guaranteed level of data quality for most core data categories (such as customer data, product data, and other core data of the business).

Microsoft has created data stewardship capabilities complete with workflows and notifications of any business user who might be impacted by core data change. Managing hierarchies is also an important part of mastering data that has a natural hierarchical structure, such as customer hierarchies (parent company to subsidiaries and so on). Each master data change within the system is treated as a transaction; and the user, date, and time of each change are logged, as well as pertinent audit details, such as type of change, member code, and prior versus new value. In addition to being a very useful audit trail, the transaction log can be used to selectively reverse changes. Customizable data quality rules create default values, enable data validation, and trigger actions such as email notifications and workflows. Rules can be built by IT professionals or business users directly from the stewardship portal.

Microsoft is still getting the kinks out of Master Data Services, so you should look for much maturing to come in the next few years. Other competing products that have many years' headstart provide this capability to companies around the globe, but Microsoft is catching up fast.

Security and Roles

Security is straightforward in SSAS. For each database or cube, roles are identified with varying levels of granularity for users. Roles are used when accessing the data in cubes. The process works like this: a role is defined, and then an individual user or group who is a member of that role is assigned that role. To create the roles you need for this data, you right-click on the Roles entry in the Solution Explorer and select New Role. Figure 51.71 shows the creation of a database role with process database and read definition permissions.

The other tabs of the role designer allow you to further specify the controls, such as which members you want to have this role (Membership tab), what data source access you want (Data Sources tab), which cubes can be used (Cubes tab), what specific cell data the role has access to (Cell Data tab), what dimensions can be accessed (Dimensions tab), what dimensional data can be accessed (Dimension Data tab), and what mining structures are allowed to be used (Mining Structures tab). These are additive. As you can see in Figure 51.72, you can also specify full MDX queries as part of the process of filtering what a member and role can have access to.

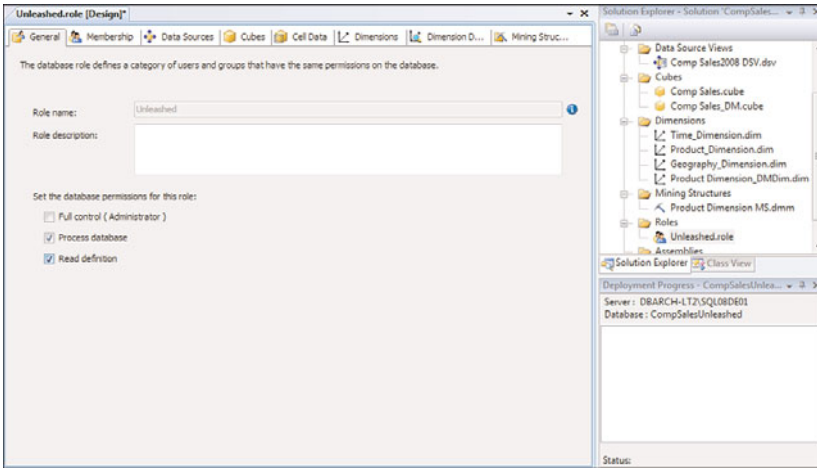

FIGURE 51.71 Creating a database role and permissions in the role designer.

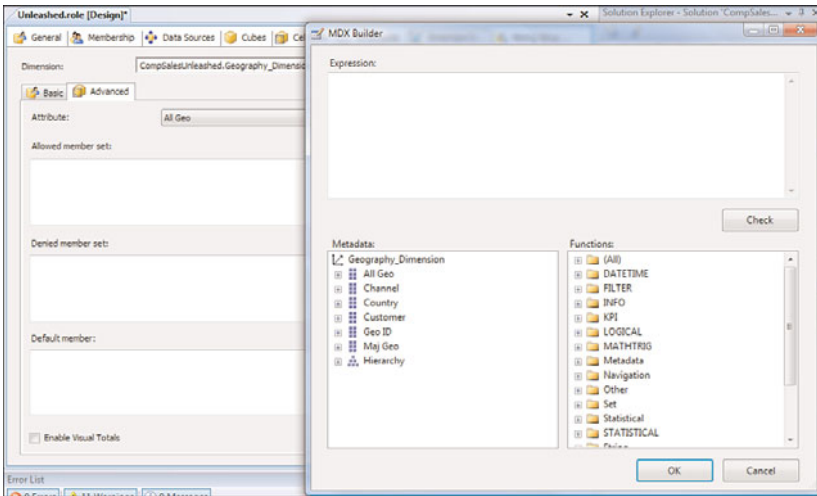

FIGURE 51.72 Specifying MDX-based filtering, using the role designer.

Summary

This chapter discusses the OLAP approach, SSAS terms, and the tools Microsoft provides to enable OLAP cubes. It presents a mini-methodology to follow that should help you get an OLAP project off the ground and running smoothly. These efforts are typically not simple, and a well-trained data warehouse analyst, BI specialist, or data architect is usually worth his or her weight in gold because of the results (and value) that can be achieved through good OLAP cube design.

Sometimes it is difficult to engage end users and get them to use an OLAP cube successfully. Easy-to-use third-party tools can greatly help with this problem.

From an SSAS point of view, the ease of control of storage methods, dimension creation, degrees of aggregation, cube partitioning, and usage-based optimization are features that make this product a serious data warehousing tool. It is getting easier and easier to publish OLAP data via websites or other means. SSAS is truly the land of the wizards, but having a wizard lead you through a good OLAP cube design is critical. The wizards significantly reduce the expense and complexity of a data warehouse or data mart OLAP solution, enabling you to build many more much-needed solutions for your end users.

This chapter also introduces the new paths Microsoft is pursuing around massively parallel data warehouse appliances and the integration of Master Data Services into their business intelligence and transactional fabric to raise their levels of performance and data quality across the board.

The next chapter, “SQL Server 2008 Integration Services,” ventures into the very robust offering from Microsoft in regards to data enablement, manipulation, and aggregation for not only Analysis Services, but most other production platforms that require complex data transformations.

This page intentionally left blank

CHAPTER 52

SQL Server Integration Services

As you may be aware, SQL Server 2000's Data Transformation Services (DTS) was completely redeployed into and integrated with the Business Intelligence (BI) Development Studio, Visual Studio environments, and SQL Server Management Studio (SSMS). This chapter describes the SQL Server Integration Services (SSIS) environment and how SSIS addresses complex data movement and integration needs.

SSIS focuses on importing, exporting, and transforming data from one or more data sources to one or more data targets. This is Microsoft's version of extraction, transformation, and loading (ETL) on steroids. Competing ETL products include Informatica, but Microsoft has simply bundled this functionality together with SQL Server, thus providing more reasons to purchase SQL Server and not have to buy any expensive competing products. Other Microsoft solutions exist for importing and exporting data (such as the Bulk Copy Program, `bcp`), but SSIS can be used for a larger variety of data transformation purposes, and its strength is in direct data access and complex data transformation.

If you have existing DTS implementations (that is, DTS packages), you can convert them to SSIS packages with little to no effort, or you can simply execute them as is (with some restrictions).

If you still use the Bulk Copy Program (`bcp`), a section at the end of this chapter describes this legacy SQL Server capability. `bcp` is still the workhorse of many production environments and cannot just be discarded every time a new version of SQL Server comes along. We estimate that `bcp` will be around for years to come.

IN THIS CHAPTER

- ▶ What's New with SSIS666
- ▶ SSIS Basics667
- ▶ SSIS Architecture and Concepts671
- ▶ SSIS Tools and Utilities676
- ▶ A Data Transformation Requirement682
- ▶ Running the SSIS Wizard682
- ▶ The SSIS Designer693
- ▶ The Package Execution Utility702
- ▶ Connection Projects in Visual Studio716
- ▶ Change Data Capture Addition with R2718
- ▶ Using `bcp`718
- ▶ Logged and Nonlogged Operations737

The alternatives to SSIS and `bcp` in the Microsoft SQL Server 2008 environment include replication, distributed queries, `BULK INSERT`, and `SELECT INTO/INSERT`. This chapter helps you determine how and when to use both SSIS and `bcp` as opposed to these other alternatives.

What's New with SSIS

In SQL Server 2008, Microsoft has further extended the capabilities of SSIS into a much more comprehensive and robust data integration platform—with the emphasis on the word *platform*. The following are some of the highlights of SSIS 2008:

- ▶ Continued support for SQL Server 2000 Data Transformation Services (DTS). This includes DTS runtime, the object model that it exposes, and the `dtsrun.exe` command-line utility. This support will likely be deprecated in the next full release of SQL Server, though. There are several 64-bit restrictions with DTS.
- ▶ Extensive performance enhancements to leverage caching for lookup transformations, previously a major performance bottleneck during transformations. This also includes sharing caches in a single package and between separate packages.
- ▶ New ADO.NET components for both source and destinations.
- ▶ New data profiling tasks and a Data Profile Viewer.
- ▶ A new Integration Services Connections Project Wizard that speeds the creation of the connection information needed by packages.
- ▶ A new script environment called Visual Studio Tools for Applications (VSTA) environment. VSTA supports both Microsoft Visual Basic 2008 and Visual C# 2008.
- ▶ Package upgrades from 2005 (or earlier) to 2008 package format.
- ▶ Enhanced data type handling in the SQL Server Import and Export Wizard and a few new data types, such as new Date and Time data types.
- ▶ SQL statement enhancements that allow you to perform multiple data manipulations at the same time with `MERGE`.
- ▶ The ability to use SQL Server 2008's Change Data Capture technology from within Integration Services. This one is really a big deal and has been added for R2 via Microsoft partners.
- ▶ The ability to create debug dump files that provide information about your package's execution.

SSIS Basics

As the world becomes ever more data oriented, much greater emphasis is being placed on getting data from one place to another. To complicate matters, data can be stored in many different formats, contexts, filesystems, and locations. In addition, the data often requires

significant transformation and conversion processing as it is being moved around. Whether you are trying to move data from Excel to SQL Server, create a data mart (or data warehouse), or distribute data to heterogeneous databases, you are essentially enabling someone with data.

This section describes the SSIS environment and how it is addressing these needs. As mentioned earlier, the focus is on importing, exporting, and transforming data from one or more data sources to one or more data targets.

Common requirements of SSIS might include the following:

- ▶ Exporting data out of SQL Server tables to other applications and environments (for example, ODBC or OLE DB data sources or via flat files)
- ▶ Importing data into SQL Server tables from other applications and environments (for example, ODBC or OLE DB data sources or via flat files)
- ▶ Initializing data in some data replication situations, such as initial snapshots
- ▶ Aggregating data (that is, data transformation) for distribution to/from data marts or data warehouses
- ▶ Changing the data's context or format before importing or exporting it (that is, data conversion)

Some typical business scenarios for SSIS might include the following:

- ▶ Enabling data marts to receive data from a master data warehouse through periodic updates (see Figure 52.1)

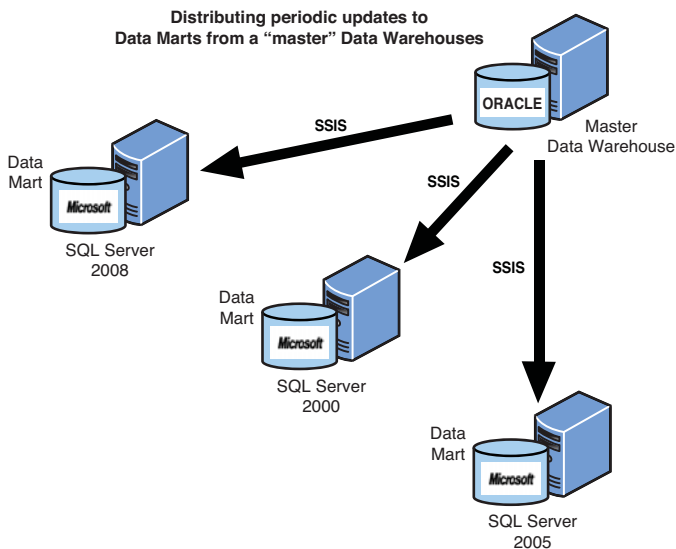

FIGURE 52.1 Distributing periodic updates to data marts.

- ▶ Populating a master data warehouse from legacy systems (see Figure 52.2)

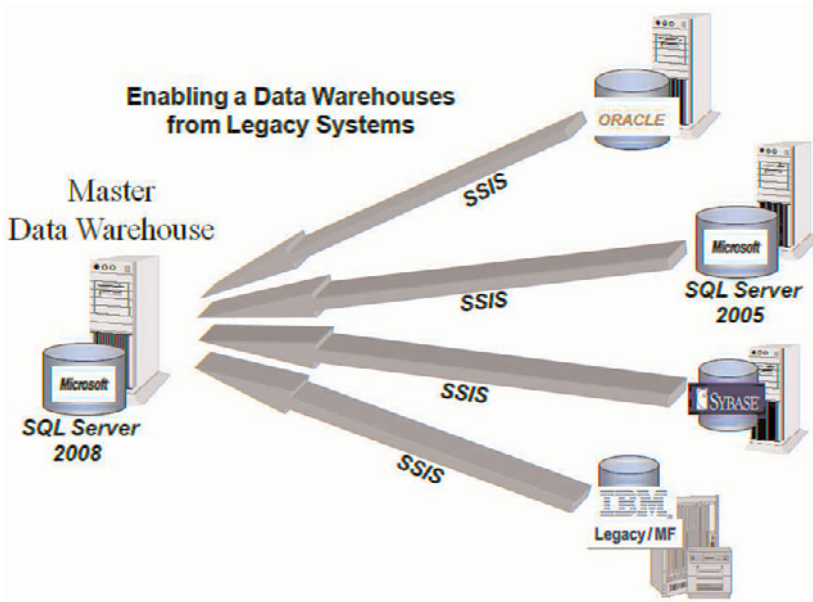

FIGURE 52.2 Populating a data warehouse from one or more data sources.

- ▶ Initializing heterogeneous replication subscriber tables on Oracle from a SQL Server 2008 Publisher (see Figure 52.3)
- ▶ Pulling sales data directly into SQL Server 2008 from an Access or Excel application (see Figure 52.4)
- ▶ Exporting static time-reporting data files (that is, flat files) for distribution to remote consultants
- ▶ Importing new orders directly or indirectly from a sales force automation or distributed sales systems

In general, you need SSIS if any of the following conditions exist:

- ▶ You need to import data directly into SQL Server from one or more ODBC data sources, .NET and OLE DB data providers, or via flat files.
- ▶ You need to export data directly out of SQL Server to one or more ODBC data sources, .NET and OLE DB data providers, or via flat files.
- ▶ You need to perform data conversions, data cleansing/data standardization, transformations, merges, or aggregations on data from one or more data sources for distribution to one or more data targets. You also need SSIS if you need to access the data directly via any ODBC data source, .NET or OLE DB data providers, or via flat files.

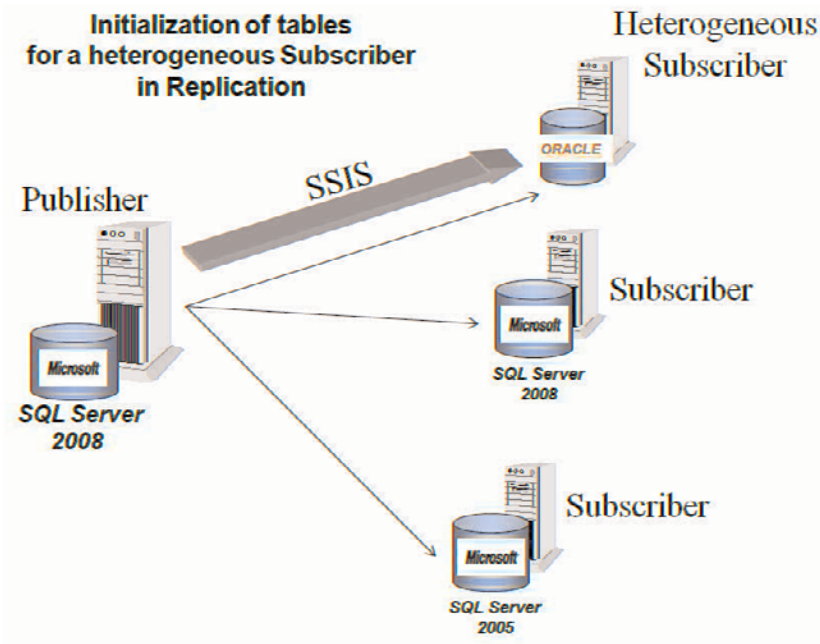

FIGURE 52.3 Initializing a heterogeneous replication subscriber (such as Oracle).

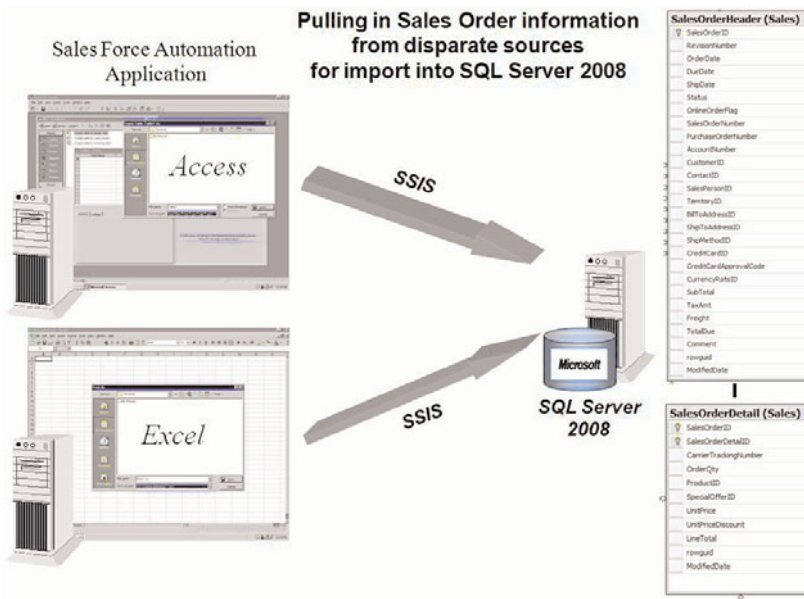

FIGURE 52.4 Pulling data from other disparate applications.

- ▶ Your bulk data movement doesn't have to be faster than the speed of light. Unfortunately, SSIS must utilize conventional connection techniques to these data sources. It must also create intermediate buffers to hold data during the transformation steps. This usually disqualifies SSIS on the high-performance side of requirements (at least for large, bulk data movements with any type of data transformations defined). However, many performance enhancements are present in SSIS and the data providers that are now supported, which has resulted in about a 50% increase in bulk data movement speeds. Alternative importing/exporting facilities such as bcp offer better performance but lack the flexibility of SSIS.

The following additional SSIS data sources and destinations are supported:

- ▶ An XML source for extracting data from XML documents directly
- ▶ Full insert and updating support for SQL Server Mobile destinations
- ▶ Reading and writing to Raw data files (sources and destinations)
- ▶ Creating an in-memory ADO DB recordset via a destination
- ▶ Direct access to a number of Analysis Services object destinations (for example, mining models, cubes, and dimensions)
- ▶ The ADO.NET DataReader source and destination for reading and writing to any .NET framework data provider

SQL Server 2008 now supports the following additional SSIS data transformations:

- ▶ Data warehousing operations, such as the Aggregate, Pivot, Un-pivot, and Slowly Changing Dimension transformations
- ▶ Enhanced text data mining via the Term Extraction and Term Lookup transformations
- ▶ Caching for Lookup transformations
- ▶ Enhancing data values from a lookup table via the Data Lookup and Fuzzy Lookup transformations
- ▶ The identification of similar data rows via the Fuzzy Grouping transformation
- ▶ Multiple downstream data flow component data distribution via the Conditional Split and Multicast transformations
- ▶ The merging and combining of data rows from multiple upstream data flow components via the Union All, Merge, and Merge Join transformations
- ▶ Extensive copying and modifying of column data values, using the Copy Column, Data Conversion, and Derived Column transformations
- ▶ Sample rowset extractions, using the Percentage Sampling and Row Sampling transformations
- ▶ Sorting of data and identification of duplicate data rows via the Sort transformation

SSIS includes a set of tools and features that support managing, editing, executing, and migrating DTS packages from earlier versions of SQL Server. You can see all available DTS

packages in SSMS (in a separate branch). You can also choose to migrate old DTS packages (from SQL Server 2000) forward to SSIS packages (to SQL Server 2008) via the Package Migration Wizard. It's quite easy. If you can't migrate your old DTS packages yet, you can directly execute DTS packages from SSIS packages. If you need to be able to design changes to existing DTS packages, you can either download the special DTS designer version for SQL Server 2008 from Microsoft's website, or just bite the bullet and migrate them forward. We recommend migration as rapidly as is feasible.

SSIS Architecture and Concepts

You can think of SSIS as a data import/export/transformation layer in the overall system architecture that you are deploying for at least most of your Microsoft-based applications and a few non-Microsoft applications (see Figure 52.5). SSIS allows you to “data enable” almost all the individual applications or systems that are part of your overall implementation, such as OLTP databases, multidimensional cubes, OLAP data warehouses, Excel files, Access databases, flat files, other heterogeneous database sources, and even web services. The Integration Services object model includes both native and managed APIs for doing most SSIS work. This includes APIs for any of the SSIS tools, the command-line utilities, and even custom applications. SSIS Designer and the Integration Services Wizard both use the Integration Services object model. SSIS includes the integration service itself (that is, the service that manages all SSIS packages), the Integration Services object model, the SSIS runtime and runtime executables, and the data flow task (which has a data flow engine, source, transformation, and destination components).

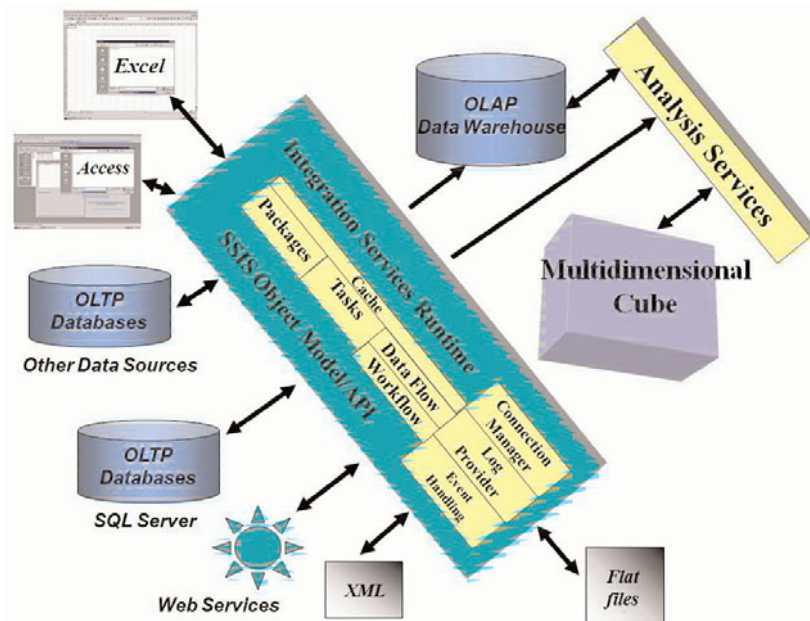

FIGURE 52.5 SSIS architecture.

Microsoft uses SSIS packages to implement any data movement/transformation. Basically, Microsoft treats SSIS packages as if they are managed code and requires that you create Integration Services projects and deployment utilities as part of managing these SSIS packages. In addition, separate Integration Services Connection projects can now be created to aid in connection and provider services. All in all, this is a very good approach that significantly reduces errors and allows you to go through a reasonably formal release to production (that is, development and deployment) cycle.

SSIS packages contain a collection of connections, control flow elements, data flow elements, event handlers, variables, and configurations. They take the form of tasks, containers, transformations, and workflows. SSIS packages go through one or more steps that are either executed sequentially or in parallel at package execution time. In a nutshell, when an SSIS package is executed, it does the following:

1. Connects to any identified data source
2. Copies data (and database objects, if needed)
3. Transforms data
4. Disconnects from the data sources
5. Notifies users, processes, and even other packages of events (such as sending an email when something is done or has errors)

The basic SSIS package consists of the following:

- ▶ **SSIS packages**—A package is a discrete, named collection of connections, control flow, and data flows that implement data movement/data transformation.
- ▶ **SSIS control flow and tasks**—One or more tasks and containers drive what the package does. You organize control flow based on what you want the package to do. *Tasks* are the actions taken to accomplish the desired data transformation and movement. A task can execute any SQL statement, send mail, bulk insert data, execute an ActiveX script, run a Visual Studio Tool for Application script (VSTA), or launch another package or an external program.
- ▶ **SSIS containers**—A container groups one or more related tasks that you want to manage together (and reuse together).
- ▶ **Workflows**—Workflows are definable precedence constraints that allow you to link two tasks, based on whether the first task executes, executes successfully, or executes unsuccessfully. Workflow containers are the wrappers for the tasks and are the means for the flow of control. A task can run alone, parallel to another task, or sequentially, according to precedence constraints. Precedence constraints are of three types:
 - ▶ **Unconditional**—It does not matter whether the preceding step failed or succeeded.
 - ▶ **On success**—The preceding step must have been successful for the execution of the next step.
 - ▶ **On failure**—This constraint returns the appropriate error.

- ▶ **SSIS data flow**—The data flow identifies the sources and destinations that extract and load data; identifies the transformations that manipulate or enhance the data; and provides the paths that link sources, transformations, and destinations.
- ▶ **SSIS data flow task**—A data flow task creates, orders, and runs the data flows themselves, using a data flow engine.
- ▶ **SSIS transformations**—Transformations are one or more functions or operations applied against a piece of data before the data arrives at the destination.

In SSIS, everything is pretty much a task or a collection of tasks (one or more containers, tasks in containers), as you can see in Figure 52.6. Control flow determines the overall execution of the package and data flows that access the data, transform it, and write it. Precedence constraints determine the overall control flow—connecting the executables, containers, and tasks into an ordered control flow.

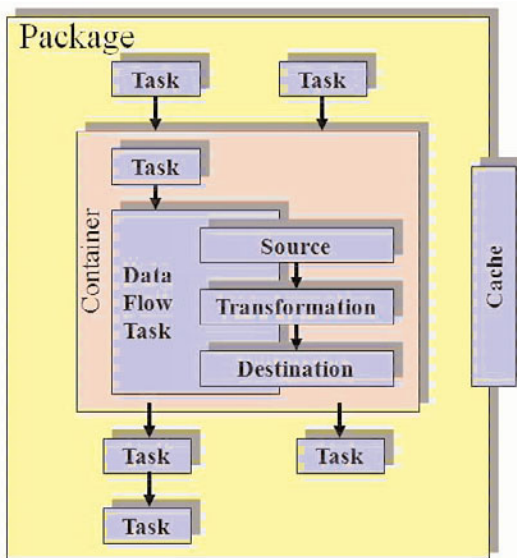

FIGURE 52.6 SSIS package elements.

SSIS also has several objects that extend package functionality:

- ▶ **SSIS event handlers**—These workflow tasks run in response to events raised by a package, task, or container. This is much the same as most programming languages, such as Java or C#. If a task (or package or container) has some issue (that is, raises an event), the event handler can be used to handle the issue appropriately. Typical events in data transformation processing that need to be handled with event handlers might include connections not being established, disk space issues, and so

on. You can even have the event handlers write out emails or initiate other workflows.

- ▶ **SSIS configurations**—These objects are used to help parameterize many of the previously hard-bound characteristics of packages at runtime. When a package is run, the configuration information is loaded (updating the values of the package's properties), and then the package is run using the new configuration values (all without having to modify the package). SSIS configurations use the classic property/value pair paradigm to represent the properties that are to be configurable. Following are the varied methods of representing configuration files:
 - ▶ **XML configuration file**—This file identifies the configuration property/value pairs for any number of configuration values. The following sample XML configuration file is for a package named `UnleashedPackage` with a property of `PKGVar`:

```
<?xml version="1.0"?>
<DTSConfiguration>
  <DTSConfigurationHeading>
    <DTSConfigurationFileInfo
      GeneratedBy="DatabaseArchitechs\PBertucci"
      GeneratedFromPackageName="UnleashedPackage"
      GeneratedFromPackageID="{3GV09721-816B-4E28-9878-0DE37A150234}"
      GeneratedDate="7/09/2009 7:12:22 AM" />
    </DTSConfigurationHeading>
    <Configuration ConfiguredType="Property"
      Path="\Package.Variables[User::PKGVar].Value"
      ValueType="Int32">
      <ConfiguredValue>0</ConfiguredValue>
    </Configuration>
  </DTSConfiguration>
```

A configuration header contains information about the configuration file. This element includes attributes such as when the file was created and the name of the person who generated the file. In addition, a configuration element contains information about each configuration. This element includes attributes such as the property path and configured value of a property.

- ▶ **Configuration table in SQL Server**—This table stores configuration entries for use by the packages.
- ▶ **Environment variables (VARs)**—These can be referenced by the package.
- ▶ **Parent package VARs**—These can be used by child packages.
- ▶ **Entry in Registry**—The Registry can also contain the configuration values.

- ▶ **SSIS Logging**—Logging can be done from any task or package to write out any type of logging information desired. When a supplied logging provider is used, a package can provide a rich runtime history. Logs are associated with packages (that is, the reference point), but any task (or container) can write to any package's log. In this way, it is possible to have consolidated logs of a driver package with the full execution history of all child packages. The log providers (out of the box) write to a flat file (text file) or to SQL Server tables. Other custom logging providers can be used, though. You can log what you need to log—start date/time, end date/time, records transformed, errors, and so on.
- ▶ **SSIS variables**—SSIS has both system variables and user-defined variables. System variables provide runtime package object information to tasks or other packages. This information is helpful when you want to reference these system variables to help decide what to do next. (They can be used in expressions, scripts, and configurations.) User-defined variables are really for specialized variables that are not found as system variables and only have to be used within a package's scope. Again, these variables can be used in expressions, scripts, and configurations within a package.

SSIS packages can run other packages. This capability is very helpful when you want to granularly break out common data transformations for reuse by many different higher-level solutions (that is, higher-level packages that execute common-detail-level transformation packages).

NOTE

When an SSIS package is first created, it is given a globally unique identifier (GUID) that is added to the package's ID property and a name that is added to its NAME property. After these are created, they become part of the reference mechanism for the package itself. If you ever copy a package as the basis of a new package, you have to rename these two properties so they are unique (that is, new GUID and new NAME property). If you simply want to give an existing package a new NAME or ID value, you can do so directly or with the `dtutil` command-line utility.

You can also create packages that can be restarted at a point of failure, including restarting specific tasks within a package (and not all the tasks in a package). This is a super addition to SQL Server 2008. If a package had more than one data flow task and one completed but the others didn't, you could restart just the data flow tasks that had not completed without rerunning the ones that had worked fine. Long-running packages can also create checkpoints to provide milestones from which to restart. This capability will save many sleepless nights for the folks doing production support for data transformation processing.

SSIS Tools and Utilities

SSIS includes several tools that simplify package creation, execution, and management. These tools are available within the Visual Studio/BI Development Studio IDE (as shown in the drop-down list in Figure 52.7) or integrated into other component-based tools (such as SSMS, as shown in Figure 52.8).

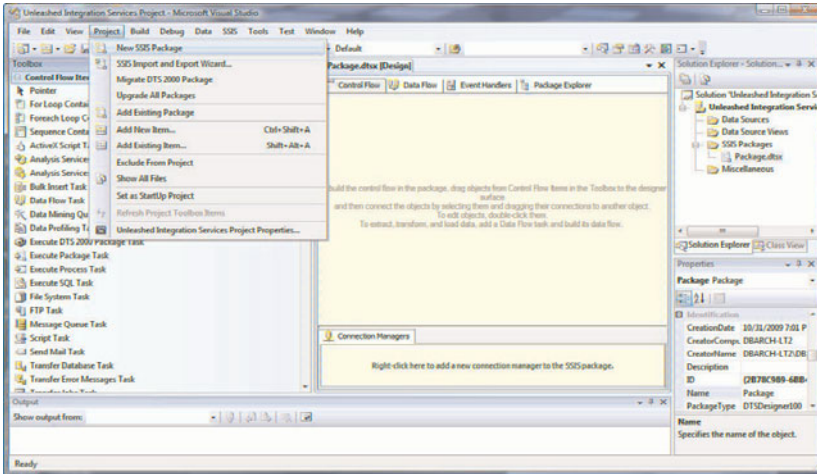

FIGURE 52.7 Package creation options within Visual Studio/BI Development Studio.

Equally as easily, you can invoke SSIS functionality (for example, the SSIS Import and Export Wizard) from within SSMS (see Figure 52.8).

Also, within SSMS, you can organize packages; execute packages (via the Execute Package utility); import and export packages to and from the SQL Server msdb database, the SSIS package store, and the filesystem (.dtsx files); and migrate DTS packages (older SQL Server version packages).

Following are the primary working environments for creating, managing, and deploying SSIS packages:

- ▶ **Import and Export Wizard**—You can use this wizard, available within Visual Studio/BI Development Studio or from SSMS, to build packages to import, export, and transform data or to copy database objects (see Figure 52.9). This is an easy way to create the basic SSIS packages that you need quickly and deploy them with great ease.
- ▶ **SSIS Designer**—This standard GUI is available in the Visual Studio/BI Development Studio, as part of an SSIS project. It lets you construct/manipulate packages containing complex workflows, multiple connections to heterogeneous data sources, and

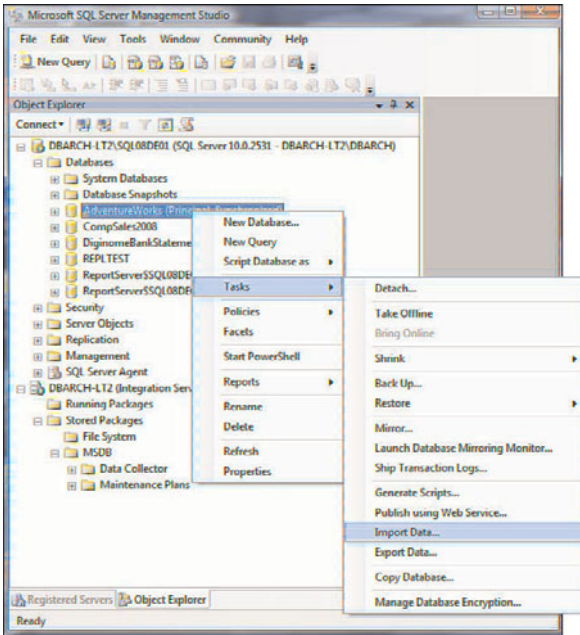

FIGURE 52.8 Invoking SSIS import/export data (package creation) capability from within SSMS.

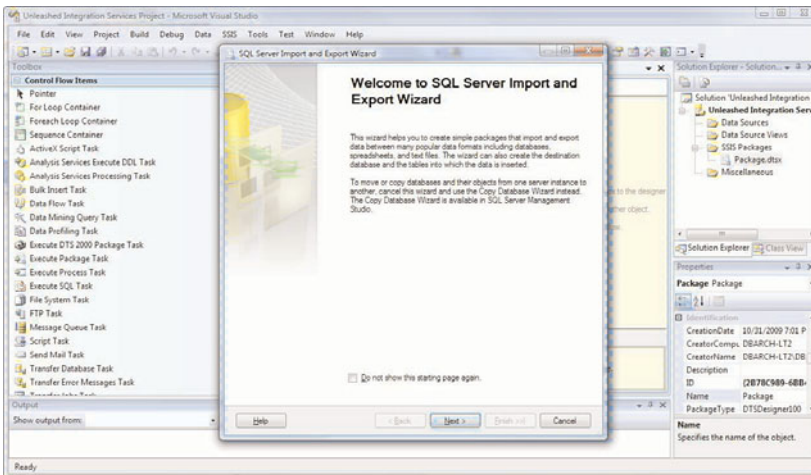

FIGURE 52.9 The Import and Export Wizard from Visual Studio/BI Development Studio.

even event-driven logic (see Figure 52.10). This is the same IDE that all code development uses in the .NET platform, making it extremely easy to start developing right away.

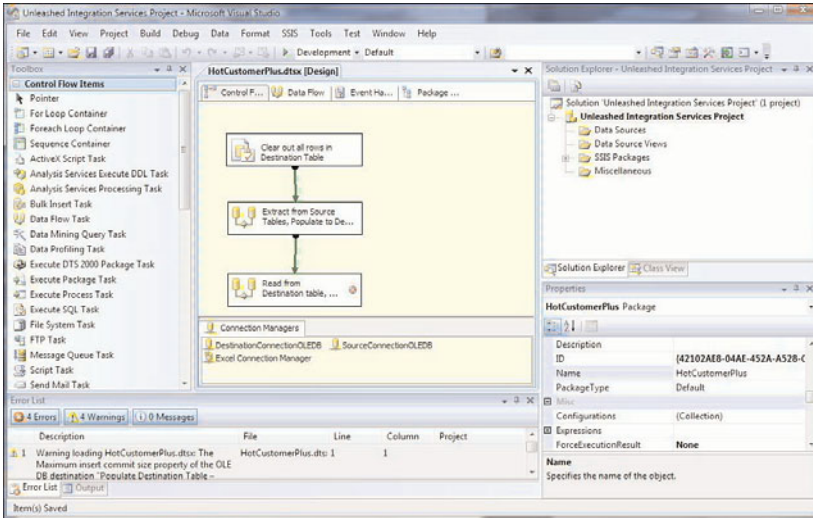

FIGURE 52.10 The SSIS Designer IDE.

- ▶ **SSIS command-line utilities**—A number of utilities are available within SSMS to aid you in running and managing SSIS packages (see Figure 52.11). One example is the Execute Package utility (which uses `dtexec` and `dtutil` command-line utilities). If the utility accesses a package that is stored in `msdb`, the command prompt may require a username and password.
- ▶ **SSIS Query Builder**—Query Builder provides an easy-to-use GUI for quickly developing SQL queries, testing the queries, and embedding them into the SSIS packages that you are developing. It is sort of like a mini SQL Query Profiler. It is entirely point-and-click oriented. Figure 52.12 shows the point at which you can invoke the Query Builder as you add Execute SQL Task as part of an SSIS package to the SQL Task Editor.

Figure 52.13 shows the full Query Builder interface, along with a SQL statement that is being developed that retrieves address information from the `AdventureWorks2008` `Person.Address` table.

- ▶ **SSIS Expression Builder**—You can use Expression Builder to develop the simple or complex expressions that get used by a package (the expression property of the package configuration). These expressions are things like validating working directories on a local machine where an SSIS package has been deployed and other complex

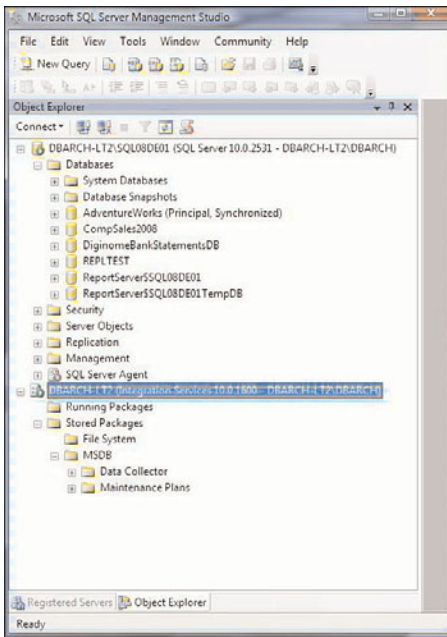

FIGURE 52.11 The Integration Services branch in SSMS.

evaluations that you want to have used by an SSIS package property. This graphical tool enhances your ability to use these types of expressions for your SSIS packages. It not only helps you develop the expressions, but also evaluates them to make sure they are providing the proper results (much like what Query Builder does for SQL statements). Figure 52.14 shows a typical expression palette of both the variables that can have expressions defined for them and some of the functions (such as string functions) that can be used with the expression.

Finally, after you have created SSIS packages, you need to execute them via command-line execution, within SQL programs, or via other .NET–supported programming languages. You can easily do this by using the `dtexec` package execution utility. You manage packages by using the `dtutil` utility.

A Data Transformation Requirement

Let's consider a true-life data export requirement that is best served by using SSIS. The requirement is for a small business intelligence data mart (on SQL Server 2008) to be spun off each week from the main OLTP database (also on SQL Server 2008) that addresses a product sales manager's need to see the total year-to-date business that a customer has generated. This data mart is merely a standard SQL Server database and tables that have been transformed (that is, aggregated) for a targeted purpose. As an option, the manager

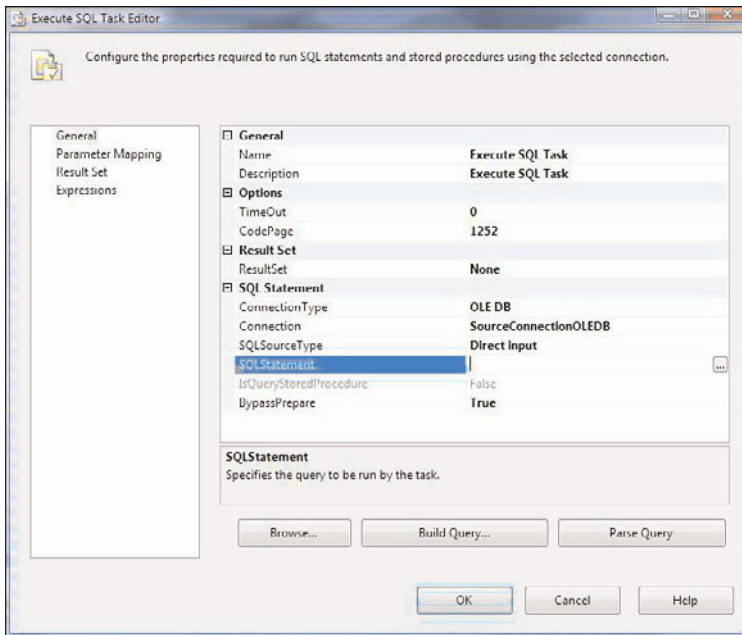

FIGURE 52.12 Invoking the Query Builder interface from the SQL Task Editor dialog.

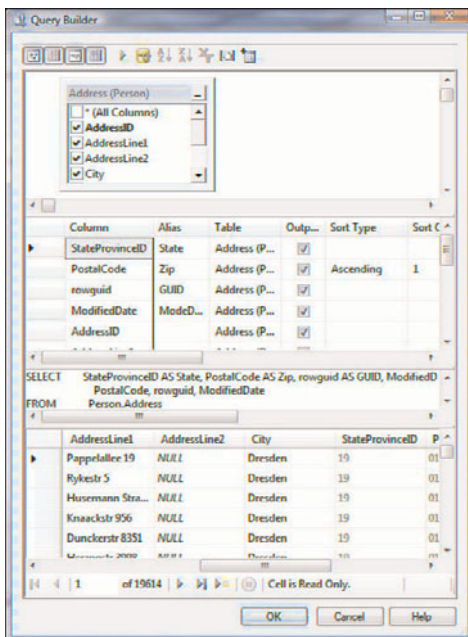

FIGURE 52.13 The Query Builder GUI for developing SQL queries.

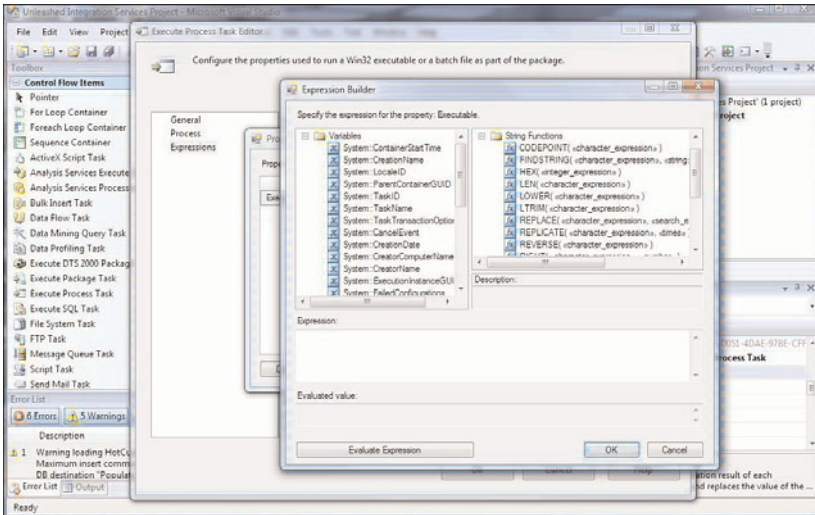

FIGURE 52.14 The SSIS Expression Builder GUI for developing expressions.

would also like to spin off an Excel version of this (or at least a comma-delimited .csv file for Excel), which will be distributed via email to all salespeople in the region. This overall requirement has been named “Hot Customers Plus” to indicate the emphasis on customers who are generating significant business for the company (and they will be customers who have made greater than \$5,000 worth of orders). The offloaded data mart is on a separate machine from the critical OLTP system for all the right reasons; no reporting or ad hoc queries are done against the OLTP system. This process must be repeated on a weekly basis as a total refresh (see Figure 52.15). We use the AdventureWorks2008 database for this example.

Essentially, order data from the OLTP database (contained in the Customer, Product, Store, SalesTerritory, SalesOrderHeader, and SalesOrderDetails tables) must be aggregated for every order for each customer. In addition, the total amount to be stored in the YTDTotalSales column in the data mart has to be extended out to reflect the summary of each product for each customer. The manager is also interested only in customers who are ordering products that total \$5,000 or more. Although the requirements are many, SSIS should be able to handle all this with no problem.

So that you can get a good feel for the two main SSIS tool capabilities, this chapter takes you through generating the solution to this requirement using the SSIS Wizard first, and then we walk through the same solution using SSIS Designer.

Running the SSIS Wizard

The SSIS Wizard is a streamlined interface solely used to generate SSIS packages for importing or exporting data. It is really quite powerful and provides an easy but sophisticated way to move data from or to any OLE DB, ODBC, or text source to another OLE DB, ODBC, or

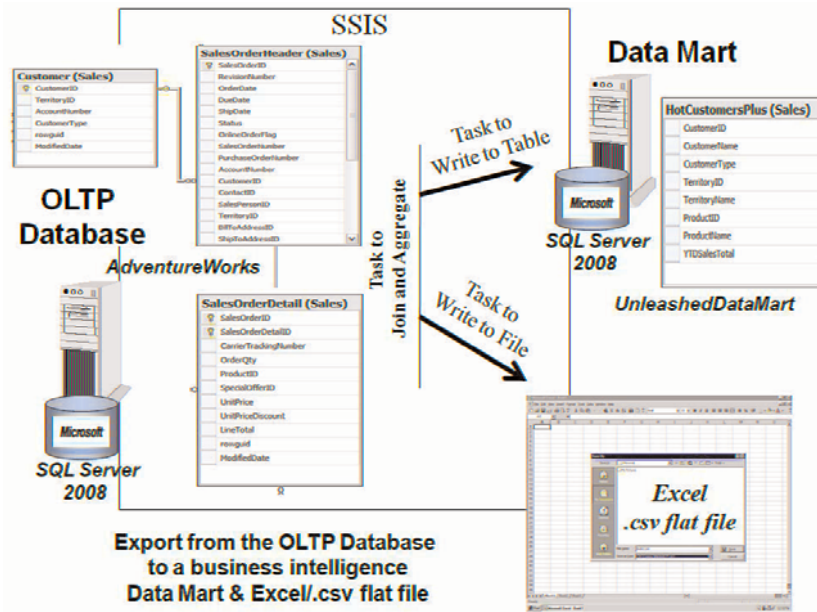

FIGURE 52.15 Creating a data mart and a comma-delimited flat file from an OLTP database, using SSIS.

text source. You can also define simple or complex data transformations using the many options provided by the wizard. The wizard can also copy database schema, but the transfer of all other database objects, such as indexes, constraints, users, permissions, stored procedures, and so on, is supported only between SQL Server 7.0 and higher SQL Servers.

The SSIS Import/Export Wizard takes the user through five basic steps for both imports and exports:

1. Select/identify the data source (source).
2. Select/identify the destination (target).
3. Select the data copy and transformation type. The options are to copy data with or without the schema, to move data based on a query, or to transfer objects and data between data stores.
4. Define any data transformations, if required.
5. Save, schedule, and execute the package.

Let’s walk through a quick wizard sequence and create a package that fulfills the “Hot Customers Plus” data movement/transformation requirement. You will be pulling and transforming data from the AdventureWorks2008 database and pushing it to another database on the same server instance (SQL08DEV01 in this example). So, first, you need to create

a database named UnleashedDataMart as the target database to hold the new HotCustomersPlus table you will be creating with SSIS. Remember that you use the SSIS Wizard for simple package creations (or data transfers). Nothing fancy here. To get started, here's what you do:

1. Fire up the SSIS Wizard from within SSMS by either right-clicking the database branch for the database from which you will be exporting data or right-clicking in the summary pane for that same database (as shown in Figure 52.16). If you select the Tasks option, you are given the option of either importing or exporting data. You want to export data from this database, so choose the Export Data option.

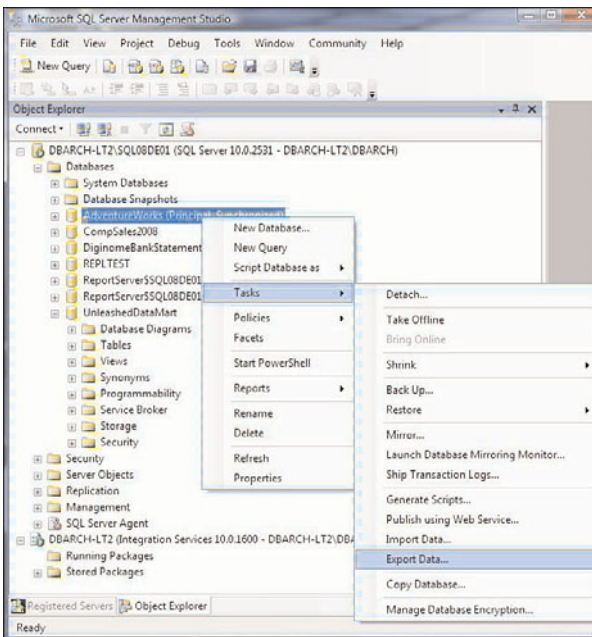

FIGURE 52.16 Invoking the Export Data Wizard.

2. Work through the steps of the SSIS Wizard. The initial step is identifying the source for the data. In this example, you need to choose a valid SQL Server and source database (in this example, DBARCH-LT2\SQL08DE01 for the server and AdventureWorks2008 for the database). In addition, you must provide the appropriate access credentials (Windows authentication or SQL Server authentication) for this source SQL Server. You have a few options of exactly what access mechanism to use (to this data source). Choose the SQL Native Client connection method (see Figure 52.17).

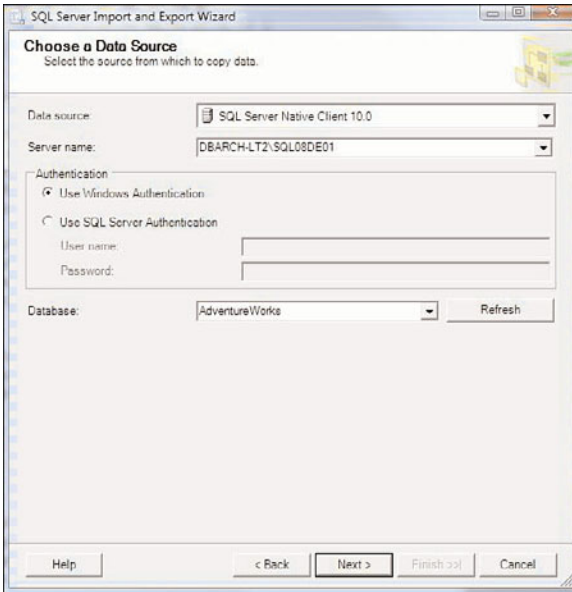

FIGURE 52.17 Identifying the SSIS source database and server locations.

3. Next is the data “destination” specification (the target). We had already created a new database (called `UnleashedDataMart`) for this purpose before we started and use that for this example. Our example uses the same SQL Server instance of `DBARCH-LT2\SQL08DE01`, using the connection method to this SQL Server instance of SQL Native Client, and the previously mentioned database of `UnleashedDataMart` (as shown in Figure 52.18). We also use Windows Authentication. You are finished with this window, so click Next.
4. The next step in the wizard asks if you will be pulling source data from one or more tables (or views) or if you will be specifying a SQL query to pull data from the source. For this example, select the Write a Query to Specify the Data to Transfer option because this approach best fits the requirement specified earlier (see Figure 52.19).
5. In the next step in the wizard, create your custom SQL statement that will be used to select data from the source database. We have provided a fairly complex SQL query that selects (and joins) data from six tables in the `AdventureWorks2008` database to fulfill the data requirement for this example. This SQL Statement is available on this book’s CD. In this step of the wizard, enter the following query:

```
SELECT  a.CustomerID,
        e.name as CustomerName,
        a.CustomerType,
        a.TerritoryID,
        d.name as TerritoryName,
        c.ProductID,
```

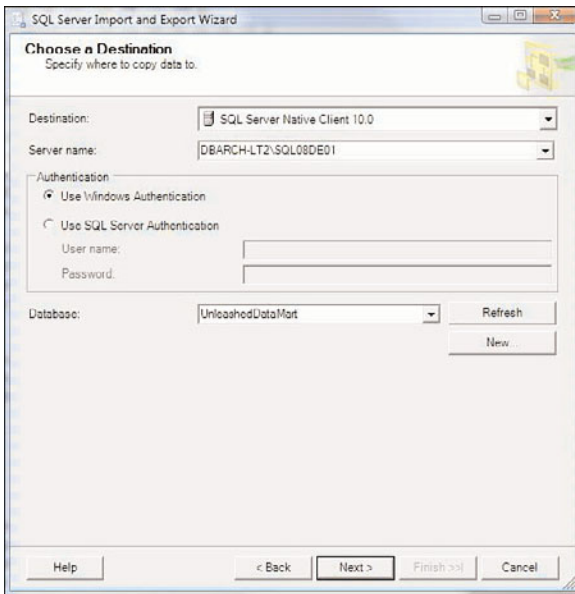

FIGURE 52.18 Identifying the SSIS destination database and server locations.

FIGURE 52.19 Specifying to use tables or a query for data transfer from the data source.

```

        f.name as ProductName,
        sum(c.LineTotal) as YTDSalesTotal
FROM
    [sales].[Customer] a
    INNER JOIN [sales].[SalesOrderHeader] b
        ON a.customerid = b.customerid
    INNER JOIN [sales].[SalesOrderDetail] c
        ON b.SalesOrderID = c.SalesOrderID
    INNER JOIN [sales].[SalesTerritory] d
        ON a.TerritoryID = d.TerritoryID
    INNER JOIN [sales].[Store] e
        ON a.customerid = e.customerid
    INNER JOIN [Production].[Product] f
        ON c.productID = f.ProductID
WHERE b.orderdate >= '2004-01-01 00:00:00.000'
GROUP BY a.customerID,
        e.name,
        a.CustomerType,
        a.TerritoryID,
        d.name,
        c.ProductID,
        f.name
HAVING sum(c.LineTotal) > 5000
ORDER BY d.name,
        e.name

```

In this window, you can select a query from a file by clicking the Browse button to search for this file, or you can simply start coding directly in the window. You can click the Parse button to guarantee that the SQL statement has valid syntax and form (see Figure 52.20). You can test it (preview the data) in the next wizard step.

However, if you chose to copy data directly from the database tables (and not use a SQL query), you would be provided a list of tables and views from the source database and would be able to map one or more of these tables to tables on the destination database. Figure 52.21 shows how this Select Source Tables and Views window would look.

6. Rename the destination table by changing [dbo].[Query] to [UnleashedDataMart].[dbo].[HotCustomersPlus] (see Figure 52.22). All subsequent references to this destination target will be what you want.
7. Click the Preview button on this dialog to actually execute the SQL query specified in step 5. Figure 52.23 shows the Preview Data results of the custom SQL query. Close this data preview window when you are finished reviewing the data results.
8. Click the Edit Mappings button to see the details of the column-level mappings being defined. At this point, you can further subset the columns, change data types, use precision or scale change, and/or not have a column mapped during the data transformation. As you can see in Figure 52.24, the Source and Destination columns

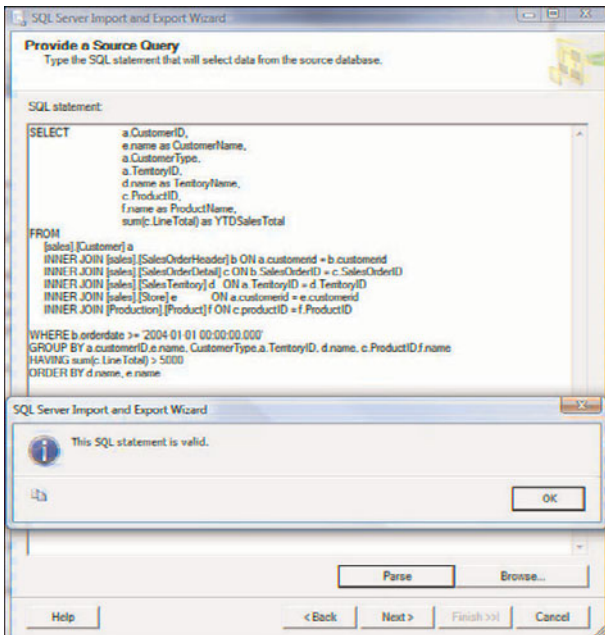

FIGURE 52.20 Providing a SQL query to select data from a data source.

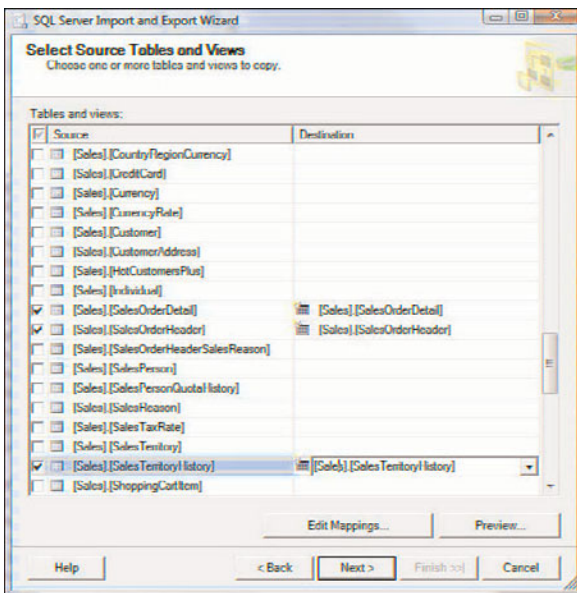

FIGURE 52.21 Mapping source tables and views to a destination.

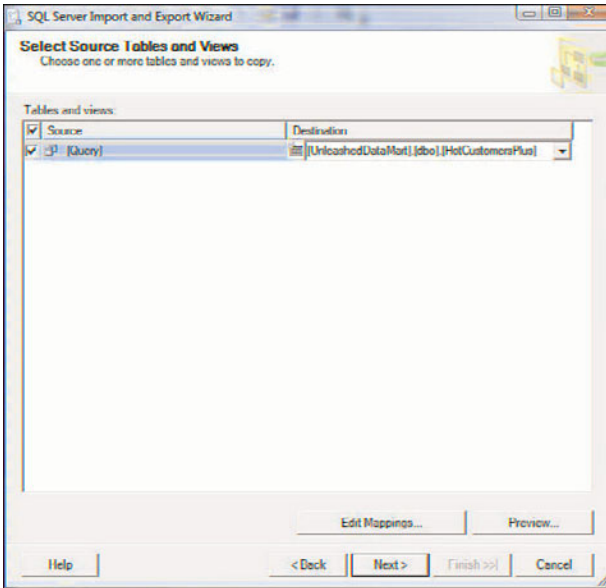

FIGURE 52.22 Source query mapping to a destination.

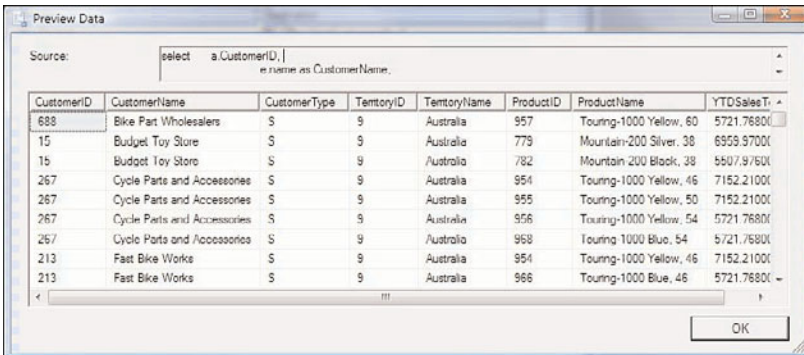

FIGURE 52.23 Previewing the data from a SQL query.

are side by side, and when you click a column name, you can adjust what you want to occur (such as ignore or map to the column). In addition, at the object level, you can have the table created at the destination, have it truncate the data in an existing table at the destination, or append data to existing data at the destination. For this example, choose to completely drop and re-create the destination table each time. You are basically done creating the logic and data mappings for this simple data transformation.

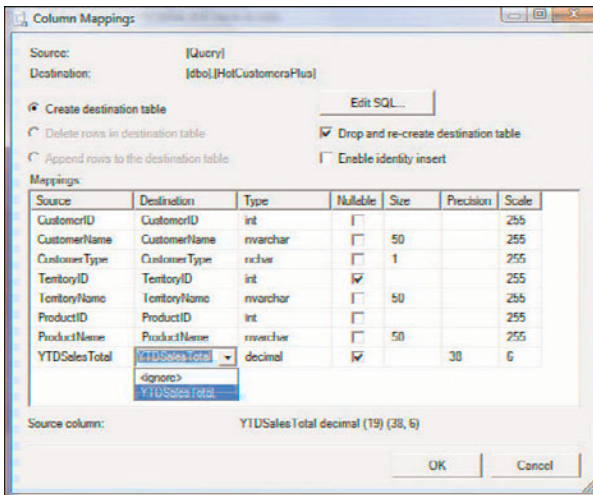

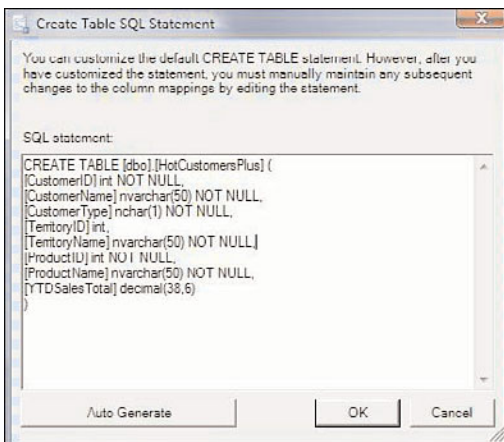

FIGURE 52.24 Column Mappings options.

- If you want, click the Edit SQL button in the Column Mappings dialog. A CREATE TABLE SQL statement appears, and you can modify it if you want (see Figure 52.25). You don't need to do any further changes at this time, however.

FIGURE 52.25 Manually customizing the default **CREATE TABLE** statement.

- In the Save and Run Package dialog that appears, choose Run Immediately and Save SSIS Package. Save the SSIS package in SQL Server in the msdb SQL Server database

(see Figure 52.26). It is also possible to save the SSIS package in a structured storage file at the filesystem level (in a .dtsx file).

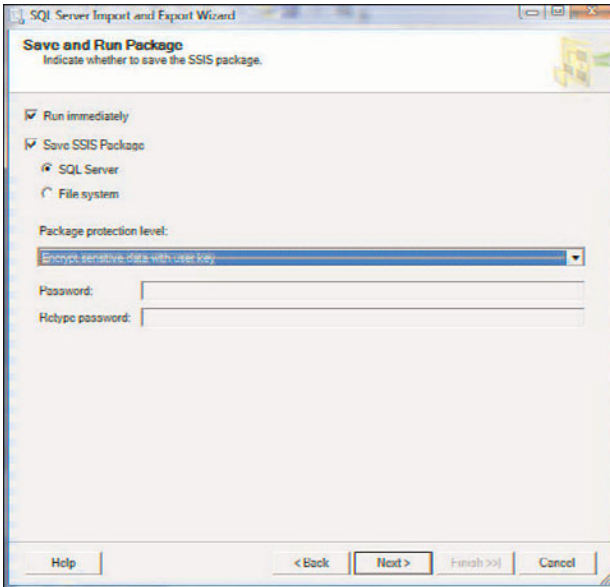

FIGURE 52.26 Options for executing and saving SSIS packages.

11. In the Save SSIS Package dialog, you specify the name of the package, description of the package, and location where the package is to be stored. For this example, specify the name “HotCustomersPlus” for the SSIS package, as shown in Figure 52.27.
12. When the SSIS Wizard displays the Complete the Wizard dialog, summarizing all the actions to be taken, carefully review the list and then click Finish when you are ready to proceed. After you click Finish, the wizard’s execution console appears, as shown in Figure 52.28. This console shows all the steps taken, the status of these steps, and informational detail, as required. In Figure 52.28 note the Copying to [Unleashed].[dbo].[HotCustomersPlus] table message that 943 rows were transferred. There is an Error in the step above the row copy that refers to the Drop of the target table not being found. This was expected since the table never existed before, this was the first time it would have been created. Subsequent runs will not have this error. Following this particular “Copying” step are the simple post execute and cleanup actions for the package.

If you would like, you can also query the system catalog table that contains the metadata for packages. In this case, the system table [msdb].[dbo].[sysssispackages] contains this metadata for SSIS packages starting with SQL Server 2005, and going forward. The following simple SQL query shows the metadata entry for the package you just created:

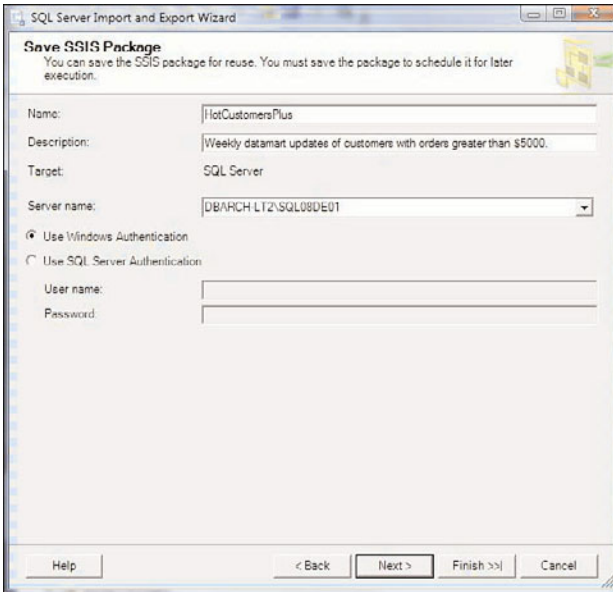

FIGURE 52.27 Saving a package for reuse.

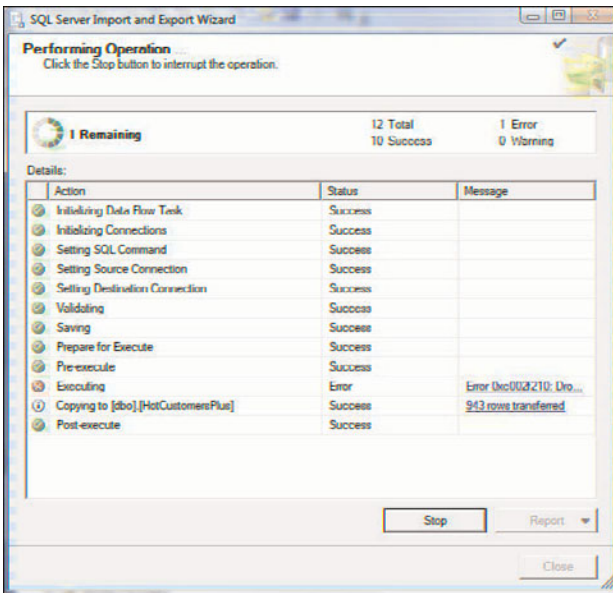

FIGURE 52.28 SSIS package initialization, saving, and execution.

```
SELECT * FROM [msdb].[dbo].[sysssispackages]
```

The results look like this:

Name	ID	Description	Datetime
HotCustomersPlus	025EBC25...	Weekly datamart updates...	2009-11-01 ...

Figure 52.29 shows the execution tasks for doing straight table copying (transferring) using SSIS packages of the tables to create a quick-and-dirty (refreshable) data mart. This method of spinning off data quickly is very useful, and it fits our requirements.

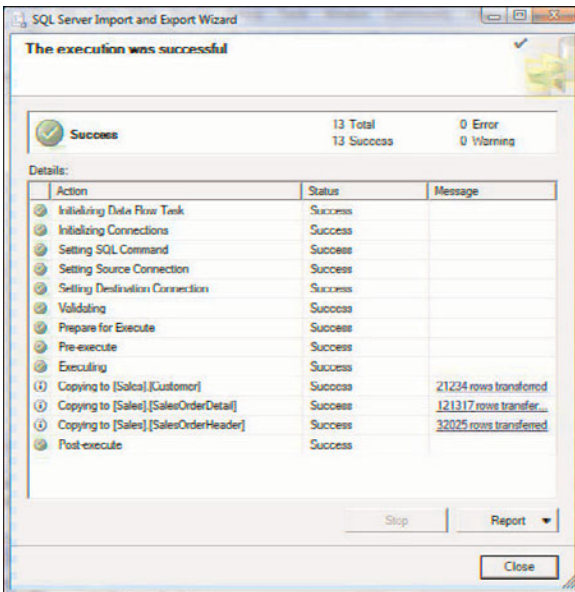

FIGURE 52.29 An SSIS package straight table copy/transfer example.

The SSIS Designer

The SSIS Designer is extremely easy to use and gives a user the flexibility of editing and manipulating any of the package properties in any order needed, as opposed to the strict sequential order of the SSIS Wizard. After you have mastered all the package concepts, you will find that you will be spending most of your time using the SSIS Designer instead of the wizard.

Because you have already created an SSIS package using the wizard, you can just open a version of this package (which you stored in the filesystem as a `.dtsx` file) with the SSIS Designer to see some of the SSIS Designer's capabilities (see Figure 52.30). You simply locate a `.dtsx` package file (such as `HotCustomersPlus.dtsx`) using the File Open option within (BI) Development Studio/Visual Studio. We have supplied one for you on the CD included with this book if you want to use this one.

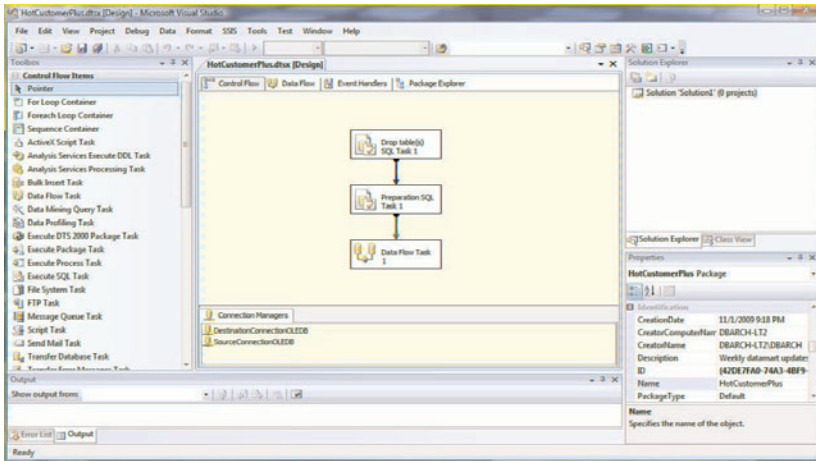

FIGURE 52.30 The SSIS Designer: opening the **HotCustomersPlus.dtsx** package.

As you can see with the SSIS Designer, you are within the common Visual Studio IDE environment, which is used for any type of managed code. SSIS package creation is now just another option of a code development project. The SSIS Designer includes a main designer pane, a palette of toolbox icons to the left, an error pane on the bottom, the Solution Explorer to the right, and Properties pane in the bottom right. The Connection Manager sits directly below the designer pane, and there are four basic tabs in the designer pane for different purposes: the Control Flow pane is for overall task, control of flow, and constraint specification; the Data Flow pane is for generating and manipulating the data mapping and transformation itself; the Event Handlers pane is for defining what error handling needs to be part of this package; and the Package Explorer pane is for an overall view of the elements of the package.

The SSIS Designer is truly a point, click, and drag working environment. For anything in the workspace, you simply click the icon, such as `DestinationConnectionOLEDB` (in the Connection Managers pane) or the Preparation SQL Task icon in the Control Flow pane to see its properties, or you click the solid line between the Preparation SQL Task and Data Flow Task boxes to see the task constraints and workflow defined for the package. If you haven't created the `HotCustomersPlus` SSIS package, you should do so now with the wizard and save it to the filesystem as well (as a `.dtsx` file). You use it in the next example.

At this point, you need to fire up Visual Studio 2008 or the BI Development Studio environment. Either way, the same IDE is started. The SSIS Designer is initiated within this IDE. When you have successfully started the Visual Studio 2008 IDE environment, you can easily open the SSIS package you just created and use it to get familiar with the SSIS Designer. Simply choose File, Open in Visual Studio 2008 and locate the `HotCustomersPlus.dtsx` SSIS package you created earlier (see Figure 52.31). You are about to modify this SSIS package to more fully support the `HotCustomersPlus` data mart and Excel comma-delimited flat file creation requirements because the wizard could not completely do that.

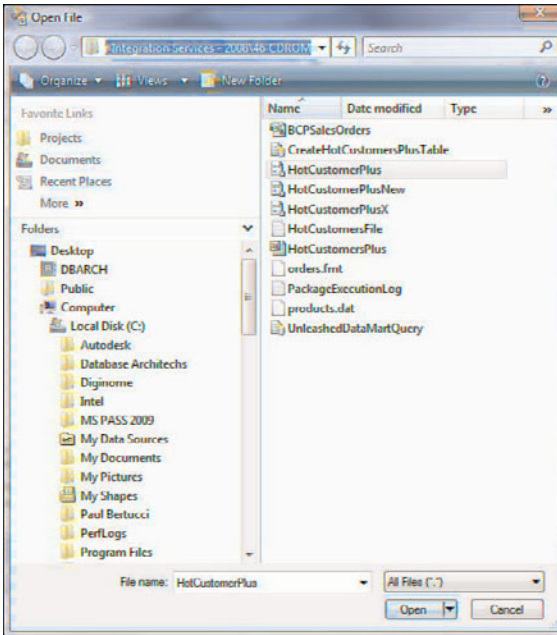

FIGURE 52.31 Opening the **HotCustomersPlus.dtsx** package.

When you open this package, you enter Visual Studio's development environment, where you can use the SSIS Designer capabilities. You will be using the SSIS Toolbox to the left to add functionality to this small SSIS package so that it will completely fulfill the data mart requirements outlined earlier. If you look back at Figure 52.30, you see this simple SSIS package within the SSIS Designer. This is what you should have as well. Now, you can modify any existing tasks or add others to this SSIS package. If you recall, you originally set up this package to create a new destination table (on the other SQL Server instance) as the first step. Because you already executed this once, that table now exists (**HotCustomersPlus** on the destination SQL Server instance). Therefore, you need to change this first step to truncate the destination table instead of re-creating it each time. In addition, you need to add another task to this package that will spin off newly populated data (from the destination table) into an Excel comma-delimited flat file that can be easily distributed to the sales team. As you change this package, you also re-label the tasks to be more reflective of what they are doing (and not use the default task naming that the wizard used).

The sales team is waiting, so follow these steps:

1. You don't need the Drop Table(s) SQL Task 1 step because you will be utilizing the existing table created from the wizard. So, first just delete this step. You can use a truncate table approach to clear the existing table out before repopulating it each time the package is run. Simply right-click on the Drop Table(s) SQL Task 1 box and choose Delete. Confirm you want to delete it.

- Right-click on the Preparation SQL Task and choose Edit. The Execute SQL Task editor comes up, and in it you can see all aspects of this SQL task. Click the SQL statement property within this window (where you see the CREATE TABLE statement) and then click the ... icon to the right of the CREATE TABLE statement. This opens an editor window that contains the full SQL statement. Now, change this CREATE TABLE statement to a TRUNCATE TABLE statement for the same table on the destination SQL Server instance:

```
TRUNCATE TABLE [UnleashedDataMart].[dbo].[HotCustomersPlus]
GO
```

This statement is clearly shown in Figure 52.32. After updating the SQL statement to a TRUNCATE, change the BypassPrepare True/False flag to False. Then click OK and click Parse Query to make sure the SQL statement is valid. You can now rename this task to something more appropriate by just clicking the Name property of this task and changing it to something like Clear out all rows in Destination Table. If all is well, click OK to exit this window. Now this task clears out the destination table before it repopulates it with new data instead of re-creating the destination table over and over.

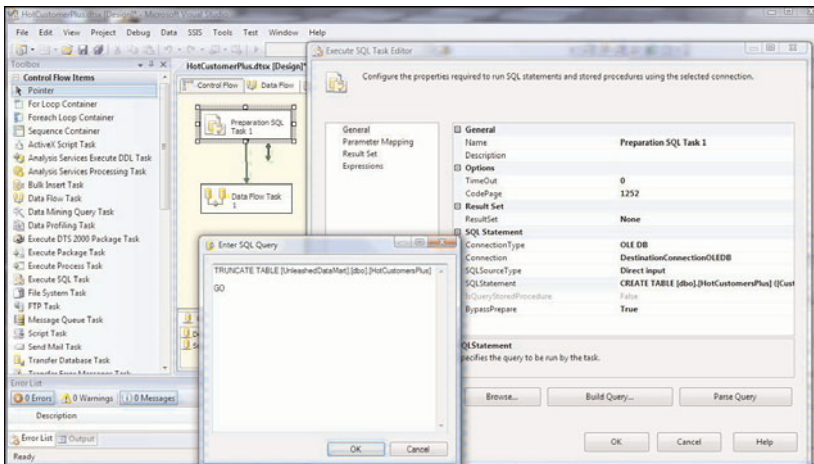

FIGURE 52.32 Modifying the Execute SQL Task from a **CREATE TABLE** statement to a **TRUNCATE TABLE** statement.

- Rename the existing Data Flow task that pulls data out of the source SQL Server tables via a SELECT statement and populates the destination table. To do so, click this current data flow task and either right-click and choose Edit or just click the Data Flow tab in the IDE. You now see the multiple steps within this data flow. Locate the

Name property of this data flow task and rename it from Data Flow Task to Extract from Source Tables, Populate to Destination table. Click the first step of the data flow (which has the name property Source – Query) and rename it Select orders from AdventureWorks2008. Now, click on the destination task (Destination – HotCustomersPlus) and rename it Populate Destination Table – HotCustomersPlus, as shown in Figure 52.33.

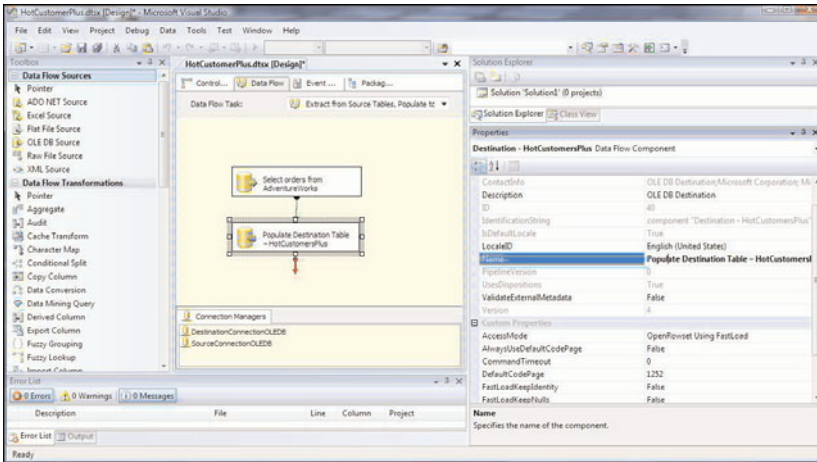

FIGURE 52.33 Modifying the data flow task within the SSIS package.

4. Add a new data flow task that will read the sales order data from the destination table being populated from the source tables and then write out an Excel flat file with this new data. From the Control Flow tab of this SSIS package, drag a new data flow task (from the Toolbox on the left) out to the Control Flow designer pane and then modify its name property to be Read from Destination table, Populate Excel flat file, as shown in Figure 52.34.
5. Click the Data Flow tab, and you are in the Data Flow designer pane. Nothing is there yet (the Data Flow design space is empty). Also note that the Toolbox entries change when you click this tab (they are now all the data flow task items). Drag an OLE DB Source item from the Toolbox over to the Data Flow designer pane. You will use this to get the data from the destination table. Rename this Data Flow step something like Pull data from Destination Table and then right-click this new Data Flow source task and choose Edit. This puts you in the OLE DB Source Editor, where you can identify which connection manager to use (DestinationConnectionOLEDB, in this example) and what table you want to get data from (HotCustomersPlus table). You want the whole table, so specify the Table or View option for the access mode (see Figure 52.35). Click the Preview button at the

bottom of this editor to verify that you will get all data from the destination table. Clicking OK returns you to the Data Flow designer pane.

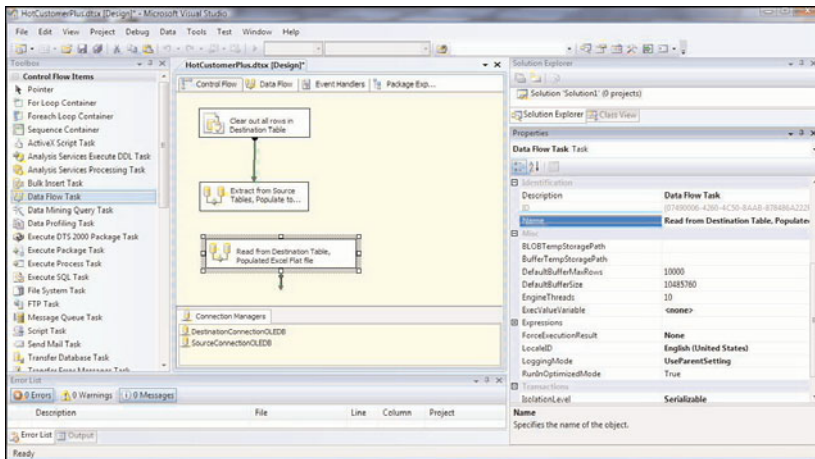

FIGURE 52.34 Creating a new data flow task to write data out to an Excel flat file.

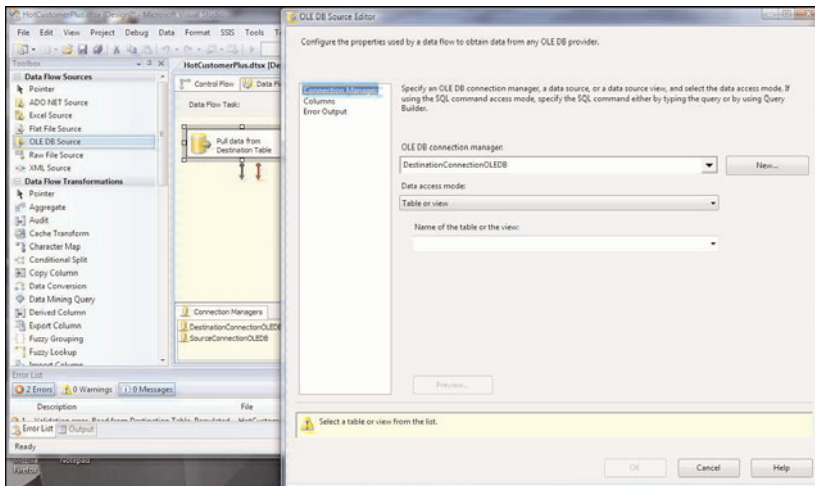

FIGURE 52.35 Specifying the Source Data Flow items for a new data flow task.

- Back in the Data Flow designer pane, scroll down in the Toolbox to the Data Flow Destinations portion and locate the Flat File Destinations item. Drag this over

to the Data Flow designer pane and rename it something like `Write data to Excel Flat file`.

- Before you go any further, you need to connect the source data flow task (and its data output) to this new Excel flat file destination. You can easily do this by just clicking the source data flow task's outbound arrow (that is just below the box and is green) and dragging it to the new Excel flat file destination box. A full arrow is redrawn that connects these two data flow tasks (as you can see in Figure 52.36).

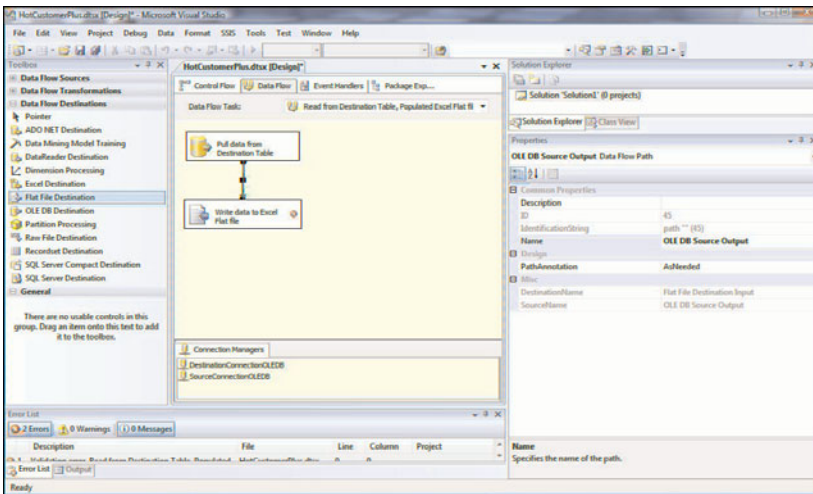

FIGURE 52.36 Connecting the data source to the data destination for the new data flow task.

- Right-click this new data flow task item (Excel Flat file Destination) and choose `Edit`. This again puts you in an editor where you can specify the flat file destination file properties you want. This starts with identifying the connection manager and the flat file to be used. Click `New` here and choose the `Delimited` format of the destination flat file. Now, specify a location and filename for the destination flatfile (`HotCustomersPlus.csv`). Figure 52.37 shows this complete flat file destination specification. Click the `Preview` button to make sure this data will be retrieved properly (column names appear across the top of the preview dialog; because the file is empty, no data shows).

You can also click the `Mappings` option in the Flat File Destination Editor dialog. As you can see in Figure 52.38, each of the columns in the source table (the `HotCustomersPlus` table) will be mapped, one to one, to the flat file columns with the same names.

- Return to the Control Flow pane of the SSIS package and connect the new data flow task to the prior one. You do this by clicking the original data flow task and grabbing its control of flow arrow beneath the box and dragging it to the new data flow

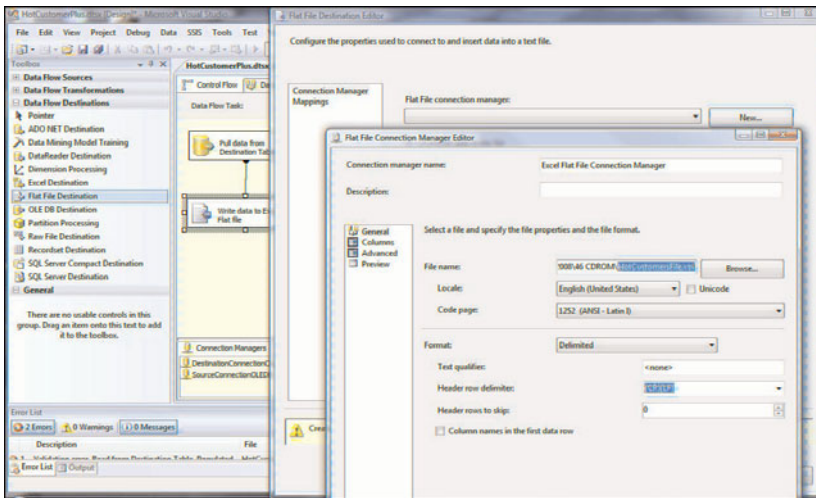

FIGURE 52.37 Specifying the flat file destination data flow items for a new data flow task.

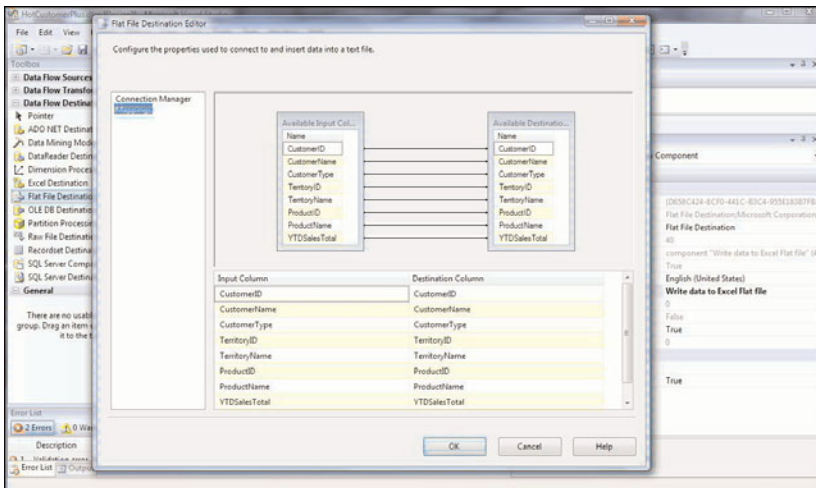

FIGURE 52.38 Source and destination column mappings.

task you just created. Accept the default to execute the task on success of the prior task, as shown in Figure 52.39. Note that the Flat File Destination connection manager now appears under the connection manager pane, and you should have zero errors in the error list. At this point, save the package by clicking the disk icon or selecting File, Save.

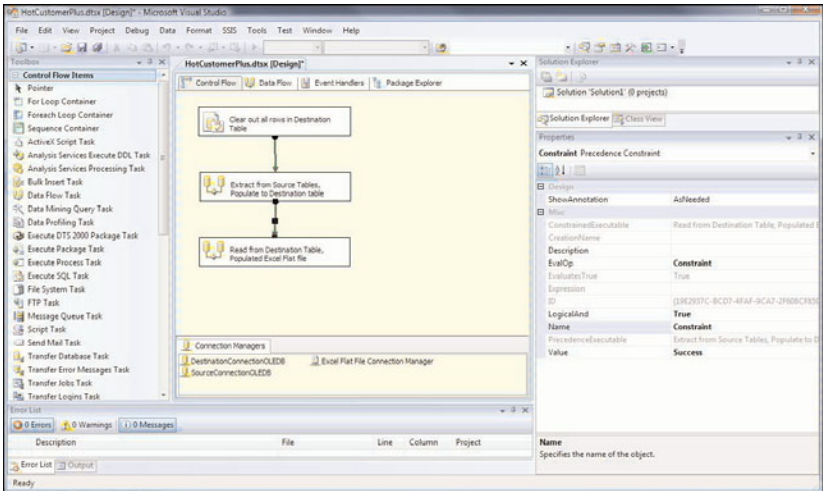

FIGURE 52.39 Control of flow between the old data flow and new data flow tasks.

10. To execute the package, double-click the .dtsx file, which automatically invokes the package execution utility. Choose Execute, and the package executes and shows all results in the execution console, as shown in Figure 52.40. That's it: you have populated the data mart and created data in an flat file for distribution to the sales team.

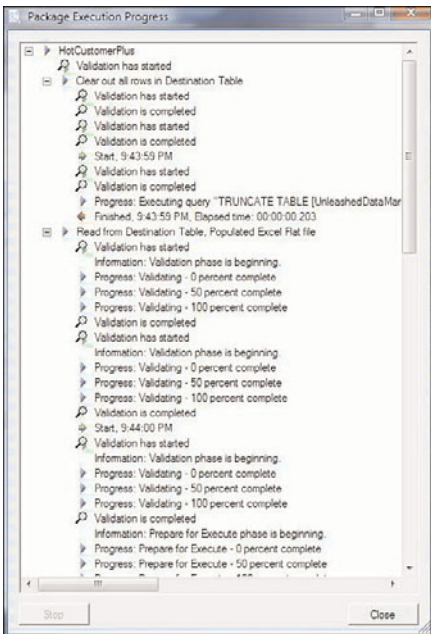

FIGURE 52.40 Executing the SSIS package.

NOTE

You could also execute this new package by using the `dtexec` utility at a command prompt:

```
C:> dtexec /FILE "C:\HotCustomerPlus.dtsx"
```

The Package Execution Utility

The `dtsrun` utility in SQL Server 2000 is no longer used within SQL Server 2008. It has been taken over by the `dtexec` utility, which is bigger and better and has more options and values to serve your every SSIS package execution need. Before you begin to use the `dtexec` utility, you should execute it at a command prompt with the help option set only and pipe the results into a text file:

```
c:> dtexec /? > dtexec.txt
```

You will quickly see all the main options and how similar this is to `dtsrun` (in SQL Server 2000). Some `dtsrun` command-line options have direct `dtexec` equivalents, such as the options for providing a server name or package name or for setting the value of a variable. Other `dtsrun` command-line options don't have direct `dtexec` equivalents. In addition, some `dtexec` command-line options support features in SSIS, such as the options to pass in connection strings and manage checkpoints.

You can create new command-line `dtexec` executions visually with the assistance of the Package Execution utility, which you open through `dtexecui`. This GUI displays all the available options and ensures the use of the correct syntax (see Figure 52.41). You start it up from the command prompt:

```
c:> dtexecui
```

Using this Package Execution utility is really the best way to create new command-line executions for SSIS packages and to run them easily. Figure 52.42 shows the Package Execution Progress console during a package execution. You can choose to stop the execution from here.

When you double-click any filesystem-stored SSIS package (that is, `.dtsx` file), you are always placed in this `dtexecui` environment (just as you automatically start up Microsoft Word when you double-click a Word document).

The `dtexec` Utility

You use the `dtexec` command-line utility to configure and execute SSIS packages. The `dtexec` utility provides access to all the package configuration and execution features, such as connections, properties, variables, logging, and progress indicators. The `dtexec` utility lets you load packages from three sources:

- ▶ A Microsoft SQL Server database
- ▶ The SSIS service (package store)

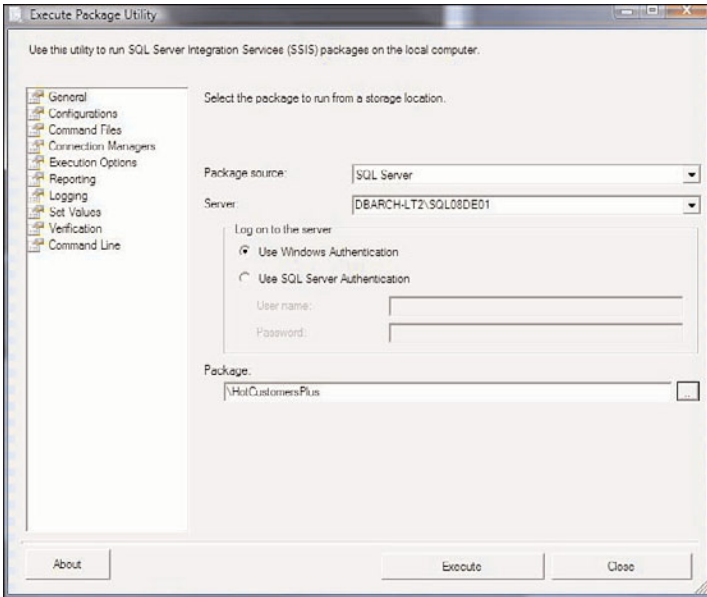

FIGURE 52.41 The user interface for executing and configuring SSIS packages.

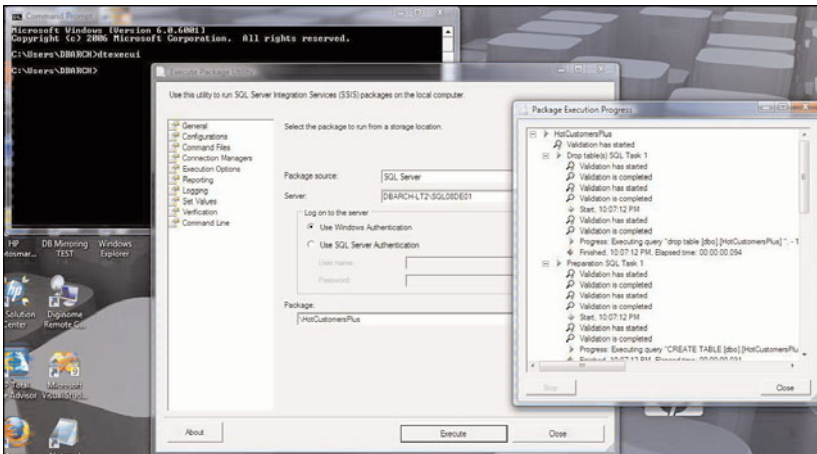

FIGURE 52.42 The Package Execution Progress console in the Execute Package utility.

- The filesystem itself

The dtexec utility proceeds through four phases as it executes:

1. **Command sourcing phase**—The command prompt reads the list of options and arguments specified. All subsequent phases are skipped if a /? or /H[ELP] option is encountered.

2. **Package-loading phase**—The package specified by the `/SQL`, `/FILE`, or `/DTS` option is loaded.
3. **Configuration phase**—These options are processed in the following order: process options that set package flags, variables, and properties; process options that verify the package version and build; and process options that configure the runtime behavior of the utility, such as reporting.
4. **Validation and execution phase**—The package is run or validated without running if the `/VALIDATE` option was specified.

When a package runs, `dtexec` can return an exit code. The exit code is used to populate the `ERRORLEVEL` variable—the value of which can then be tested in conditional statements or branching logic within an operating system batch file. The `dtexec` utility can set the following exit code values:

Exit Code Value	Description
0	Successful package execution.
1	Package execution failure.
3	User-canceled package execution.
4	Package could not be found.
5	Package could not be loaded.
6	Utility encountered an internal error.

Running Packages

The `dtexec` options are additive. Depending on what you are trying to do, you are able to string one or more options and their values together in the following form:

```
dtexec /option [value] [/option [value]] ...
```

To show available options for `dtexec`, you use `'/?'` or `'/H'` or `'/Help'`. Alternatively, you can see the details for a particular option by using the available options indicator followed by the option name (`'/? [option name]`). This invokes SQL Server Books online for that particular option. Note that a dash (-) may be substituted for `/` in this command.

The `dtexec` package execution options include the following:

- ▶ **`/~CheckF[ile] filespec`**—This option sets the `CheckpointFileName` property on the package to the path and file specified in `filespec`. This file is used when the package restarts.
- ▶ **`/~CheckP[ointing]{on\off}`**—The value `on` specifies that a failed package is to be rerun. When the failed package is rerun, the runtime engine uses the checkpoint file to restart the package from the point of failure. The default value is `on` if the option is declared without a value. Package execution fails if the value is set to `on` and the checkpoint file cannot be found. If this option is not specified, the value set in the package is retained.

NOTE

Using the `/CheckPointing` option of `dtexec` is equivalent to setting the `SaveCheckpoints` property of the package to `True` and the `CheckpointUsage` property to `Always`.

- ▶ `/-Com[mandFile] filespec`—This option specifies that during the command sourcing phase of the utility, the file specified in `filespec` is opened, and options from the file are read until the EOF is found in the file. `filespec` is a text file that contains additional `dtexec` command options. The `filespec` argument specifies the filename and path of the command file to associate with the execution of the package.
- ▶ `/-Conf[igFile] filespec`—This option specifies a configuration file to extract values from. Using this option, you can set a runtime configuration that differs from the configuration specified for the package at design time.
- ▶ `/-Conn[ection] id_or_name;connection_string [[:id_or_name;connection_string]...]`—This option specifies the specific connection manager name or GUID and the specific connection string to use. This option requires that both parameters be specified.
- ▶ `/-Cons[oleLog] [[displayoptions];[list_options;src_name_or_guid]...]`—This option displays specified log entries to the console during package execution.

The `displayoptions` values are *N* (name), *C* (computer), *O* (operator), *S* (source name), *G* (source GUID), *X* (execution GUID), *M* (message), and *T* (time start and end).

One `list_options value` is *I*, which specifies the inclusion list. With this value set, only the source names or GUIDs that are specified are logged. The value *E* specifies the exclusion list. With this value set, the source names or GUIDs that are specified are not logged. The `src_name_or_guid` parameter specified for inclusion or exclusion is an event name, a source name, or a source GUID.

- ▶ `/-D[*] package_path`—This option is used to load a package from the SSIS package store. The `package_path` argument specifies the relative path of the SSIS package, starting at the root of the SSIS package store, and includes the name of the SSIS package. The `/DTS` option cannot be used together with the `/File` or `/SQL` option.
- ▶ `/-De[crypt] password`—This option provides the decryption password used when you load a package with password encryption.
- ▶ `/-F[ile] filespec`—This option is used to load a package saved at the filesystem level. The `filespec` argument specifies the path and filename of the package.
- ▶ `/-L[ogger] classid_orprogid;configstring`—This option associates one or more log providers with the execution of an SSIS package. The `classid_orprogid` parameter specifies the log provider and can be specified as a class GUID. `configstring` is the string used to configure the log provider.

Following are the available log providers:

```

Text file:
  ProgID: DTS.LogProviderTextFile.1
  ClassID: {59B2C6A5-663F-4C20-8863-C83F9B72E2EB}
SQL Server Profiler:
  ProgID: DTS.LogProviderSQLProfiler.1
  ClassID: {5C0B8D21-E9AA-462E-BA34-30FF5F7A42A1}
SQL Server:
  ProgID: DTS.LogProviderSQLServer.1
  ClassID: {6AA833A1-E4B2-4431-831B-DE695049DC61}
Windows Event Log:
  ProgID: DTS.LogProviderEventLog.1
  ClassID: {97634F75-1DC7-4F1F-8A4C-DAF0E13AAA22}
XML File:
  ProgID: DTS.LogProviderXMLFile.1
  ClassID: {AFED6884-619C-484F-9A09-F42D56E1A7EA}

```

- ▶ **/-M[axConcurrent] concurrent_executables**—This option is used to identify the number of executable files the package can run concurrently. The value specified must be either a non-negative integer or -1. With a value of -1, SSIS allows a maximum number of concurrently running executables equal to the total number of processors on the computer executing the package, plus two.
- ▶ **/-P[assword] password**—This option is used together with the **/User** option to retrieve the package from SQL Server. If the **/Password** option is omitted and the **/User** option is used, a blank password is used.
- ▶ **/-Rem comment**—This option creates a comment on the command prompt or in command files. The comment is a string that must be enclosed in quotation marks, and it must contain no whitespace.
- ▶ **/-Rep[orting] level [;event_guid_or_name[;event_guid_or_name[...]]**—This option identifies what types of messages to report. Available reporting option levels are **N** (no reporting), **E** (errors are reported), **W** (warnings are reported), **I** (informational messages are reported), **C** (custom events are reported), **D** (data flow task events are reported), **P** (progress is reported), and **V** (verbose reporting; all details of each type). If the **/Reporting** option is not specified, the default level is **E**, **W**, and **P**.
- ▶ **/-Res[tart] {deny | force | ifPossible}**—This option enables you to set a new value for the **CheckpointUsage** property on the package. The possible values are **Deny** (sets the **CheckpointUsage** property to **DTSCU_NEVER**), **Force** (sets the **CheckpointUsage** property to **DTSCU_ALWAYS**), and **ifPossible** (sets the **CheckpointUsage** property to **DTSCU_IFEXISTS**).
- ▶ **/-Set propertyPath;value**—This option overrides the configuration of a variable, property, container, log provider, **Foreach** enumerator, or connection within a package. When this option is used, **/SET** changes the **propertyPath** argument to the value specified. You can specify more than one **/SET** option at a time.

- ▶ **/-Ser[ver] server**—This option identifies the name of the server from which to retrieve the package. If you do not specify the **/Server** option, the package execution is attempted against the local server.
- ▶ **/-SQ[L] package_path**—This option is used to load a package stored in SQL Server (in the **msdb** database).
- ▶ **/-Su[m]**—This option displays the incremental counter that contains the number of rows that will be received by the next package component.
- ▶ **/-U[ser] user_name**—This option identifies the SQL Server user ID needed to retrieve the package.
- ▶ **/-Va[lidate]**—This option is used to complete the validation phase of package execution only. The package is not executed.
- ▶ **/-VerifyB[uild] major[;minor[;build]]**—This option is a verification of the build number of a package against the build numbers specified during the verification phase in the major, minor, and build arguments. If a mismatch occurs, the package does not execute. These values are long integers.
- ▶ **/-VerifyP[ackageID] packageID**—This option verifies the GUID of the package to be executed by comparing it to the value specified in the **package_id** argument.
- ▶ **/-VerifyS[igned]**—If specified, this option causes the package to fail if the package is not signed.
- ▶ **/-VerifyV[ersionID] versioned**—This option verifies the version GUID of a package to be executed by comparing it to the value specified in the **version_id** argument during the package validation phase.
- ▶ **/-W[arnAsError]**—This option cause the package to consider a warning as an error. In other words, the package fails if a warning occurs during validation. If no warnings occur during validation and the **/Validate** option is not specified, the package is executed.

Running Package Examples

To execute an SSIS package saved to SQL Server using Windows authentication, you use the following code:

```
dtexec /SQL UnleashedPackage1SQL /SER DBARCH-LT2\SQL08DE01
```

To execute an SSIS package saved to the package store (on the filesystem), you use the following code:

```
dtexec /DTS "\File System\UnleashedPackage99PS"
```

To execute an SSIS package saved in the filesystem, you use the following code:

```
C:> dtexec /FILE "C:\HotCustomerPlus.dtsx"
      /MAXCONCURRENT " -1 " /CHECKPOINTING OFF /REPORTING EWCDI
```

Figure 52.43 shows the command prompt and subsequent execution of the `HotCustomersPlus.dtsx` SSIS package. Now, the package can be set up for regular batch execution using SQL Agent or any scheduling software.

```

Command Prompt
dtexec /FILE "HotCustomerPlusZ.dtsx" /MAXCONCURRENT "-1" /CHECKPOINTING OFF /REPORTING EMGBI
Microsoft (R) SQL Server Execute Package Utility

run this package as an administrator, or on the system's console.

```

FIGURE 52.43 Command-line execution of an SSIS package.

To execute an SSIS package saved in the filesystem and specify logging options, you use the following code:

```
C:> dtexec /FILE "C:\HotCustomerPlus.dtsx"
      /I "DTS.LogProviderTextFile;c:\log.txt"
```

To execute a package that uses Windows authentication and is saved to the default local instance of SQL Server, and to verify the version before it is executed, you use the following code:

```
dtexec /sq UnleashedPackage1 /verifyv {b399e360-38c5-11c5-99x1-ae62-08002b2b79ef}
```

The dtutil Utility

You use the `dtutil` command-line utility to copy, move, delete, or verify the existence of a package. These actions can be performed on any SSIS package, regardless of whether it is stored in a Microsoft SQL Server database, the SSIS package store, or at the filesystem.

The `dtutil` options are additive. Depending on what you are trying to do, you string one or more options and their values together in the following form:

```
dtutil /option [value] [/option [value]] ...
```

To show available options for `dtutil`, you use `'/?'` or `'/H'` or `'/Help'`, as follows:.

```
c:> dtutil /?
```

Note that a dash (-) may be substituted for / in this command.

Alternatively, you can see the details for a particular option by using the available options indicator followed by the option name ('/?' *option name*). This invokes SQL Server Books online for that particular option.

The `dtutil` options include the following:

- ▶ **`/-C[opy][StorageLocation];[PackageName]`**—This option identifies where the package is to be stored (`StorageLocation` value of DTS, FILE, or SQL) and the full destination path and filename of the package (`PackageName`). When the Copy action encounters an existing package at the destination, `dtutil` prompts you to confirm package deletion. `Y` overwrites the package, and `N` aborts the overwrite of the destination package. If you include the `/Q` (quiet) option, no prompt appears, and the existing destination package is overwritten.
- ▶ **`/-Dec[rypt] Password`**—This option sets the decryption password used when loading a package with password encryption.
- ▶ **`/-Del[ete]`**—This option deletes the package specified by the SQL, DTS, or FILE option.
- ▶ **`/-DestP[assword] Password`**—This option specifies the password used with the **SQL** option to connect to a destination SQL Server instance using SQL Server authentication.
- ▶ **`/-DestS[erver] Server`**—This option specifies the server name used with any action that causes a destination to be saved to SQL Server or a nonlocal or nondefault server when saving an SSIS package.
- ▶ **`/-DestU[ser] User name`**—This option specifies the SQL Server username at the destination SQL Server instance.
- ▶ **`/-DT[S] PackagePath`**—This option specifies that the SSIS package referenced is located in the SSIS package store, and the `PackagePath` argument is a relative path that commences at the root of the SSIS package store.
- ▶ **`/-En[crypt] [StorageLocation];[;Path;ProtectionLevel[;Password]`**—This option encrypts the loaded package with the specified protection level and password and saves it to the location specified in `Path`. `StorageLocation` types are DTS, FILE, and SQL. `ProtectionLevel` determines whether a password is required.

The possible `ProtectionLevel` values are 0 (strips sensitive information), 1 (sensitive information is encrypted using local user credentials), 2 (sensitive information is encrypted using the required password), 3 (package is encrypted using the required password), 4 (package is encrypted using local user credentials), and 5 (package uses SQL Server storage encryption).
- ▶ **`/-Ex[ists]`**—This option is used to determine whether a package exists.
- ▶ **`/-FC[reate] [StorageLocation];FolderPath;NewFolderName`**—This option creates a new folder with the name specified by `NewFolderName`. `StorageLocation` is SQL or DTS only. The location of the new folder is indicated by `FolderPath`.

- ▶ **/~FDe[lete] [StorageLocation] ExistingFolderPath;ExistingFolderName**—This option deletes the folder specified by the name in ExistingFolderName from SQL Server (SQL) or SSIS (DTS). StorageLocation is SQL or DTS only. The location of the folder to delete is indicated by ExistingFolderPath.
- ▶ **/~FDi[rectory] [StorageLocation] FolderPath[;S]**—This option lists the contents, both folders and packages, in a folder on SSIS (DTS) or SQL Server (SQL). The optional ExistingFolderPath parameter specifies the folder whose contents you want to view. StorageLocation is SQL or DTS only. The optional S parameter specifies that you want to view a listing of the contents of the subfolders for the folder specified in ExistingFolderPath.
- ▶ **/~FE[xists] [StorageLocation] ExistingFolderPath**—This option verifies whether the specified folder exists on SSIS (DTS) or SQL Server (SQL). The ExistingFolderPath parameter is the path and name of the folder for which you need to verify its existence. StorageLocation is SQL or DTS only.
- ▶ **/~FR[ename] [StorageLocation]; ExistingFolderPath; ExistingFolderName; NewFolderName**—This option renames a folder on the SSIS (DTS) or SQL Server (SQL). StorageLocation is SQL or DTS only. ExistingFolderPath is the location (path) of the folder to rename. ExistingFolderName is the name of the folder to be renamed, and NewFolderName is the new name to give the folder.
- ▶ **/~Fi≤ PathName**—This option specifies that the SSIS package to be operated on is located in the filesystem, and the PathName value contains either a universal naming convention (UNC) path or local path.
- ▶ **/~I[DRegenerate]**—This option creates a new GUID for the package and updates the package ID property.
- ▶ **/~M[ove] [StorageLocation]; PathandName**—This option specifies a move action for an SSIS package. StorageLocation may be DTS, FILE, or SQL. PathandName indicates the package path (location) and/or package name: SQL uses the package path and package name, FILE uses a UNC or local path, and DTS uses a location relative to the root of the SSIS package store. If an existing package at the destination has the same name, dtutil prompts you to answer Y to overwrite this existing package or N to not do the move. If you specify the /Q (quiet) option, no prompt appears when an existing package may exist at the move destination, and it is just overwritten.
- ▶ **/~Q[uiet]**—This option disables the Y/N prompts when a package with the same name as the specified package already exists at the destination location or if the specified package is already signed.
- ▶ **/~R[emark] [Text]**—This option is a comment to the command line. There can be multiple remarks in a command line.
- ▶ **/~Si[gn] [StorageLocation]; ExistingPath; Hash**—This option signs an SSIS package. StorageLocation may be DTS, FILE, or SQL. ExistingPath specifies the path

(location) of the package to be signed. Hash specifies a certificate identifier expressed as a hexadecimal string of varying length.

- ▶ **/~SourceP[assword] Password**—This option provides the password used with the **SQL** and **SOURCEUSER** options to connect to a SQL Server instance that uses SQL Server authentication.
- ▶ **/~SourceS[erver] Server**—This option provides the name of the server where the package is to be stored.
- ▶ **/~SourceU[ser] User Name**—This option provides the SQL Server username to use to access the SSIS package.
- ▶ **/~SQL[L] PathName**—This option specifies the path (location) of the SSIS package stored in the **msdb** database.

Next, let's look at various examples of running `dtutil`.

dtutil Examples

The following example copies an existing package in SQL to the SSIS package store:

```
C:> Dtutil /SQL ExistingPackage /COPY DTS;destPackage
```

The following example copies an existing package from one location on the filesystem to another location on the filesystem:

```
C:> dtutil /FILE c:\Unleashed\HotCustomersPlus.dtsx /COPY
FILE;c:\UnleashedProduction\HotCustomersPlus.dtsx
```

The following example creates a new GUID (usually after you copy a package):

```
C:> dtutil /I /FILE HotCustomersPlus.dtsx
```

The following example deletes a package stored in the local server (msdb database):

```
C:> dtutil /SQL HotCustomersPlus /SOURCEUSER PBertucci
/SOURCEPASSWORD xyz /DELETE
```

The following example deletes a package stored in the filesystem:

```
c:> dtutil /FILE c:\UnleashedProduction\HotCustomersPlus.dtsx /DELETE
```

The following example verifies whether a package exists in a local server (msdb database):

```
C:> dtutil SQL HotCustomersPlus /SOURCEUSER Pbertucci /SOURCEPASSWORD xyz /EXISTS
```

The following example verifies whether a package exists on the local filesystem:

```
C:> dtutil /FILE c:\UnleashedProduction\HotCustomersPlus.dtsx /EXISTS
```

The following example moves a package from one server (msdb database) to another server (msdb database):

```
C:> dtutil /SQL HotCustomersPlus /SOURCEUSER Pbertucci
      /SOURCEPASSWORD xyz /MOVE SQL;HotCustomersPlus
      /DESTUSER sa /DETPASSWORD zwx
```

The following example moves a package from one filesystem location to another:

```
c:> dtutil /FILE c:\Unleashed\HotCustomersPlus.dtsx /MOVE
      FILE;c:\UnleashedProduction\HotCustomersPlus.dtsx
```

The following example signs a package on the filesystem:

```
dtutil /FILE c:\Unleashed\HotCustomersPlus.dtsx /SIGN FILE;
      c:\Unleashed\HotCustomersPlus.dtsx;98737773999af33df399999333
```

Connection Projects in Visual Studio

Microsoft is trying to make it easier to get data sources or data targets defined and ready to utilize with SSIS packages. From Visual Studio, you can now create an Integration Services Connection Project. A wizard takes you through defining the data sources and connections for an SSIS package. As you can see in Figure 52.44, this wizard allows you to jumpstart the data source/connection managers you might need for a new SSIS package.

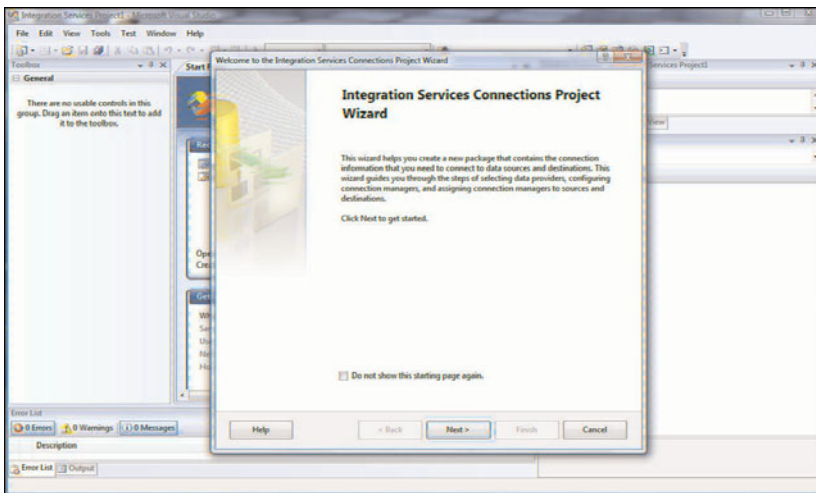

FIGURE 52.44 The Visual Studio Integration Services Connection Project Wizard.

You can then step through the buildup and testing of the connection one connection manager at a time. Figure 52.45 shows the various data providers available through this wizard and the creation and testing of one to SQL Server.

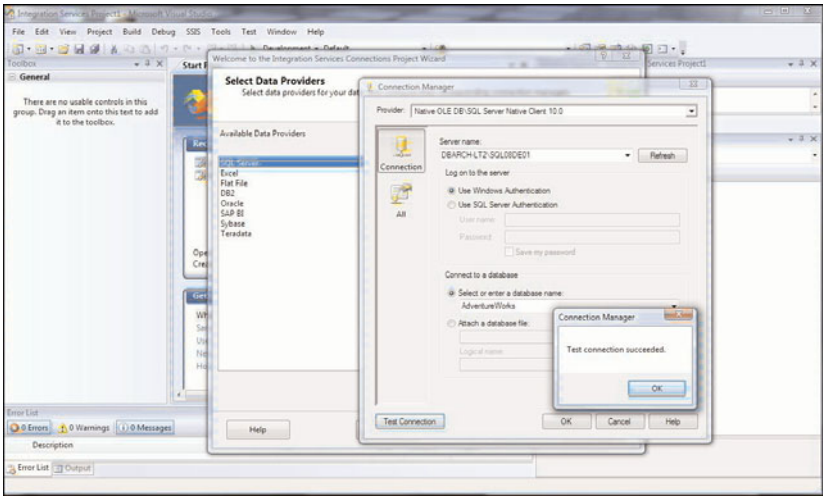

FIGURE 52.45 Select Data Providers Integration Services Connection project wizard.

After you finish using this wizard, you are set to start defining your SSIS package with the data sources and connection managers ready for use in your data flows, as you can see in Figure 52.46.

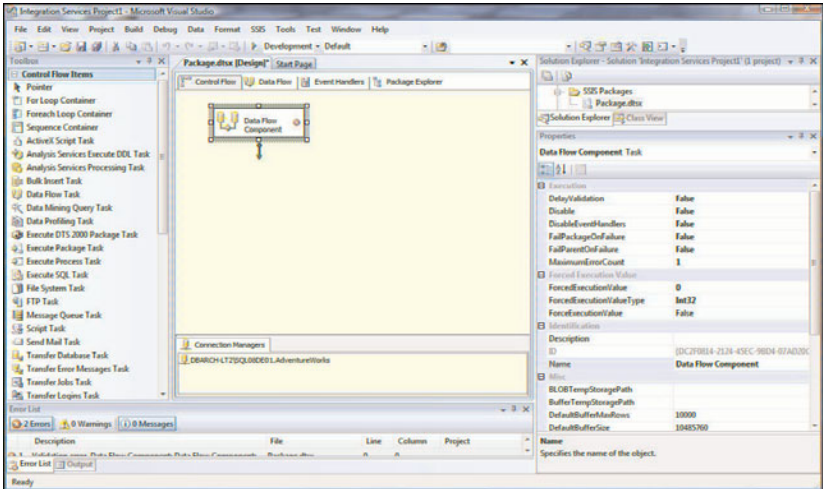

FIGURE 52.46 The Visual Studio Designer with connections ready for use.

Change Data Capture Addition with R2

With SQL Server 2008 R2, Microsoft has introduced some additional capability around grabbing changes from tables as a part of SSIS. A series of new adapters are now available from Attunity; they have implemented a streaming agent that detects changes in several different database platforms and makes these changes available to SSIS package processing. Attunity CDC products for SQL Server Integration Services provide end-to-end operational data replication (ODR) solutions for many heterogeneous sources. Using these products, you can enable efficient and real-time data warehousing, set operational business intelligence requirements, replicate data from one source to another, and synchronize two or more data sources to ensure data consistency.

Attunity CDC Suite for SSIS includes products for the following:

- ▶ SQL Server (Attunity CDC Accelerator)
- ▶ Oracle (Attunity Oracle-CDC for SSIS)
- ▶ DB2 on IBM iSeries (Attunity iSeries DB2-CDC for SSIS)
- ▶ DB2 on IBM Mainframe (Attunity z/OS DB2-CDC for SSIS)
- ▶ SQL/MP on HP NonStop (Attunity SQL/MP-CDC for SSIS)
- ▶ Nonrelational legacy data sources (Attunity CDC Accelerator)

These adapters in SSIS allow you to feed the deltas (changes) to any target data platform as opposed to full refreshes—very much like data replication approaches but via SSIS package control.

Using bcp

As you have seen in this chapter, it is fairly easy to create and implement SSIS packages to do data transformations from one or more data sources to one or more data destinations. However, many organizations still really just need a vanilla and very fast mechanism to export data out of SQL Server or import data into SQL Server. `bcp` fills this need well (and has done so from the beginning of SQL Server).

The following sections outline the primary execution methods of `bcp`, the many switches of `bcp`, the format file, and ways to improve performance when using `bcp`. By the end of these sections, you will be able to optimally execute `bcp` successfully for several common production scenarios. Microsoft has added a new execution switch that generates an XML format file. Most other features of `bcp` have remained the same.

First, you need to see whether you have the right version of `bcp`. A quick check of your version of `bcp` guarantees that you won't run into any limitations from older versions of `bcp` that might be left on your servers. You can do this by executing `bcp` at the command prompt with the `-v` option and no other parameters. (Note that all `bcp` switch options are case sensitive; for example, `-v` and `-V` are two very different switches.) Here's an example:

```
C:> bcp -v
```

BCP - Bulk Copy Program for Microsoft SQL Server.
 Copyright (C) Microsoft Corporation. All Rights Reserved.
 Version: 10.0.1600.22

This is version 10.0, which is distributed with MS SQL Server 2008 (SQL Server 10.0). If a version other than 10.x is present here, you must re-install bcp immediately.

At any time, you can see the proper usage and bcp switch options available by executing bcp at the command prompt with a question mark (?):

```
C:> bcp ?
usage: bcp {dbtable | query} {in | out | queryout | format} datafile
[-m maxerrors]          [-f formatfile]          [-e errfile]
. . .
```

You use the following syntax for bcp, along with one or more switches:

```
bcp {dbtable | query} {in | out | queryout | format} datafile
```

In this syntax, *dbtable* is the *database_name*, *schema*, and *table_name* | *view_name* (for example, AdventureWorks2008.Production.Product or "AdventureWorks2008.Production.Product"):

- ▶ **database_name**—This is the name of the database in which the specified table or view resides. If not specified, this is the default database for the user.
- ▶ **owner**—This is the name of the schema of the table or view.
- ▶ **table_name** | **view_name**—This is the name of the destination table or view when copying data into SQL Server (in), and it is the name of the source table when copying data from SQL Server (out).

query is a T-SQL query that returns a result set. *queryout* must also be specified when bulk-copying data from a query.

in | *out* | *queryout* | *format* specifies the direction of the bulk copy (*in* copies from a file in to the database table or view, *out* copies from the database table or view to a file). *queryout* must be specified when bulk-copying data from a query. *format* creates a format file based on the switch specified (*-n*, *-c*, *-w*, *-V*, or *-N*) and the table or view delimiters. If *format* is used, the *-f* option must be specified as well.

data_file is the data file used when bulk-copying a table or view into or out of SQL Server.

All the available bcp switches are listed in Table 52.1.

TABLE 52.1 **bcp** Switches

Switch	Description	Example
-m	Specifies the maximum number of errors to allow before stopping the transfer. The default is 10.	[-m max_errors]
-f	Specifies the format file used to customize the load or unload data in a specific style.	[-f format_file]
-e	Specifies the file to write error messages to.	[-e err_file]
-F	Specifies the first row in the data file to start copying from when importing. The default is 1.	[-F first_row]
-L	Specifies the last row in the data file to end copying with when importing. The default is 0, which indicates the last row in the file.	[-L last_row]
-b	Specifies the number of rows to include in each committed batch. By default, all data rows in a file are copied in one batch.	[-b batch_size]
-n	Specifies that native (database) data type formats are to be used for the data.	[-n]
-c	Specifies that character data type format is to be used for the data. In addition, \t (tab character) is used as the field separator, and \n (newline character) is used as the row terminator.	[-c]
-w	Specifies that the Unicode data type format is to be used for the data. In addition, \t (tab character) is used as the field separator, and \n (newline character) is used as the row terminator.	[-w]
-N	Specifies to use Unicode for character data and native format for all others. This can be used as an alternative to the -w switch.	[-N]
-V	Specifies to use data type formats from earlier versions of SQL Server.	[-V (70 80 90)]
-q	Tells bcp to use quoted identifiers when dealing with table and column names.	[-q]
-C	If you are loading extended characters, allows you to specify the code page of the data in the data file.	[-C code_page]
-t	Specifies the terminating character(s) for fields. The default is \t (tab character).	[-t field_term]

TABLE 52.1 **bcp** Switches

Switch	Description	Example
-r	Specifies the terminating character(s) for rows. The default is \n (newline character).	[-r row_term]
-i	Specifies a file for redirecting input into bcp (the response file containing the responses to the command prompts).	[-i input_file]
-o	Specifies the file for receiving redirected output from bcp.	[-o output_file]
-a	Specifies the network packet size (in bytes) used to send to or receive from SQL Server. Can be between 4,096 and 65,535 bytes. The default size is 4,096.	[-a packet_size]
-S	Specifies the SQL Server name to connect to. <i>Local</i> is the default.	[-S server_name server_name\instance_name]
-U	Specifies the user account to log in as; this account must have sufficient privileges to carry out either a read or a write of the table.	[-U login_id]
-P	Specifies the password associated with the user account.	[-P password]
-T	Makes a trusted connection to the server, using the network user/security credentials instead of the <i>login_id/password</i> .	[-T]
-v	Displays the bcp version information.	[-v]
-R	Uses the regional format for currency, date, and time data, as defined by the locale settings of the client computer.	[-R]
-k	Overrides a column's default and enforces NULL values being loaded into the columns as part of the bcp operation.	[-k]
-E	Uses the identity values in the import file rather than generating new ones.	[-E]
-h	Specifies special hints to be used during the bcp operation. They include the following: the sort order of the data file, number of rows of data per batch, number of kilobytes of data per batch, whether to acquire a table-level lock, whether to check constraints, and whether to fire insert triggers.	[-h hint_type, ..]

TABLE 52.1 **bcp** Switches

Switch	Description	Example
-x	Generates an XML format file.	[-x]

Fundamentals of Exporting and Importing Data

One of the great things about bcp is its ease of use. This section runs through a couple simple examples and provides full explanations. All tables used here can be found in the AdventureWorks2008 sample database supplied by Microsoft in SQL Server 2008.

Let's start by exporting product data from AdventureWorks2008 that may be needed by a sales team for reference in Excel format (a .csv file). To do this, you simply export the Product table data into a comma-delimited file. You need to specify the following with bcp in this case:

- ▶ The full table name (in this case, AdventureWorks2008.Production.Product)
- ▶ The direction of bcp (OUT in this case because it is exporting data out)
- ▶ Data filename to hold the exported data (in this case, products.dat)
- ▶ The server name DBARCH-LT2\SQL08DE01 for this example (in this case, -S DBARCH-LT2\SQL08DE01)
- ▶ The username SA (in this case, -U sa)
- ▶ The password (in this case, -P xyz)
- ▶ A comma as the column delimiter (in this case, -t ",")
- ▶ That this should be exported in character data format (in this case, -c)

At the command prompt, you execute the following:

```
C:> BCP AdventureWorks2008.Production.Product OUT products.dat
      -S DBARCH-LT2\SQL08DE01 -U sa
-P xyz -t "," -c
Starting copy...
```

```
504 rows copied.
```

```
Network packet size (bytes): 4096
```

```
Clock Time (ms.): total: 10 Average: (50400.00 rows per sec.)
```

Here's a sample of the data in the Products.dat file that was just exported:

```
1,Adjustable Race,AR-5381,0,0,,
2,Bearing Ball,BA-8327,0,0,,
3,BB Ball Bearing,BE-2349,1,0,,
4,Headset Ball Bearings,BE-2908,0,0,,
. . .
```

Now let's look at importing data into SQL Server 2008.

Let's say that each salesperson is providing a flat file that contains his or her new sales orders summaries. These files are emailed to a person in the ordering department and need to be imported into SQL Server every week. The file that you will import will be a comma-delimited file (.csv) that the salesperson created using Excel. The new entries will be the salesperson's hottest customer's totals. A sample input data file (named BCPHotCustomersPlus.csv) is included on the book's CD for this chapter.

You need to specify the following with bcp in this case:

- ▶ The full table name (in this case, AdventureWorks2008.Sales.HotCustomersPlus).
- ▶ The direction of bcp (IN in this case because it is importing data).
- ▶ The names of the data files that contain the import data (in this case, BCPHotCustomersPlus.csv). The following is a sample of the input data file (BCPHotCustomersPlus.csv):

```
268,Cycle Parts and Accessories,S,9,Australia,954,Touring-1000 Yellow,7152.210000
268,Cycle Parts and Accessories,S,9,Australia,955,Touring-1000 Yellow,7152.210000
268,Cycle Parts and Accessories,S,9,Australia,956,Touring-1000 Yellow,5721.768000
268,Cycle Parts and Accessories,S,9,Australia,968,Touring-1000 Blue,5721.768000
. . .
```

- ▶ The server name (in this case, -S DBARCH-LT2\SQL08DE01)
- ▶ The username SA (in this case, -U sa).
- ▶ The password (in this case, -P xyz).
- ▶ A comma as the column delimiter (in this case, -t ",").
- ▶ That this should be exported in character data format (in this case, -c).
- ▶ The -q option (in this case, -q), to be sure quoted identifiers are handled properly.

At the command prompt, you execute the following:

```
C:> BCP AdventureWorks2008.Sales.HotCustomersPlus IN BCPHotCustomersPlus.csv
-S DBARCH-LT\SQL08DE01 -U sa -P xyz -t "," -c -q
Starting copy...
```

```
4 rows copied.
Network packet size (bytes): 4096
Clock Time (ms.): total : 241 Average : (99.59 rows per sec.)
```

A quick SELECT * from the HotCustomersPlus table shows the success of this operation:

CustomerID	CustomerName	CustomerType		TerritoryID	TerritoryName
268	Cycle Parts and Accessories	S	9	Australia	954
268	Cycle Parts and Accessories	S	9	Australia	955

268	Cycle Parts and Accessories	S	9	Australia	956
268	Cycle Parts and Accessories	S	9	Australia	968
. . .					

The sales team can now send in their sales orders as they make sales. This brief example illustrates the beauty and power of using bcp.

The following sections look at how bcp can work with basic data representations (character, native, or Unicode), the use of a format file, and a few other extended bcp capabilities.

File Data Types

bcp can handle data in one of three forms: character (ASCII), native, or Unicode. You have the choice of which character format is used, depending on the source or destination of the data file:

- ▶ The character format (-c) is the most commonly used of the three data types because it reads or writes using ASCII characters and carries out the appropriate data type conversion for the SQL Server representations. The CHAR data type is the default storage type; it uses tabs as field separators and the newline character as the row terminator.
- ▶ The native format (-n) is used for copying data between servers. This format allows bcp to read and write using the same data types used by server, which results in a performance gain. This format does, however, render the data file unreadable by any other means.
- ▶ The Unicode option (-w) uses Unicode characters rather than ASCII characters. The NCHAR data type is the default storage type; it uses tabs as field separators and the newline character as the row terminator.

Format Files

By using a format file, you can customize the data file created by bcp or specify complex field layouts for data loads. There are two ways to create a format file: by using interactive bcp and by using the format switch.

Customizing a Format File by Using Interactive bcp

If you do not specify one of the -n, -c, or -w data type format switches, bcp (in or out) prompts you for the following information for each column in the data set:

- ▶ File storage type
- ▶ Prefix length
- ▶ Field length
- ▶ Field terminator

bcp offers a default for each of these prompts that you can either accept or reject. If you accept all the defaults, you wind up with the same format file you would have by specifying the native format (with the -n switch). The prompts look like this:

Enter the file storage type of field au_id [char]:
 Enter prefix length of field au_id [0]:
 Enter length of field au_id [11]:
 Enter field terminator [none]:

or like this:

Enter the file storage type of field ProductID [int]:
 Enter prefix length of field ProductID [0]:
 Enter field terminator [none]:

By pressing the Enter key at the prompt, you accept the default. Alternatively, you can type your own value at the prompt if you know the new value and it is different from the default.

Creating a Format File by Using the format Switch

By using the format option, you can create a format file without actually transferring any data. Here is an example of creating a format file for the SalesOrderHeader table in the AdventureWorks2008 database:

```
C:> BCP AdventureWorks2008.Sales.SalesOrderHeader format orders.dat
      -S DBARCH-LT2\SQL08DE01
      -U sa -P xyz -f orders.fmt -c
```

The format file created looks like this:

```
10.0
27
1  SQLCHAR    0   12   ""\t""      1   SalesOrderID      """"
2  SQLCHAR    0    5   ""\t""      2   RevisionNumber    """"
3  SQLCHAR    0   24   ""\t""      3   OrderDate         """"
4  SQLCHAR    0   24   ""\t""      4   DueDate           """"
5  SQLCHAR    0   24   ""\t""      5   ShipDate          """"
6  SQLCHAR    0    5   ""\t""      6   Status            """"
7  SQLCHAR    0    3   ""\t""      7   OnlineOrderFlag   """"
8  SQLCHAR    0   50   ""\t""      8   SalesOrderNumber  SQL_...
9  SQLCHAR    0   50   ""\t""      9   PurchaseOrderNumber SQL_...
10 SQLCHAR    0   30   ""\t""     10   AccountNumber     SQL_...
11 SQLCHAR    0   12   ""\t""     11   CustomerID        """"
12 SQLCHAR    0   12   ""\t""     12   ContactID         """"
13 SQLCHAR    0   12   ""\t""     13   SalesPersonID     """"
14 SQLCHAR    0   12   ""\t""     14   TerritoryID       """"
15 SQLCHAR    0   12   ""\t""     15   BillToAddressID   """"
16 SQLCHAR    0   12   ""\t""     16   ShipToAddressID   """"
17 SQLCHAR    0   12   ""\t""     17   ShipMethodID      """"
18 SQLCHAR    0   12   ""\t""     18   CreditCardID      """"
19 SQLCHAR    0   15   ""\t""     19   CreditCardApprovalCode SQL_...
```

20	SQLCHAR	0	12	""\t"	20	CurrencyRateID	""
21	SQLCHAR	0	30	""\t"	21	SubTotal	""
22	SQLCHAR	0	30	""\t"	22	TaxAmt	""
23	SQLCHAR	0	30	""\t"	23	Freight	""
24	SQLCHAR	0	30	""\t"	24	TotalDue	""
25	SQLCHAR	0	256	""\t"	25	Comment	SQL_...
26	SQLCHAR	0	37	""\t"	26	rowguid	""
27	SQLCHAR	0	24	""\r\n"	27	ModifiedDate	""

The following is a description of the lines and columns in the preceding format file example:

- ▶ The first line shows the version of bcp.
- ▶ The second line shows the number of columns.
- ▶ The third line, first column shows the data field position.
- ▶ The third line, second column shows the data type.
- ▶ The third line, third column shows the prefix.
- ▶ The third line, fourth column shows the data file field length.
- ▶ The third line, fifth column shows the field or row terminator.
- ▶ The third line, sixth column shows the column position.
- ▶ The third line, seventh column shows the column name.
- ▶ The third line, eighth column shows the column collation.

You get different format files depending on your table and whether you chose character, native, or Unicode as the data type. As you can see in the preceding example, only the last two columns in the format file relate to the actual table; the remaining columns specify properties of the data file.

File Storage Types

The storage type is a description of how the data is stored in the data file. Table 52.2 lists the definitions used during interactive bcp and what appears in the format file. The storage type allows data to be copied as its base type (native format), as implicitly converted between types (tinyint to smallint), or as a string (in character or Unicode format).

TABLE 52.2 Storage Data Types

File Storage Type	Interactive Prompt	Host File Data Type
char	c[har]	SQLCHAR
varchar	c[har]	SQLCHAR
nchar	w	SQLNCHAR
nvarchar	w	SQLNCHAR
text	T[ext]	SQLCHAR

TABLE 52.2 Storage Data Types

File Storage Type	Interactive Prompt	Host File Data Type
ntext	W	SQLNCHAR
binary	x	SQLBINARY
varbinary	x	SQLBINARY
image	I[image]	SQLBINARY
datetime	d[ate]	SQLDATETIME
smalldatetime	D	SQLDATETIME4
decimal	n	SQLDECIMAL
numeric	n	SQLNUMERIC
float	f[loat]	SQLFLT8
real	r	SQLFLT4
int	i[nt]	SQLINT
smallint	s[mallint]	SQLSMALLINT
tinyint	t[inyint]	SQLTINYINT
money	m[oney]	SQLMONEY
smallmoney	M	SQLMONEY4
bit	b[it]	SQLBIT
uniqueidentifier	u	SQLUNIQUEID
timestamp	x	SQLBINARY

NOTE

If the table makes use of user-defined data types, these customized data types appear in the format file as their base data type.

If you are having problems loading certain fields into your table, you can try the following tricks:

- ▶ Copy the data in as char data types and force SQL Server to do the conversion for you.
- ▶ Duplicate the table and replace all the SQL Server data types with char or varchar of a length sufficient to hold the value. This trick allows you to further manipulate the data with T-SQL after it is loaded.

Prefix Lengths

To maintain compactness in native data files, bcp precedes each field with a prefix length that indicates the length of the data stored. The space for storing this information is specified in characters and is called the *prefix length*.

Table 52.3 indicates the value to specify for prefix length for each of the data types.

TABLE 52.3 Prefix Length Values

Prefix Length	Data Types to Use
0	Non-null data of type bit or numerics (int, real, and so on). Use this value when no prefix characters are wanted. This value causes the field to be padded with spaces to the size indicated for the field length.
1	Non-null data of type binary or varbinary or null data, with the exception of text, ntext, and image. Use this value for any data (except bit, binary, varbinary, text, ntext, and image) that you want stored using a character-based data type.
2	When storing the data types binary or varbinary as character-based data types, 2 bytes of char file storage and 4 bytes of nchar file storage are required for each byte of binary table data.
4	For the data types text, ntext, and image.

Prefix lengths are likely to exist only within data files created using bcp. It is unlikely that you will encounter a reason to change the defaults bcp has chosen for you.

Field Lengths

When using either the native or character data format, you must specify the maximum length of each field. When converting data types to strings, bcp suggests lengths large enough to store the entire range of values for each particular data type. Table 52.4 lists the default values for each of the data formats.

TABLE 52.4 Default Field Lengths for Data Formats

Data Type	Length (/c)	Length (/n)
bit	1	1
binary	Column length × 2	Column length
datetime	24	8
smalldatetime	24	4
float	30	8
real	30	4
int	12	4

TABLE 52.4 Default Field Lengths for Data Formats

Data Type	Length (/c)	Length (/n)
smallint	7	2
tinyint	5	1
money	30	8
smallmoney	30	4
decimal	41	up to 17
numeric	41	up to 17
uniqueidentifier	37	16

NOTE

You must specify a field length that is long enough for the data being stored. bcp error messages regarding overflows indicate that the data value has been truncated in at least one of the fields. If the operation is a load, an overflow error usually results in bcp terminating. However, if you are dumping the data to a file, the data is truncated without error messages.

The field length value is used *only* when the prefix length is 0 and you have specified no terminators. In essence, you are doing a fixed-length data copy. bcp uses exactly the amount of space stated by the field length for each field; unused space within the field is padded out.

NOTE

Preexisting spaces in the data are not distinguished from added padding.

Field Terminators

If you are not making use of fixed-width fields or length prefixes, you must use a field terminator to indicate the character(s) that separates fields; for the last field in the data row, you must also indicate which character(s) ends the line.

bcp recognizes the indicators for special characters shown in Table 52.5.

TABLE 52.5 **bcp** Indicators for Special Characters

Terminator	Escape Code
Tab	\t
Backslash	\\
Null terminator	\0
Newline	\n
Carriage return	\r

You cannot use spaces as terminators, but you can use any other printable characters. You should choose field and row terminators that make sense for your data. Obviously, you should not use any character you are trying to load. You must combine the `\r` and `\n` characters to get your data into an ASCII data file with each row on its own line.

TIP

By specifying the `-t` and `-r` switches, you can override the defaults that appear for the prompts during interactive bcp.

NOTE

You can specify terminators for data copied in native format. You should be careful if you decide to go this route; the accepted approach is to use lengthy prefixes.

The prefix length, field length, and terminator values interact with one another. In the following examples, T indicates the terminator character(s), P indicates the prefix length, and S indicates space padding.

For data of type char, the data file has the following repeating pattern:

	Prefix Length=0	Prefix Length=1, 2, 4
No Terminator	<i>stringSstringS</i>	<i>PstringSPstringS</i>
Terminator	<i>stringSTstringST</i>	<i>PstringSTPstringST</i>

For data of other types converted to char, the data file has the following repeating pattern:

	Prefix Length=0	Prefix Length=1, 2, 4
No terminator	<i>stringSstringS</i>	<i>PstringPstring</i>
Terminator	<i>stringTstringT</i>	<i>PstringTPstringT</i>

The next few sections examine how to load data into tables when there are differences in column number and layout.

Different Numbers of Columns in a File and Table

If you want to load data into tables when you have fewer fields in the data file than in the table, you have to “dummy up” an extra line in your format file.

Let's suppose you want to load a data file that is missing most of the address information for each customer (into a customer table of some kind that has full address columns in it). To do this, you create a format file for this table by using the `format` option with `bcp`. With this format file, you can still load this abbreviated data easily. Suppose that the data file looks like this:

```
WELLI    Wellington Importadora    Jane Graham    Sales (14)555-8122
        (14)555-8111
WHITC    White Clover Markets      Donald Bertucci    Owner (206)555-4112
        (206)555-4113
```

To introduce a dummy value for the missing ones, in the format file, you need to make the prefix and data lengths `0` and set the field terminator to nothing (`"`). The modified format file should look like this:

```
10.0
11
1    SQLCHAR 0    10    "\t"  1    CustomerID    SQL_Latin1_General_
    CP1_CI_AS
2    SQLCHAR 0    80    "\t"  2    CompanyName    SQL_Latin1_General_
    CP1_CI_AS
3    SQLCHAR 0    60    "\t"  3    ContactName    SQL_Latin1_General_
    CP1_CI_AS
4    SQLCHAR 0    60    "\t"  4    ContactTitle    SQL_Latin1_General_
    CP1_CI_AS
5    SQLCHAR 0    0     ""    5    Address        SQL_Latin1_General_
    CP1_CI_AS
6    SQLCHAR 0    0     ""    6    City           SQL_Latin1_General_
    CP1_CI_AS
7    SQLCHAR 0    0     ""    7    Region         SQL_Latin1_General_
    CP1_CI_AS
8    SQLCHAR 0    0     ""    8    PostalCode     SQL_Latin1_General_
    CP1_CI_AS
9    SQLCHAR 0    0     ""    9    Country        SQL_Latin1_General_
    CP1_CI_AS
10   SQLCHAR 0    48    "\t"  10   Phone          SQL_Latin1_General_
    CP1_CI_AS
11   SQLCHAR 0    48    "\r\n"  11   Fax           SQL_Latin1_General_
    CP1_CI_AS
```

Now `bcp` can load the data file by using this new format file, with the `Address`, `City`, `Region`, `PostalCode`, and `Country` columns containing `NULL` values for the new rows.

For data files that have more fields than the table has columns, you change the format file to add additional lines of information. Suppose that your customer data file contains an additional `CreditStatus` value at the end (shown here in ***bold italic***):

```

WELLI  Wellington Importadora  Martin Sommer  Sales Manager  Rua do Mercado,
12  Resende  SP  08737-363  Uruguay  (14) 555-8122  NULL 1
WELP  Well Drilling P  Thierry Gerardin  Sales Manager  Rue de Vaugirard,
997  Paris  FR  08737-363  France  (11) 555-8122  NULL 1
WF  WF Enterprises  Yves Moison  Sales Manager  Rue de Sevres,
4123  Paris  FR  08737-363  France  (14) 555-8122  NULL 1
WGZR  Wellsley Granite  Jack McElreath  Sales Manager  Hillsboro,
131  Hillsboro  MA  08737-363  USA  (781) 555-8122  NULL 1
WHITC  White Clover Markets  Scott Smith  Owner  305 - 14th Ave. S.
Suite 3B  Boston  MA  98128  USA (508) 555-4112  (508) 555-4115 2

```

You need to modify a format file in two important areas: you change the second line to reflect the actual number of values, and you add new lines for the extra column in the file that is not in the table (from 11 to 12 entries). Notice that the column position has a value of 0 to indicate the absence of a column in the table. The result is that your source data file will import all data into the table, except the extra field (that is, the `CreditStatus` field).

Thus, the modified format file looks like this (where the ***bold italic*** indicates the changes made):

```

10.0
12
1  SQLCHAR 0 10  "\t"  1  CustomerID  SQL_Latin1_General_
CP1_CI_AS
2  SQLCHAR 0 80  "\t"  2  CompanyName  SQL_Latin1_General_
CP1_CI_AS
3  SQLCHAR 0 60  "\t"  3  ContactName  SQL_Latin1_General_
CP1_CI_AS
4  SQLCHAR 0 60  "\t"  4  ContactTitle  SQL_Latin1_General_
CP1_CI_AS
5  SQLCHAR 0 120 "\t"  5  Address  SQL_Latin1_General_
CP1_CI_AS
6  SQLCHAR 0 30  "\t"  6  City  SQL_Latin1_General_
CP1_CI_AS
7  SQLCHAR 0 30  "\t"  7  Region  SQL_Latin1_General_
CP1_CI_AS
8  SQLCHAR 0 20  "\t"  8  PostalCode  SQL_Latin1_General_
CP1_CI_AS
9  SQLCHAR 0 30  "\t"  9  Country  SQL_Latin1_General_
CP1_CI_AS
10 SQLCHAR 0 48  "\t" 10  Phone  SQL_Latin1_General_
CP1_CI_AS
11 SQLCHAR 0 48  "\t" 11  Fax  SQL_Latin1_General_
CP1_CI_AS

```

```

12      SQLCHAR 0      1  "\r\n"  0  CreditStatus      SQL_Latin1_General_
      CP1_CI_AS

```

These two examples show you the possibilities that the format file offers for customizing the loading and unloading of data.

Renumbering Columns

Using the techniques described in the section “Different Numbers of Columns in a File and Table,” you can also handle data file fields that are in different orders than the target tables. All you need to do is change the column order number to reflect the desired sequence of the columns in the table. The fields are then automatically mapped to the corresponding columns in the table.

For example, suppose that a customer data file you got from another source system came with the fields in this order:

1. Address
2. City
3. Country
4. PostalCode
5. Region
6. CompanyName
7. ContactName
8. ContactTitle
9. Fax
10. Phone
11. CustomerID

The SQL Server table has columns in a different order. To load your data file into this table, you modify the format file to look like this (where the ***bold italic*** indicates the changes made):

```

10.0
11
1      SQLCHAR 0      10  "\t"  11  CustomerID      SQL_Latin1_General_
      CP1_CI_AS
2      SQLCHAR 0      80  "\t"  6    CompanyName     SQL_Latin1_General_
      CP1_CI_AS
3      SQLCHAR 0      60  "\t"  7    ContactName     SQL_Latin1_General_
      CP1_CI_AS
4      SQLCHAR 0      60  "\t"  8    ContactTitle    SQL_Latin1_General_
      CP1_CI_AS
5      SQLCHAR 0     120  "\t"  1    Address         SQL_Latin1_General_
      CP1_CI_AS
6      SQLCHAR 0      30  "\t"  2    City            SQL_Latin1_General_
      CP1_CI_AS

```

7	SQLCHAR 0 CP1_CI_AS	30	"\t"	5	Region	SQL_Latin1_General_
8	SQLCHAR 0 CP1_CI_AS	20	"\t"	4	PostalCode	SQL_Latin1_General_
9	SQLCHAR 0 CP1_CI_AS	30	"\t"	3	Country	SQL_Latin1_General_
10	SQLCHAR 0 CP1_CI_AS	48	"\t"	10	Phone	SQL_Latin1_General_
11	SQLCHAR 0 CP1_CI_AS	48	"\r\n"	9	Fax	SQL_Latin1_General_

The principal point to remember with the format file is that all but the last three columns deal with the data file. The last three columns deal with the database table.

Using Views

bcp can use views to export data from a database. This means an export of data can be a result set of data from multiple tables (and with distributed queries, even multiple servers).

You can also use a view with bcp to load data back into tables. However, as is the case with normal T-SQL inserts, you can load into only one of the underlying tables at a time.

Logged and Nonlogged Operations

Bulk-copy operations can occur in two modes: logged and nonlogged (also known as slow and fast bcp, respectively). The ideal situation is to operate in nonlogged mode because this arrangement dramatically decreases the load time and consumption of other system resources, such as memory, processor use, and disk access. However, the default runs the load in logged mode, which causes the log to grow rapidly for large volumes of data.

To achieve a nonlogged operation, the target table must not be replicated (the replication log reader needs the log records to relay the changes made). The database holding the target table must also have its SELECT INTO/BULK COPY option set, and finally, the TABLOCK hint must be specified.

NOTE

Remember that setting the SELECT INTO/BULK COPY option disables the capability to back up the transaction log until a full database backup has been performed. Transaction log dumps are disabled because if the database had to be restored, the transaction log would not contain a record of the new data.

Although you can still perform fast loads against tables that have indexes, it is advisable to drop and re-create the indexes after the data transfer operation is complete. In other words, the total load time includes the loading of the data and index creation time. If there is existing data in the table, the operation is logged; you achieve a nonlogged operation only if the table is initially empty.

Generally, you get at least a 50% drop in transfer speed if the table has an index. The more indexes, the greater the performance degradation. This is due to the logging factor: more log records are being generated, and index pages are being loaded into the cache and modified. This can also cause the log to grow, possibly filling it (depending on the log file settings).

NOTE

Despite the name, even a nonlogged operation logs some things. In the case of indexes, index page changes and allocations are logged, but the main area of logging is of extent allocations every time the table is extended for additional storage space for the new rows.

Batches

By default, `bcp` puts all the rows that are inserted into the target table into a single transaction. `bcp` calls this a *batch*. This arrangement reduces the amount of work the log must deal with; however, it locks down the transaction log by keeping a large part of it active, which can make truncating or backing up the transaction log impossible or unproductive. By using the `bcp` batch (`-b`) switch, you can control the number of rows in each batch (or, effectively, each transaction). This switch controls the frequency of commits; although it can increase the activity in the log, it enables you to trim the size of the transaction log. You should tune the batch size in relation to the size of the data rows, transaction log size, and total number of rows to be loaded. The value you use for one load might not necessarily be the right value for all other loads.

Note that if a subsequent batch fails, the prior batches *are* committed, and those rows become part of the table. However, any rows copied up to the point of failure in the failing batch are rolled back.

Parallel Loading

A great enhancement of `bcp` is that you can now use it to do parallel loads of tables. If you want to take advantage of this feature, the following must be true:

- ▶ The bulk-copy operation must be nonlogged; all requirements specified in the previous discussion on nonlogged operations must be met.
- ▶ There must be no indexes on the target table.

Only applications using the ODBC or SQL OLE DB–based APIs can perform parallel data loads into a single table.

The procedure is straightforward. After you ascertain that the target table has no indexes (which could involve dropping primary or unique constraints) and is not being replicated, you must set the database option `SELECT INTO/BULK COPY` to `true`. The requirement to drop all indexes has to do with the locking that must occur to load the data. Although the table itself can have a shared lock, the index pages are an area of contention that prevents parallel access.

Now all that is required is to set up the parallel bcp loads to load the data into the table. You can use the `-F` and `-L` switches to specify the range of the data you want each parallel bcp to load into the table if you are using the same data file. Using these switches removes the need to manually break up the file. Here is an example of the command switches involved for a parallel load with bcp for the customers table:

```
bcp AdventureWorks2008.Sales.SalesOrderHeader IN SalesOrders10000.dat -T
  -S servername -c -F 1
-L 10000 -h "TABLOCK"
```

```
bcp AdventureWorks2008.Sales.SalesOrderHeader IN SalesOrders20000.dat -T
  -S servername -c -F 10001
-L 20000 -h "TABLOCK"
```

The `TABLOCK` hint (`-h` switch) provides improved performance by removing contention from other users while the load takes place. If you do not use the hint, the load takes place using row-level locks, and this is considerably slower.

SQL Server 2008 allows parallel loads without affecting performance by making each bcp connection create extents in nonoverlapping ranges. The ranges are then linked into the table's page chain.

After the table is loaded, it is also possible to create multiple nonclustered indexes in parallel. If there is a clustered index, you work with that one first, followed by the parallel nonclustered index.

Supplying Hints to bcp

The SQL Server 2008 version of bcp enables you to further control the speed of data loading, to invoke constraints, and to have insert triggers fired during loads. To take advantage of these capabilities, you use hint switches to specify one or more hints at a time. Following is the syntax:

```
-h "hint [, hint]"
```

This option cannot be used when bulk-copying data into versions of SQL Server before version 7.0 because, starting with SQL Server 7.0, bcp works in conjunction with the query processor. The query processor optimizes data loads and unloads for OLE database rowsets that the latest versions of bcp and `BULK INSERT` can generate.

The following sections describe the various hints you can specify with the `-h` switch.

The `ROWS_PER_BATCH` Hint

The `ROWS_PER_BATCH` hint is used to tell SQL Server the total number of rows in the data file. This hint helps SQL Server optimize the entire load operation. This hint and the `-b` switch heavily influence the logging operations that occur with data inserts. If you specify both this hint and the `-b` switch, they must have the same values, or you get an error message.

When you use the `ROWS_PER_BATCH` hint, you copy the entire result set as a single transaction. SQL Server automatically optimizes the load operation, using the batch size you specify. The value you specify does *not* have to be accurate, but you should be aware of the practical limit, based on the database's transaction log.

TIP

Do not be confused by the name of the `ROWS_PER_BATCH` hint. You are specifying the *total file size* and *not* the batch size (as is the case with the `-b` switch).

The CHECK_CONSTRAINTS Hint

The `CHECK_CONSTRAINTS` hint controls whether check constraints are executed as part of the `bcp` operation. With `bcp`, the default is that check constraints are not executed. This hint option allows you to turn the feature on (to have check constraints executed for each insert). If you do not use this option, you should either be very sure of your data or rerun the same logic as in the check constraints you deferred after the data has been loaded.

The FIRE_TRIGGER Hint

The `FIRE_TRIGGER` hint controls whether the insert trigger on the target table is executed as part of the `bcp` operation. With `bcp`, the default is that no triggers are executed. This hint option allows you to turn the feature on (to have insert triggers executed for each insert). As you can imagine, when this option is used, it slows down the `bcp` load operation. However, the business reasons to have the insert trigger fired might outweigh the slower loading.

The ORDER Hint

If the data you want to load is already in the same sequence as the clustered index on the receiving table, you can use the `ORDER` hint. The syntax for this hint is as follows:

```
ORDER( {column [ASC | DESC] [,...n]} )
```

There *must* be a clustered index on the same columns, in the same key sequence as specified in the `ORDER` hint. Using a sorted data file (in the same order as the clustering index) helps SQL Server place the data into the table with minimal overhead.

The KILOBYTES_PER_BATCH Hint

The `KILOBYTES_PER_BATCH` hint gives the size, in kilobytes, of the data in each batch. This is an estimate that SQL Server uses internally to optimize the data load and logging areas of the `bcp` operation.

The TABLOCK Hint

The `TABLOCK` hint is used to place a table-level lock for the `bcp` load duration. This hint gives you increased performance at a loss of concurrency, as described in the section "Parallel Loading," earlier in this chapter.

Summary

It is fairly easy to create and implement a typical data export, data import, or complex data transformation by using SSIS. You can either use the wizard for basic data transformation needs or the SSIS Designer for massively complex transformations (which may have multiple data sources and/or multiple data destinations). This very robust environment has adopted a very formal, managed code rigor. With the SSIS capabilities, you get a self-contained place to build these data transformation solutions, and you can do so very rapidly. SSIS is completely integrated into the Visual Studio/BI Development Studio environment as well, making it that much easier to start producing rock-solid implementations. And, with Change Data Capture for SSIS, a new dimension of trickling data changes to various platforms becomes available with SSIS processing.

This chapter also shows how to bulk-load data into and out of SQL Server by using the `bcp` utility. The multitude of switches `bcp` offers are very comprehensive and address most, if not all, importing and exporting situations. More importantly, with the advent of some additional switches, such as `ORDER` (within hints), `TABLOCK` (within hints), batches (`-b`), network packet sizes (`-a`), and others, it is significantly easier to increase the performance of `bcp` in a big way. `bcp` has been around for a long time, and it will continue to be the workhorse of bulk data loading and unloading.

Chapter 53, “SQL Server 2008 Reporting Services” discusses this significant SQL Server capability and how to maximize its use for a production environment.

This page intentionally left blank

CHAPTER 53

SQL Server 2008 Reporting Services

This chapter introduces SQL Server Reporting Services 2008 (SSRS). It provides an overview of the product's features and architecture, covers the most important functional areas, and gives examples of how to get started developing on the platform. Although this chapter is by no means a comprehensive description of everything in SSRS, its purpose is to get you excited about the capabilities of this potent technology.

SSRS is an enterprise-class reporting platform that provides all the tools and services needed to support data-driven reporting. SSRS empowers you to design reports using a variety of advanced data visualization controls; populate them with data culled from a variety of sources; deploy, secure access to, and schedule execution of reports; and deliver them to the Web, SharePoint, email recipients, file shares, and more, on a scheduled or on-demand basis.

The first version of SSRS shipped in January 2004 as part of SQL Server 2000, generating enthusiasm and enjoying rapid adoption, as did the enhancements that came in the SQL Server 2005 release. The latest version of SSRS, included with SQL Server 2008, comes with a bevy of enhancements geared toward better performance, increased interoperability, consolidation of tools and services, reductions in dependencies, improved user experience, finer control over design, and overall ease of use.

What's New in SSRS 2008

From design to architecture, SSRS 2008 includes a number of platform changes across all areas of the product. The list

IN THIS CHAPTER

- ▶ What's New in SSRS 2008
- ▶ Reporting Services Architecture
- ▶ Installing and Configuring SSRS
- ▶ Developing Reports
- ▶ Management and Security
- ▶ Performance and Monitoring

is long, but it should be duly noted because some of these changes may have a significant impact on your design, development, monitoring, and tuning processes.

In the following sections, we cover all the features that have been discontinued and any changes that could break your existing applications. After that, we detail all the enhancements included in this release. Be forewarned: it's a lot of ground to cover in a short space, so the pace is quick.

Discontinued Functionality and Breaking Changes

With SSRS 2008, a number of features have been discontinued or significantly changed. They include

- ▶ SSRS 2008 no longer relies on Internet Information Services (IIS) *at all*. This means there are no IIS-based websites used by the platform in this release.

To process HTTP requests for SSRS web services, Report Manager ASPX pages, and other calls, SSRS 2008 now *natively* hosts the .NET Framework and ASP.NET.

SSRS ties directly in with operating-system–level (or *kernel-mode*) HTTP, listening for requests by way of the HTTP API (sometimes referred to as `http.sys`). This means that under the covers, SSRS registers its virtual paths (also known as URIs, for example, `www.myserver.com/Reports`) with `http.sys` in the same way that IIS would register a virtual directory. The operating system redirects incoming HTTP requests to IIS or SSRS, based on the path specified in the request.

Be aware that any ISAPI extensions, virtual directory settings, or other advanced Web customizations you may have built might not be compatible with the new SSRS HTTP architecture.

- ▶ Because of the HTTP architecture changes in SSRS 2008, a few HTTP port-related concerns are noteworthy:
 - ▶ When you are installing SSRS 2008 on 32-bit Windows XP, SSRS reserves port 8080 (because IIS 5.1 has already exclusively reserved port 80).
 - ▶ When you are installing SSRS on other operating systems (including 64-bit XP), port 80 is used in the default native configuration. This means that when configuring your SSRS URIs using the Reporting Services Configuration Tool (RSCT), you must be sure to use paths and ports that are not already in use in any IIS site or virtual directory (to avoid unintended collisions).

TIP

If you try to use a port already reserved by a website or other network service, RSCT usually warns you. However, if that website or server is configured but in the stopped state, RSCT may allow you to use that port. This could cause a resource conflict when that website or service is started.

- ▶ Email aliases (when doing report deliveries via email) are no longer supported on Vista or Windows Server 2008.
 - ▶ The SQL Server 2000 Report Server web service endpoint has been removed.
 - ▶ Several trace log files have been removed, including
 - ▶ ReportServerWebApp_*[timestamp]*.log
 - ▶ ReportServer_*[timestamp]*.log
 - ▶ ReportServerService_main_*[timestamp]*.log
 - ▶ Only ReportServerService_*[timestamp]*.log remains, and it is now your one-stop location for studying trace activity.
 - ▶ Web application settings have been consolidated from RSWebApplication.config (now obsolete) into RSReportServer.config.
 - ▶ Support for rendering Internet Explorer 5.5-compatible reports is discontinued.
 - ▶ Support for the HTML 3.2 and Office Web Components (OWC) rendering extensions is discontinued.
 - ▶ The Excel rendering extension no longer automatically generates spreadsheet formulas from your Report Definition Language (RDL) expressions.
 - ▶ The comma-separated value (CSV) rendering extension no longer attempts to preserve formatting (spacing) according to the report's appearance. However, it now supports two styles of rendering: *default* mode, which is optimized for Excel, and *compliant* mode, which is the standard, format-free CSV you would expect to see rendered.
 - ▶ The SSRS Rendering Object Model itself has changed, and earlier versions are no longer supported.
 - ▶ The capability to automatically upgrade an SSRS database is discontinued (it has been removed from RSCT).
 - ▶ Running Report Builder in .NET's partial trust mode (which requires verification of managed code and limits the ability to call native code) is discontinued. Report Builder now runs only in full trust mode.
- In SSRS 2005, two separate URLs were used to start Report Builder in each trust level. With SSRS 2008, the only supported URL is now the full trust URL, which is `http://[server-name]/[path-to-report-server]/ReportBuilder/ReportBuilder[version].application`.
- ▶ In RDL, object names are now limited to 256 characters in length.
 - ▶ In report rendering, overlapping data regions, repeating items (such as headers and footers), page breaks, and aggregate visibility may be handled differently according to the rendering extension in use. SQL Server Business Intelligence Development Studio (BIDS) warns you upon compilation of your reports if such overlapping occurs.

- ▶ The namespace for Report Object Model classes has changed. Microsoft recommends that you reference these classes using only their unqualified (rather than fully qualified) names to avoid or resolve this issue in your code. (Note: At compile time, the currently installed version of the SSRS classes is used by default. You can change this by modifying the `SpecificVersion` attribute in your assembly reference's properties.)
- ▶ The SSRS Windows Management Instrumentation (WMI) provider is incompatible with its previous version. This could break scripts you may have written for the `rs.exe` tool (covered later in this chapter). It also means that, when connecting to an SSRS 2005 instance using SQL Server Management Studio (SSMS), instead of `servername\instancename`, you must supply the appropriate full SSRS URL.
- ▶ In SSMS, the `Home` folder (which formerly provided GUI-based management of all SSRS objects) has been removed. This means you can now use only Report Manager (or, if using SharePoint integration, your site's SSRS management pages) to manage SSRS content.
- ▶ In Report Manager, you can no longer manage roles and jobs. SSMS is now the only place for these tasks.
- ▶ SSRS 2008 is not supported on Windows 2000 servers.

Enhancements

SSRS 2008 includes a wide range of important enhancements to all aspects of the platform. The following sections examine these changes according to functional area.

Enhancements in Report Development

SSRS 2008 R2 includes a number of enhancements to the suite of tools used in designing, developing, and deploying reports. The following sections detail these enhancements.

Enhancements in Report Design The Report Designer, integrated into Visual Studio 2008 (VS; known in SSRS as BIDS) offers a number of improvements. It includes the following upgrades and changes:

- ▶ Two new subpanes for controlling data grouping:
 - ▶ The Row Grouping pane, which you use to define and manipulate row groups in your reports
 - ▶ The Column Grouping pane, which you use to define and manipulate column groups (when developing matrix-style reports)

Both new subpanes include a number of visual cues indicating your current grouping settings, as well as drop-down boxes that allow you to add, remove, change, and nest data groups, and also define your subtotal and grand total aggregates.

NOTE

Control over data grouping was accessible via Property pages in SSRS's data-bound controls in former versions of BIDS; these new panes make it much easier to access and manipulate your group settings quickly.

- ▶ The Report Data tab has been removed from the Report Designer. It has been replaced with a new tool window within VS (of the same name) that displays all built-in fields, data sources, datasets (shared and nonshared), report parameters, and images, all in an easy-to-navigate tree. From this tree, most of these objects may be dragged and dropped onto the report design surface. The menu bar located at the top of the Report Data tool window offers commands for creating and editing data sources, datasets, parameters, and images.
- ▶ The designer surface includes new context-sensitive rulers, a revamped Report Properties dialog, and a simplified context menu.
- ▶ Using the Report menu (in BIDS), you can now publish report parts to the SSRS catalog (report parts are covered later in this chapter in the section "Using Report Parts").
- ▶ You can now create, modify, use, and deploy shared datasets (covered later in this chapter in the section "Using Shared Datasets").
- ▶ The Report Designer now supports rotation of text boxes, vertically or horizontally, up to 270°.

The Report Designer's Toolbox tool window offers a number of new data visualization controls:

- ▶ **Tablix**—At first glance, the Table, Matrix, and List controls still appear to be the same as in the previous edition of SSRS. However, they have actually been changed to become *data region templates*, a kind of layout device for the *Tablix*, a new super-control that embodies all the functionality of the Table, Matrix, and List combined.

The Tablix provides functionality for all manner of data grouping; hierarchical nesting of groups; header, footer, and detail row display. Each Tablix cell may contain any other type of Tablix data region or control, enabling an endless variety of layouts.

- ▶ **Gauge**—Gauges enable the graphical representation of a single data field or aggregate value (sometimes referred to as a *key performance indicator* or *KPI*). Each gauge has its own *gauge panel*, whereupon you may drag and drop additional gauges to display multiple values. Gauges are displayed in either a radial or linear fashion.
- ▶ **Indicator**—Actually, a type of small gauge, an indicator enables fast visual comprehension of a single data field or aggregate value. You may add additional indicators or gauges to an indicator's gauge panel. When selecting the icons used by your indicator, you choose from a small set of predefined images, usually corresponding to

commonly understood symbols, such as traffic signals, directional arrows, rating starts, and so on.

- ▶ **Data Bar**—Actually a type of small chart, the data bar allows for the graphical representation of one or more data series, just as you would find in a chart (a data bar may also be promoted to a full chart control with a click of the context menu). These bars can be drawn as horizontal or vertical bars and can express multiple groups (categories) of values within a series.
- ▶ **Sparkline**—Also a type of small chart (and also promotable to a full chart), a Sparkline is much like a data bar in that it enables the visual expression of one or more data series (grouped or ungrouped). Sparklines come in a range of styles, including chart types such as column, line, area, shape, and range. Sparklines and data bars are meant to be small and quickly comprehended; as such, they lack legends, tick marks, labels, and axis lines.
- ▶ **Map**—The map control enables the visualization of geospatial (mapping) data that you may combine with related analytical data. Every map begins with a map layer, which you can source from one of three places:
 - ▶ A predefined U.S. country or state map (these come with SSRS) that you may select one from the map gallery
 - ▶ An Environmental Systems Research Institute, Inc. (ESRI) *shapefile* (a vector format that contains geographical data and other attributes)
 - ▶ A query against spatial data stored in SQL Server using the new geography or geometry data types (discussed in Chapter 24, “Creating and Managing Tables” and Chapter 42, “What’s New for Transact-SQL in SQL Server 2008”)

As for your related analytical data, you can source it from any related dataset, or it may be embedded in the spatial data source itself. For example, if the data you want to visualize includes product orders by region, you can relate that regional data to fields in the spatial dataset using *match fields*. This topic is covered later in this chapter in the section “Working with Maps.”

Finally, and perhaps most exciting, the map control supports the overlay of Bing map tiles (to Internet-connected users) on your map, providing a professional look and feel.

General changes to the control suite include the following:

- ▶ All Properties pages for every control are completely revamped. Tabs that used to be across the top are now tabs down the left side, presented in a more visually friendly tab/detail layout.
- ▶ All right-click menus for each control have been enhanced to allow for easier menu navigation. For example, when you are accessing the properties of a cell’s text box nested in a Tablix data region, one set of commands is shown for the text box itself and another for the enclosing Tablix, preventing you from having to click all over the report to access the context menu you need.

- ▶ Text and HTML formatting capabilities are enhanced for all controls, allowing for font and style mixing, import and display of HTML stored in report field data, and paragraph styling.
- ▶ The Chart control offers a number of enhancements, including the following:
 - ▶ New and updated chart types, include pie, doughnut, pyramid, candlestick, stock, radar, polar, pareto, histogram, funnel, range column or bar, smooth area, smooth and stepped line, box plot, bar and column cylinder
 - ▶ Support for secondary and custom axes, custom rotation angles, scales, strip lines, multiple combined areas, legends, and titles; custom intervals; and enhanced interval labeling
 - ▶ Better color, text, and other formatting capabilities; 3D effects (for some chart types); and the ability to edit labels directly on the chart at design-time
 - ▶ Built-in statistical and financial calculations

Shared Datasets A shared dataset is exactly as it sounds—a dataset that you define using one of the designers and then deploy to the SSRS catalog for reuse. Shared datasets are parameterizable; when you enable query caching for a dataset, each combination of parameters creates a snapshot in the cache. Shared datasets are covered in detail later in the section “Using Shared Datasets.”

Report Parts With previous SSRS editions, when you wanted to reuse a portion of a report, such as a data-bound table, you would make that section of the report into a subreport and then use that subreport on different reports. This functionality is, of course, still supported in SSRS 2008, but in addition, you can now reuse charts (including data bars and Sparklines), gauge panels (including gauges and indicators), images, lists, maps, matrices, report parameters, rectangles, tables, or shared datasets. To do this, you simply publish them to the SSRS catalog, making them available for reuse using Report Builder or BIDS. This process is covered in this chapter in the section “Using Report Parts.”

New Data Sources Report Designer includes a new report data source that enables developers to consume Teradata and SAP BI content in reports.

New Report Definition Language (RDL) Elements RDL has been updated to include support for all the new report controls and all changes to existing controls. In addition, RDL provides finer-grained control over page naming, page breaks, and pagination (which can now be restarted within a page range); margins; header and footer visibility; and null value handling.

RDL also includes a new element (`ReportSections`) for SSRS 2008 R2 reports, used to model the content of the map control and related functionality.

New Version of Report Builder SSRS 2008 R2 includes the release of Report Builder 3.0 (at the time of this writing, Report Builder 1.0 comes with SSRS 2008; Report Builder 2.0 is a separate download from Microsoft; Report Builder 3.0 comes with SSRS 2008 R2).

The user interface (UI) has been completely rewritten to have the look and feel of an Office 2007 application, including its Ribbon bar. It offers data visualization and formatting enhancements; on-demand rendering; and support for multiple data sources, shared datasets, and report parts. It is available as a ClickOnce application that you launch from Report Manager or SharePoint (if using SharePoint-integrated SSRS mode, a topic outside the scope of this chapter).

In terms of overall usability, previewing of reports in Report Builder has been accelerated, thanks to the use of *edit sessions* that enable reuse of cached dataset data.

Enhancements in Report Processing and Rendering

SSRS report processing and rendering has been improved in the following ways:

- ▶ Page rendering now happens *on demand*, meaning that as a user scrolls or pages through a report, the next page of the report is dynamically rendered.
 - ▶ The report rendering object model has been updated to reflect these changes, most notably in regards to how page breaking and pagination are handled.
 - ▶ Report page counts are not always known at runtime (until the last page is rendered). This is reflected in the Report Viewer toolbar (page counts are now displayed as 1 of ?).
- ▶ A Microsoft Word rendering extension has been added (compatible with versions 2000 and higher).
- ▶ An Atom rendering extension has been added, enabling users to export a report as an Atom Publishing Protocol (APP) service.
- ▶ The Microsoft Excel rendering extension now supports rendering data regions and subreports that are nested inside Tablix cells.
- ▶ When you are exporting to Excel, worksheet tabs can be named. You achieve this at design time by setting the value of the `InitialPageName` property of your report to an expression that returns a name.
- ▶ Extra whitespace in the body of your reports is no longer eliminated during rendering (you may change this behavior using the `ConsumeContainerWhitespace` property of the report).
- ▶ Images are retrieved from the server only when the report page containing them is rendered on demand (except in the case of snapshot creation, when they are all retrieved up front).

Tool and Service Enhancements

SSRS 2008 R2 includes a number of enhancements to the tools and services which form the backbone of the platform.

Changes to Report Manager

Report Manager comes with a totally revamped Web user interface (with a new SharePoint-like color scheme). It's a welcome upgrade that makes liberal use of Asynchronous JavaScript and XML (AJAX) technology for a faster overall experience (less navigation per click).

The new Report Manager also includes a new SharePoint-style context menu for each folder item. This works in a manner similar to what happens when you click a list item in a SharePoint site. These context menus offer actions that you can take without navigation, depending on the type of item you select. Not surprisingly, the new Web UI seems to work best with Internet Explorer because the context menus do not work with Firefox (as tested with Firefox 3.6).

Report Manager now allows you to administer report models (used with Report Builder reports, covered in this chapter in the "Report Builder" section), model security, and click-through reports.

SSRS 2008 includes a new web service (a.k.a. *endpoint*), `ReportService2010.asmx`, which subsumes all the functionality of `ReportService2005.asmx` and `ReportService2006.asmx`. It supports all the new features discussed in this section.

SharePoint Integration Improvements

SSRS 2008 brings tighter integration with SharePoint. It includes the following:

- ▶ A set of SharePoint application pages for administering SSRS content (that is, Report Manager functionality), viewing reports, configuring report settings, and running Report Builder
- ▶ Support for data-driven subscriptions for reports that live in a SharePoint library
- ▶ A new Add-In for SharePoint Technologies, which provides a web GUI that includes job management pages and enables you to view or cancel running reports
- ▶ The `ReportService2006` and `ReportService2010` web services, which include several new methods that permit programmatic management of SSRS under SharePoint-integrated mode
- ▶ Support for using a SharePoint list as a report data source (an eagerly awaited enhancement)
- ▶ New capability to manage SSRS in SharePoint-integrated mode using `ReportService2010.asmx`

NOTE

SharePoint integration is not covered in this chapter. (SharePoint components are installed separately using a SharePoint utility called `STSADM.exe`.) For more information, see the MSDN article "Viewing Reports with SharePoint 2.0 Web Parts."

Service Changes and Improvements

Because IIS is no longer part of the platform, the Report Server Service now stops and starts all aspects of SSRS, including Report Manager, the web services, and the background processing engine (a.k.a., the *Scheduling and Delivery Processor*). SSRS also includes a new native authentication layer (as opposed to using IIS for authentication), as well as native HTTP logging and server memory usage configuration.

For a complete list of which administrative tasks may be performed by which tools, see the MSDN article “Behavior Changes in SQL Server Reporting Services.”

Programming Enhancements

SSRS 2008 R2 includes a number of enhancements to the VB.NET script used in expressions, as well as to the report rendering engine.

New Simple Expression Syntax

Report expression syntax has been reorganized into two logical groups: *simple* and *complex*. Complex expressions are simply the Visual Basic .NET (VB .NET) expressions you’ve used for years. Simple expressions are a new kind of syntax, allowing for shorthand expression of simple values. For example, instead of expressing a ProductID field value as `Fields!ProductID.Value`, you can now express it simply as `[ProductID]`. Simple expression syntax is summarized with examples in Table 53.1 (complex expressions are summarized in Table 53.3).

TABLE 53.1 New Simple Expression Syntax

Report Item	Sample Expression	Equivalent Complex Expression
Built-in field	<code>{BuiltInFieldName}</code>	<code>=Globals! BuiltInFieldName.Value</code>
Data source field	<code>[FieldName]</code>	<code>=Fields! FieldName.Value</code>
Parameter	<code>[@ParameterName]</code>	<code>=Parameters! ParameterName.Value</code>
Aggregate on data source field	<code>[StDev(FieldName)]</code>	<code>=StDev(Fields! FieldName.Value)</code>
Literal text (with escaped brackets)	<code>\[LiteralText\]</code>	<code>[LiteralText]</code>

Enhancements to Expressions

You may now create expressions that perform aggregation of an aggregate—for example, `=StDev(Sum(Fields!Stocks.Price))`.

The expression engine includes the following new global variables:

- ▶ **RenderFormat.Name**—Returns the name of the current rendering format. You use it in expressions to produce different output behavior depending on the rendering format.
- ▶ **PageName**—Returns the name of the current page.
- ▶ **OverallTotalPages**—Returns the total number of pages in the entire report.
- ▶ **OverallPageNumber**—Returns the current absolute page number (not impacted by page number resetting).

The expression engine includes the following new functions that operate on datasets structured as rows of name-value pairs:

- ▶ **Lookup**—Given two datasets whose rows hold a one-to-one relationship, looks up a single value from a sibling record (by field name and matching value), just as you would when doing a T-SQL JOIN. This function returns a single value.
- ▶ **LookupSet**—Works similarly to **Lookup**, except that you use this function when your datasets hold a one-to-many relationship. It returns the matching set of corresponding values.
- ▶ **MultiLookup**—Works just like **Lookup** (on datasets that hold a one-to-one relationship), except that it returns a matching set of corresponding values.

New Report Customization Extension

SSRS includes a new Report Customization Extension (RCE), enabling developers to alter the RDL stream on the fly. This feature is implemented as a processing event into which you can wire your custom RDC code to change the layout, language, and so on. (This topic is not covered in this chapter.)

Reporting Services Architecture

When referring to SSRS as a platform, we are actually talking about a cohesive set of development tools, configuration tools, web services, applications, and utilities, all working together to deliver enterprise-grade reporting.

In a nutshell, the platform includes the following components:

- ▶ A single Windows service, listed in the Windows Service Control applet as SQL Server Reporting Services (`InstanceName`), which acts as a host for and provides centralized control of SSRS's background processing engine, web services, and Report Manager web application. It also handles encryption and decryption of stored credentials and connection information.

- ▶ Two databases, known as the Report Server catalogs (note that the following are their default names; you can name them whatever you want using the Reporting Services Configuration Manager, or RSCM):
 - ▶ **ReportServer**—Stores all reporting objects, including reports, security settings, schedules, subscriptions, snapshots, users, configuration settings, and encryption keys.
 - ▶ **ReportServerTempDB**—Stores ephemeral report data (sometimes called *intermediate processing products*), such as cached reports, session and execution data.
- ▶ Four .NET web services, which serve as SSRS's programmatic APIs:
 - ▶ **ReportService2005.asmx**—Provides methods for managing all aspects of an SSRS instance configured in native mode.
 - ▶ **ReportService2006.asmx**—Provides methods for managing all aspects of an SSRS instance configured in SharePoint-integrated mode.
 - ▶ **ReportService2010.asmx**—Subsumes functionality of ReportService2005.asmx and ReportService2006.asmx.
 - ▶ **ReportExecution2005.asmx**—Provides methods for custom report rendering and execution.
- ▶ Three command-line applications, all located in %PROGRAMFILES%\Microsoft SQL Server\100\Tools\Binn:
 - ▶ **RSKeyMgmt.exe**—Provides encryption management for securing database-stored Report Server content, such as credentials, connection strings, accounts, and the encryption key itself. This tool is also used to join servers in an SSRS farm configuration (via the -j option).
 - ▶ **RS.exe**—Enables developers to write scripts in VB .NET that leverage the web service APIs.
 - ▶ **RSConfig.exe**—Enables you to programmatically change SSRS configuration values in RSReportServer.config (the configuration file for the web service APIs), either on a single or multiple machines.
- ▶ Report Manager, an administrative website that provides Web-based control over SSRS, including the ability to
 - ▶ Add or remove, organize, configure, and run all kinds of SSRS objects, including
 - ▶ Reports, report resources, data sources, shared datasets, report parts, and folders.
 - ▶ Report models and data source views (used with Report Builder).
 - ▶ Administer the SSRS security model, including
 - ▶ Users and roles.
 - ▶ Role assignments (remember to keep these simple).
 - ▶ Manage
 - ▶ Report snapshot, history, and caching configuration.
 - ▶ Schedules, subscriptions, and related settings (Note: SQL Agent must be enabled for automated report execution).
 - ▶ Report execution timeout duration.

- ▶ Reporting Services Configuration Manager (RSCM), a configuration GUI application (covered in detail in the following section).
- ▶ A suite of SharePoint Web parts, pages, and documentation.
- ▶ Report Builder, a ClickOnce application for designing and executing ad hoc reports.
- ▶ BIDS, which includes Report Designer; Model Designer; specialized tool windows; and other capabilities for report development, testing, and deployment.
- ▶ Two Microsoft .NET Report Viewer controls (one for ASP.NET, one for Windows Forms), for integrating reporting in custom applications. Report Viewer offers a rich programming interface for controlling report execution and interactivity and is available for C#, VB .NET, and the other .NET languages.
 - ▶ The Report Viewer control is capable of processing SSRS reports using two modes:
 - ▶ **Local**—Using this mode, report processing happens in your application, meaning that *SSRS is not required to run your application's reports*.
 - ▶ **Remote**—Using this mode, report processing happens via the Report Server web services.
 - ▶ A Windows Management Instrumentation (WMI) provider, which exposes a set of WMI interfaces that programmers can use to configure the Report Server or build other configuration utilities.

Figure 53.1 provides a tiered view of the SSRS architecture, illustrating each platform component.

In the next section, you learn how to install SSRS, where to find each installed component on your file system, and how to use RSCM to optimally configure your installation of SSRS. After configuring SSRS, we move on to report development with BIDS and Report Builder.

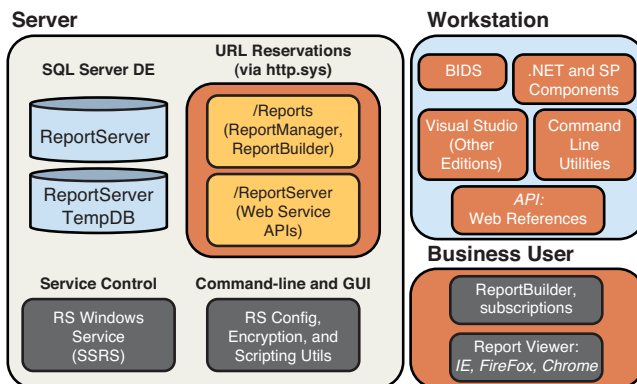

FIGURE 53.1 SSRS Tiered Architecture Diagram.

Installing and Configuring SSRS

When you launch the SQL Server installer, the setup application checks the prerequisites on your system to determine whether SSRS can be installed without issue. If your system meets all the requirements, you may proceed, following the steps described in the following sections.

The Installation Sequence

To install SSRS, you need to run the SQL Server installer and be sure to check the Reporting Services check box on the Feature Selection installation step, as shown in Figure 53.2. (Note that the figures in this section show the installation screens as they appear when adding the SSRS feature to an existing SQL Server instance.)

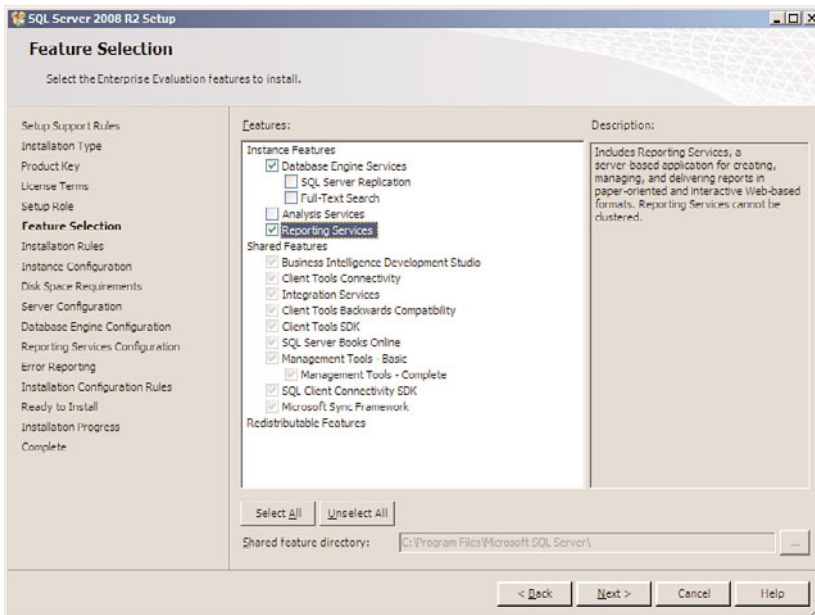

FIGURE 53.2 Selecting SSRS on the Feature Selection installation step.

Next, on the Server Configuration step (illustrated in Figure 53.3), select an account to use for the SSRS Windows service. You can use NETWORK SERVICE (an okay choice), or create and use a dedicated account (recommended).

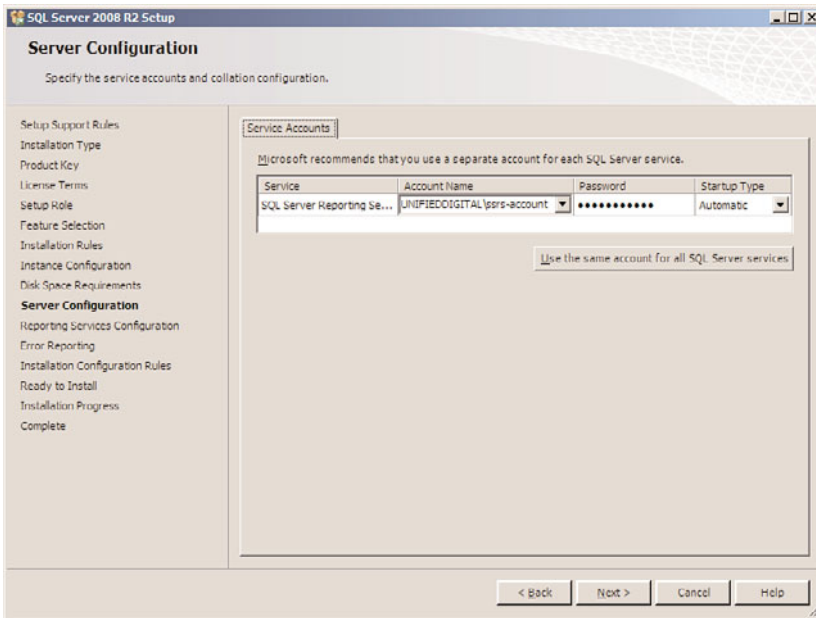

FIGURE 53.3 Configuring the SSRS Windows service account on the Server Configuration installation step.

When you reach the Reporting Services Configuration mode selection step (illustrated in Figure 53.4), you have up to three configuration options, depending on your server's configuration:

- ▶ The installer detects if SharePoint is running on the target server. If it is, you have the option of installing SSRS in SharePoint-integrated mode (otherwise this option is grayed out) and having it automatically configured with the default settings.

TIP

Accepting the default installation settings means that setup creates and sets up the database catalogs, configures the web service URLs, installs all needed files and Registry settings, and sets up all necessary security settings and permissions. The only configuration option you have in this scenario is selecting the Windows service account.

- ▶ You can install SSRS in native mode and have it configured with the default settings
- ▶ You can install SSRS but not configure it. For this example, you should make this selection because the next learning task is how to use RSCM to configure SSRS.

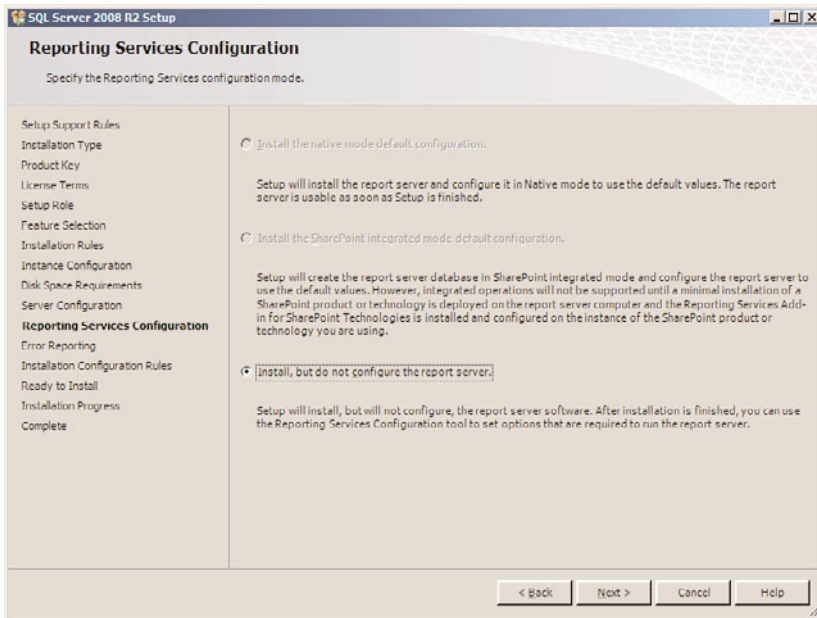

FIGURE 53.4 Choosing an SSRS configuration mode during installation.

In this scenario, Setup copies all necessary files, creates the appropriate Registry settings, and sets up the Windows service, but otherwise leaves the Report Server unconfigured.

In the final step, Ready to Install, the installer shows the name of the new SSRS instance (you need this later to locate the installed files) and the configuration mode selected (illustrated in Figure 53.5). In this example, the installer reports that the SSRS install is being performed in `FilesOnlyMode`, meaning that you must use RSCM to completely configure SSRS after installation completes (or you won't have a working platform).

Assuming all went well, your next task is to open Windows Explorer and navigate to your install location to examine what's on the file system. This might seem like a trivial exercise, but in times of immediate need, it's critical to know where things live.

File Locations

The root folder you should care about most is `%PROGRAMFILES%\Microsoft SQL Server\MSRS10_5[InstanceName]\Reporting Services`.

Below this folder, you find all the items listed in Table 53.2 in their respective locations.

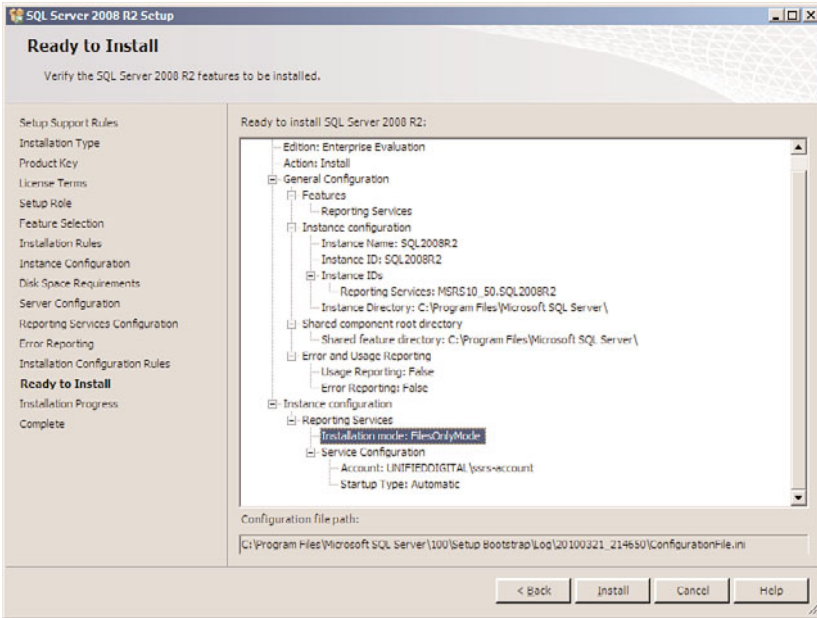

FIGURE 53.5 SSRS Installation, Final Step.

TABLE 53.2 SSRS Folder Content

SSRS Item	Installation Subfolder
Log files (most importantly, ReportServerService_[timestamp].log).	LogFiles
Report Manager (SSRS's administrative website).	ReportManager
Location of cascading style sheets (use them to tweak the look of the Report Manager website).	ReportManager\Styles
Web service APIs (and associated configuration files).	ReportServer
Windows service (and associated configuration file).	ReportServer\Bin
Report Builder 1.0 (if using SSRS 2008) or Report Builder 3.0 (if using SSRS 2008 R2). Remember, Report Builder 2.0 is a separate download from Microsoft.	ReportServer\Report Builder
Command-line utilities.	Found in %PROGRAMFILES%\Microsoft SQL Server\100\Tools\Binn
SharePoint web parts.	Found in %PROGRAMFILES%\Microsoft SQL Server\100\Tools\Reporting Services\SharePoint

SSRS Configuration Using RSCM

RSCM is a comprehensive configuration tool that enables you to perform the following platform tasks:

- ▶ Set up `http.sys` URL reservations (for Report Manager and the reporting web services)
- ▶ Create the SSRS databases (ReportServer and ReportServerTempDB)
- ▶ Generate and back up SSRS's symmetric encryption keys (used for encrypting sensitive data stored in the SSRS databases)
- ▶ Configure the SMTP account settings used for scheduled report delivery
- ▶ Configure the unattended execution account, used by report data sources that don't require authentication (such as images, XML files, and so on)
- ▶ Configure multiserver scale-out (for building SSRS web farms that share a common SSRS catalog)
- ▶ Start and stop the SSRS Windows service
- ▶ Change the SSRS Windows service account
- ▶ View SSRS version information for your instances

You can use RSCM at the end of a custom installation or at any time to change the platform settings. When working with RSCM, you navigate the tree displayed on the left of the GUI from top to bottom, from task to task, configuring all appropriate settings.

Next, let's walk through a typical configuration scenario using RSCM. This step is necessary because in the installation example you ask the installer not to configure SSRS.

The first step is to launch the program, located in your Programs menu under Microsoft SQL Server 2008 R2\Configuration Tools. When RSCM starts, it prompts you for an SSRS instance to which to connect.

Windows Service Configuration with RSCM

After you connect to your instance, notice the configuration choices available on the left side of the main window. Click your SSRS instance name (at top left) and ensure that your SSRS Windows service is running. Keep in mind that the Report Server Windows service is an essential Report Server component. It needs to be running for reports to be executed either on demand or offline. You can change its service account and/or password by clicking the Service Account node.

Web Service Configuration with RSCM

The Report Server web service exposes the Simple Object Access Protocol (SOAP) interfaces clients use to interact with the platform.

Using the tree on the left of the screen, click on Web Service URL. On the detail pane (located on the right side of the main window), under Report Server Web Service Virtual

Directory, enter ReportServer (or similar) in the Virtual Directory text box (if it is not already present). This is the directory name users have come to expect.

In the next group box, select an IP address, port, and optional SSL certificate and SSL port. Save your configuration changes by clicking the Apply button (at bottom right). When the settings are applied successfully, your window should look something like the one in Figure 53.6. Click the link located under Report Server Web Service URLs to test your new virtual path. Keep in mind that later, when you begin developing reports with VS, you need to enter this service URL on your Report Server project's properties to be used as your deployment path (covered later in the section "Deploying Reports").

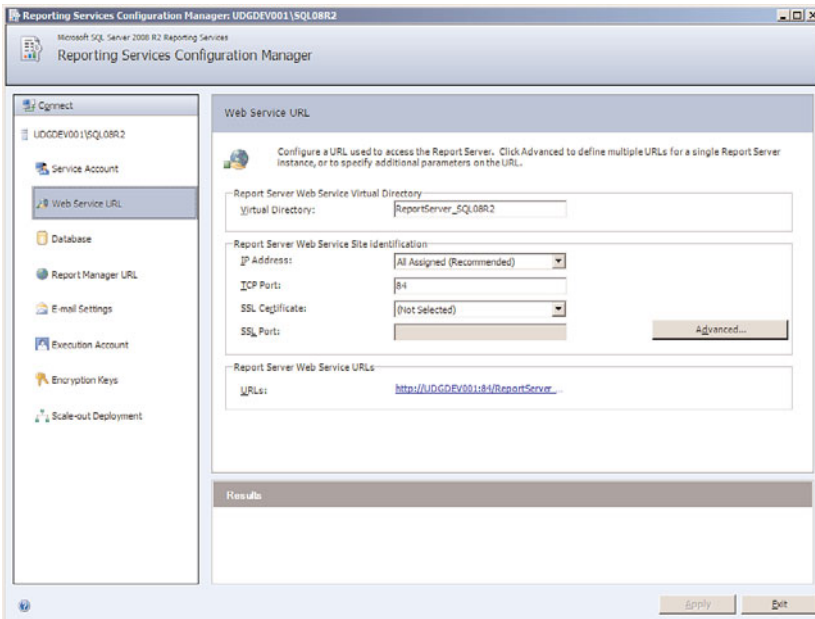

FIGURE 53.6 Configuring the SSRS Web Service URL with RSCM.

The setting changes you make in this area of RSCM are saved to the following file:

```
%PROGRAMFILES%\Reporting Services\ReportServer\rsreportserver.config
```

These settings are saved to an XML node that you can locate in the configuration file via the following XPath:

```
\Configuration\UrlReservations\Application[Name='ReportServerWebService']
```

Database Configuration with RSCM

As mentioned previously, SSRS relies on two databases: the main store for metadata (named ReportServer by default) and a temporary store for user sessions (named

ReportServerTempDB). ReportServerTempDB is created in simple recovery mode and doesn't need to be backed up periodically because it contains only transient data—data about the in-flight sessions being actively served by SSRS. ReportServer is created in full recovery mode; it houses all the critical components of your reporting system. SSRS cannot run without it.

Click on the Database node in the tree on the left. On the detail pane, click the Change Database button. On the ensuing Change Database dialog, select the radio button labeled Create a New Report Server Database. Next, select your target SQL Server instance on the Database Server dialog. On the next step (Database), enter ReportServer as your database name and leave the Native Mode radio button selected (unless you are using SharePoint integration). Click Next.

On the Credentials screen, select the SQL Server instance (local or remote) and login credentials you want you use for the database account. This account is granted the SQL Server role RSExecRole on both SSRS databases. This role is critical because it contains all the permissions necessary for report administration. For convenience, you can make this the same account you selected for the Report Server service (illustrated in Figure 53.7).

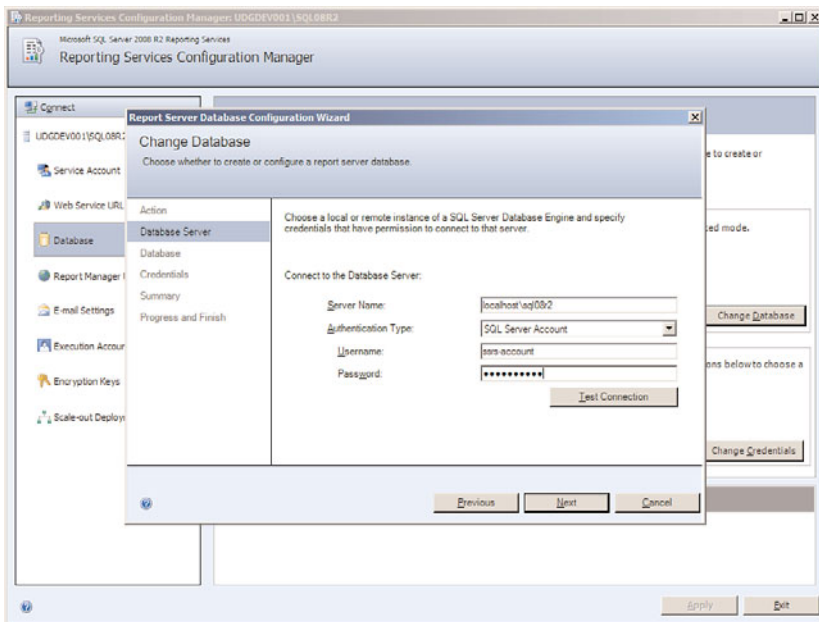

FIGURE 53.7 Configuring the SSRS databases using RSCM.

When this process completes, open SSMS and verify that your new databases are present on your target instance of SQL Server. Next, open Object Explorer and navigate to the Security\Users node for each database. Check the properties of the user you specified in your database credentials and ensure that the user is a member of the RSExecRole.

Report Manager Configuration with RSCM

Click the Report Manager URL node in the tree on the left. In the Virtual Directory text box, enter Reports or something similar (Reports is the default name for the Report Manager virtual path). Click Apply and then click the URL link to test that Report Manager is working properly. Your browser should open to Report Manager, looking something like the window shown in Figure 53.8 (depending on what works for your particular system configuration).

FIGURE 53.8 Viewing Report Manager in Internet Explorer.

Your web settings are saved to `rsreportserver.config` in an XML node you can locate via the following XPath:

```
\Configuration\UrlReservations\Application[Name='ReportManager']
```

Email and Execution Account Configuration with RSCM

If you plan to deliver reports over SMTP (something your users will really appreciate), click the Email Settings node in the RSCM tree and enter your mail server account settings. If you plan to use externally stored images or XML data sources in your reports, click on Execution Account in the RSCM tree and enter credentials for an account that has access to those file systems.

Encryption Configuration with RSCM

As mentioned earlier, SSRS is capable of securely storing sensitive information (for example, connection strings to data sources for reports, subscription information) in the

SSRS catalogs. To be able to do so, it uses the Windows Crypto APIs, which are based on the account under which the service is configured to run.

When the service is first started and it connects to an empty Report Server database, it creates a symmetric key used for encryption. It then encrypts this symmetric key with the public key of the account used to run Report Server Windows services. It then stores the encrypted keys in the SSRS catalog and uses the keys to encrypt and decrypt data. You can also use this RSCM screen to manually delete encrypted content, change the encryption key itself, and restore an existing key.

It's a good idea to make a password-protected backup file of this encryption key. To do this, click on the Encryption Keys tree node and then click Backup. Select a file location and enter your password. Now, if anything should go wrong with your SSRS installation, you can still decrypt your encrypted data. This capability is quite important because if you lose your key, there is no way to retrieve it again and all your encrypted data is rendered inaccessible.

You should always change the service account under which the Report Server service runs via RSCM because, when you do this, the system needs to back up and restore the encryption keys as well as make sure the new account has access to the Report Server database. This explains why you are prompted to save the encryption key when you perform this operation.

Scale-out Architecture Configuration with RSCM

The final RSCM screen to discuss is the Scale-out Deployment screen. If you plan to deploy the SSRS runtime components to a number of servers but use only a single SQL Server instance for SSRS data storage, you're ready to scale out (although this does require SQL Server Enterprise Edition). You use this screen to join or unjoin servers to and from your web farm (you can also use the `RSKeyMgmt.exe` command-line utility for this purpose).

For a list of the available features in each SSRS edition, see "Compare Edition Features" at the following URL:

<http://www.microsoft.com/sqlserver/2008/en/us/editions-compare.aspx>

Developing Reports

Now that you understand the SSRS architecture and your instance of SSRS is properly installed and configured, you're ready to dive into report development.

Tools of the Trade

SSRS 2008 provides two primary design tools for building reports and related objects:

- ▶ BIDS, a powerful development tool integrated with VS 2008
- ▶ Report Builder, a simpler-to-use yet no-less-powerful application for designing ad hoc reports

NOTE

Report Builder no longer depends solely on logical report models developed using BIDS, as was the case with version 1.0 (report models are covered later in this chapter in the “Report Builder” section).

Both tools provide rich graphical design surfaces and allow for a (mostly) WYSIWYG experience, and you can achieve almost all the same results with either. BIDS, however, is marketed heavily toward developers, whereas Report Builder is marketed more at advanced business users.

In practice, Report Builder users usually depend on having at least one hard-core BIDS developer to lean on, not only for questions on how to work with the platform, but also to prepare reports, report data sources, and report datasets, and to maintain the management system, in order to succeed. As a developer, you really need to master both tools because your end users will almost certainly bring their Report Builder questions to you.

Report Basics

What is a report? A *report* is a means of visualizing data derived from one or more sources. Typically, these sources have always been datasets coming from T-SQL statements or stored procedures. But with the advent of the mapping features in SSRS 2008 R2 (covered in this chapter in the section “Working with Maps”), reports can now rely on information stored in ESRI (geospatial) data files.

A report may

- ▶ Display data-bound and non–data-bound controls, offering static and interactive views on the data
- ▶ Include a header, footer, table of contents (called a *document map*), links, images, and linear art (lines and rectangles)
- ▶ Make use of various layouts, styles, and file formats
- ▶ Include sorting, filtering, and grouping functionality (on row data)
- ▶ Accommodate input parameters, whose values are passed from user or programmatic input to your report’s queries
- ▶ Reference embedded or externally stored credentials and data sources

All reports are internally described by RDL, an Extensible Markup Language (XML)-based dialect understood by a variety of design tools available from Microsoft as well as a select few third parties. (The report file extension is `.rdl`.)

RDL is a content model describing the report layout, formatting, and instructions on how to fetch the data. It may also contain custom code written in VB.NET that is executed during report rendering. You can write such code in two ways:

- ▶ Using the built-in functionality provided with SSRS’s VB.NET–style expressions

- ▶ Referencing and calling methods against custom or core .NET Framework assembly classes

(Expressions are covered in this chapter in the section “Understanding Expressions.”)

Keep in mind that you do not need to learn the RDL dialect to develop reports. It becomes important only when you need to generate or manipulate the markup directly—for example, when generating your own RDL files from an XML source using XSL for Transformations (XSLT) or when developing a custom rendering extension.

Overview of the Report Development Process

Generally speaking, report development follows four or five phases (illustrated in Figure 53.9):

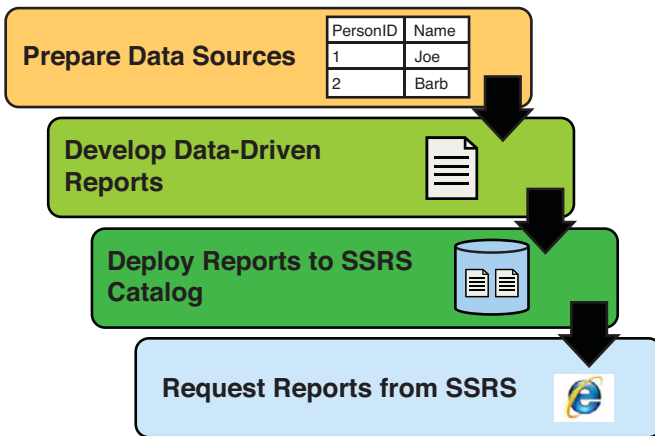

FIGURE 53.9 Phases of report development.

1. Preparing your data sources and datasets for use with BIDS and/or Report Builder
2. Designing your report using BIDS or Report Builder—that is, laying out your visual controls and wiring up the datasets
3. Deploying your reports, report parts, data sources, and shared datasets to the ReportServer catalog, where they are stored (BIDS and Report Manager both provide this function)
4. Testing your reports using a supported web browser (Firefox, Internet Explorer, Netscape, or Safari) via Report Manager or your development tool of choice
5. (Optionally) Securing your reports and setting up data caching rules and a delivery schedule (both covered later in this chapter)

Data Planning and Preparation

The first step in report development is to prepare your data for use with SSRS. Generally speaking, when you are working with non-file data, this means creating the T-SQL tables, views, procedures, and functions from which your data sources will retrieve rows. Any complex logic required to get to report data should happen within the Database Engine, not within SSRS.

The rule of thumb is to keep complex logic and intricate calculations out of your reports and to prepare them ahead of time in your sources. A good reason to put this policy into practice is that, from a maintenance perspective, it will be much easier for you and your colleagues to modify a report if all that is necessary is to change the underlying T-SQL. You don't want to bury your business logic in extensive RDL expressions and embedded code that will be difficult to find.

Another thought to keep in mind during the data planning phase is to ensure that your database server is capable of handling the increased data storage and execution loads that SSRS will bring. Plan and discuss this issue with your database and network administrators.

If your increased loads warrant it, consider the idea of dedicating a separate instance of SQL Server to SSRS storage and execution, or even a separate machine. In addition, you might want to build or make use of content available in a data mart or data warehouse; doing so prevents your reports' execution from impacting the transactional performance of your online databases.

Using Shared Data Sources

Unless you use shared data sources, the data source for your report is embedded into its RDL. This means that when you want to change that data source, you must modify the report or, at the very least, change its data source properties using Report Manager. If you don't use shared data sources, each of your reports requires its own data source, and these data sources cannot be used by any other report.

It's truly a best practice to use shared data sources. When the time comes to make a connection change, you have to look in only one place. Think of how useful (and time-saving) this will be when you need to test your reports in a development environment and then run them against production. Save yourself the headache and start using shared data sources from the onset of your report development.

Using Datasets

Every meaningful report relies on at least one dataset. In SSRS terms, a *dataset* is simply an abstraction of some set of source data generated by a query and used within a report. Datasets remember the data structure of the queries whose output they contain (the fields,

field names, field data types, collation, case sensitivity, and so on). Datasets also store the underlying query used to derive report data from a data source and are aware of any parameters needed to obtain that data—for example, in cases where the underlying data source is a stored procedure.

Every data-bound control on your report needs a dataset from which it will be populated at report (and query) execution time. In BIDS, datasets are listed in the Report Data window's tree listing, and, after you create a dataset, you can simply drag its fields from the tree onto the appropriate drop zones of your data-bound controls to create a link between the two. In simple terms, this means that for every row your query returns, an instance of that field is repeated in the data-bound control. This description is, of course, an oversimplification; you can slice and dice your data in many other ways, as you'll soon see.

Using Shared Datasets

New to SSRS 2008 R2, shared datasets further improve the decoupling of report data from reports. They also encourage reuse and accelerate report execution. A *shared dataset* is simply a dataset you define at design time that can then be reused by any number of reports. You may modify or delete a shared dataset independently of any reports or report parts that depend on it and vice versa. Using shared datasets prevents the need for re-creating the same dataset in multiple reports. Redundancy is the enemy of maintainable code, and using shared datasets prevents you from letting small differences in your underlying queries produce inconsistent results (something end users tend to intensely dislike).

Like regular datasets, shared datasets may make use of input parameters. At execution time, shared dataset output is cached according to unique combinations of parameter input (much like SQL Server stored procedures). This leads to efficiency gains at report execution time.

Like reports and other SSRS objects, shared datasets are deployed to the SSRS catalog during report project deployment. When they are published, you can manage your shared datasets using Report Manager. You can also modify or delete them using BIDS or Report Builder. Shared datasets are XML files stored with the `.rds` extension. You can take the `.rds` file created by BIDS and deploy it to other SSRS catalogs by uploading it with Report Manager.

Let's look at how to create a shared dataset using BIDS.

Creating a Shared Dataset

Once you've opened up BIDS and created a Report Server project, open your Solution Explorer window, right-click the Shared Datasets folder, and then click Add New Dataset. The Dataset Properties window appears. Select your data source (preferably a *shared* data source), and then using Query Designer (or the text window), design or type in a T-SQL query or EXEC statement (for running stored procedures) that will return at least a few rows.

Click on the Fields tab on the left; here, you can create calculated fields (using expressions), or add, remove, rename, or provide a data type for the fields in your shared dataset. Using the left navigation tabs, you can also set various dataset options (such as case sensitivity) and add any necessary parameters or filters. When your dataset is set up as you like it, click OK.

The following sample query creates a simple shared dataset that takes one input parameter:

```
SELECT
    BusinessEntityID,
    PersonType,
    Title,
    FirstName,
    LastName
FROM Person.Person
WHERE FirstName LIKE @FirstLetter + N'%'
ORDER BY FirstName ON p.BusinessEntityID = h.BusinessEntityID
```

In the sample project (in the code samples on the CD), you can find this shared dataset file named `sdsPeopleByLetter.rsd`.

After saving it, right-click your shared dataset in Solution Explorer; then click **Deploy** to publish it to the SSRS catalog. When it is deployed, you can use your new shared dataset in any report. To do this, right-click the **Datasets** folder in the Report Data tool window and then click **Add Dataset**. On the ensuing **Dataset Properties** window, select the **Use a Shared Dataset** radio button, click on the icon representing your shared dataset, and then click **OK**.

You can use Report Manager (covered later in this chapter in the section “Using Report Manager”) to manage your shared dataset: move it to another folder or delete it, change its caching rules, alter its inherited permissions, switch its underlying data source, and, most importantly, view a list of all reports that depend on it. Figure 53.10 illustrates how to accomplish these tasks.

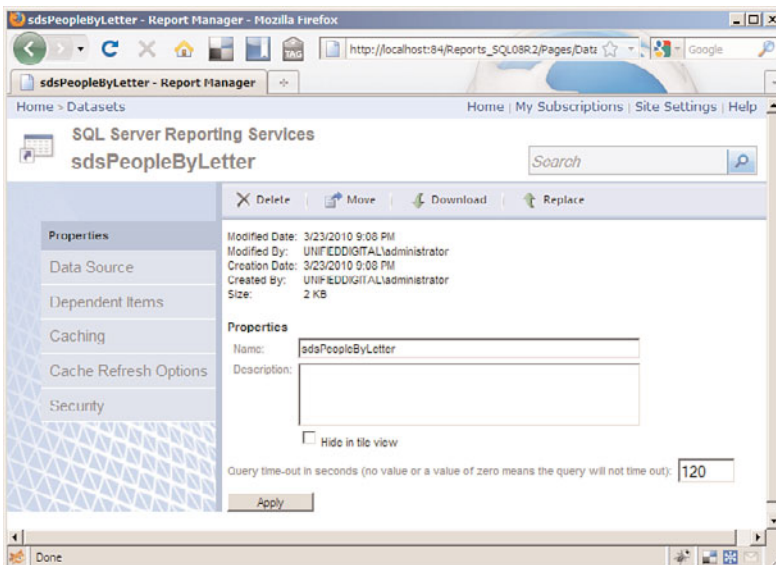

FIGURE 53.10 Managing a shared dataset using Report Manager.

Developing Reports Using BIDS

When your data sources are in order, the next step is to create a Report Server Project. This SSRS-specific project type enables the development and organization of most report objects. Launch BIDS, and, using its main menu, click File, New, Project. In the New Project dialog, click the Business Intelligence Projects node in the tree at the left of the screen; then click Report Server Project under Visual Studio Installed Templates (shown in Figure 53.11).

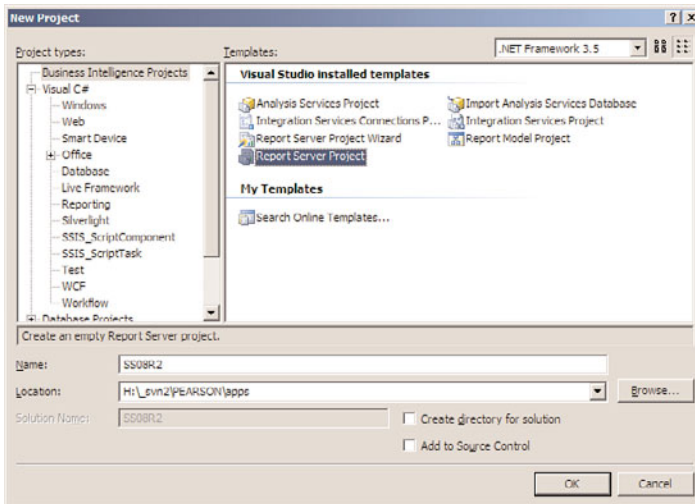

FIGURE 53.11 Creating a Report Server Project using BIDS.

When your new project is successfully created, open Solution Explorer, right-click the Reports folder, and then click Add New Report. This launches the Report Wizard, which leads you through all essential report-creation steps for building a simple report. If you want to skip the wizard and get directly to the design surface, choose Add New Item and then select Report instead of selecting Add New Report.

The first step in the Report Wizard is to create a data source for your reports; this is your reports' connection to the database from which it will cull report data. In this case, connect to AdventureWorks2008R2, the sample database for all the work in this chapter.

If you check the check box labeled Make This a Shared Datasource (on the Select the Data Source screen), the data source is deployed to the server and can be used by other reports. When you are deployed to the Report Server, the connection string and credentials are encrypted using the Report Server encryption keys. Keep in mind that a report can use zero, one, or several data sources, and a data source can be referenced by one or more datasets.

In the next wizard step (Design the Query), you can either paste a T-SQL statement (including statements such as EXEC *stored_procedure_name*) directly into the Query string window, or you can use Query Builder. Query Builder enables you to select tables and

columns, build relationships, and apply filters to your input data. By either means, you end up with a T-SQL statement that will be created as a report dataset.

When building reports without using the Report Wizard, you always have the same options of either typing your T-SQL directly or using Query Designer (illustrated in Figure 53.12). This functionality is accessible via the Report Data tool window; you right-click your data source name and then click Add Dataset to create a new one or click Dataset Properties to modify an existing one.

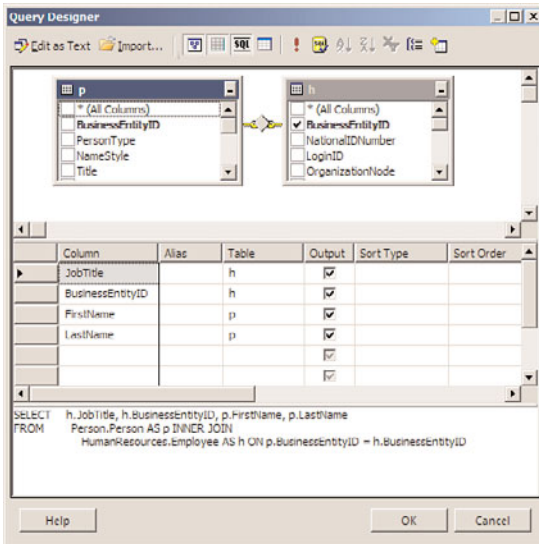

FIGURE 53.12 Creating a new report dataset using the Query Designer.

The Query Designer supports out-of-the-box queries against SQL Server databases, Analysis Services cubes, Oracle databases, and any generic OLE DB and ODBC drivers. If your queries contain parameters, the Query Designer prompts you to provide the necessary values when you execute the report.

Type or paste the code in Listing 53.1 into the Query string window.

LISTING 53.1 T-SQL Code for a Simple Wizard-Generated Report

```
SELECT
    h.JobTitle,
    h.BusinessEntityID,
    p.FirstName,
    p.LastName
FROM Person.Person p
JOIN HumanResources.Employee h
ON p.BusinessEntityID = h.BusinessEntityID
```

When the wizard finishes, it executes your T-SQL and saves the result in a dataset, the storage container for your report data. You see this new (non-shared) dataset displayed on the Data Sources Toolbox window after the wizard is complete.

In the next step (Select the Report Type), you can set up your report in either a tabular or matrix format. For this example, select Tabular and click Next. In the Design the Table step, you choose which fields to display on the report. The three sections displayed on this screen are implemented as follows:

- ▶ **PageFields**—added here end up on the top of the report.
- ▶ **GroupFields**—added here create the groupings for your report data (including a summary row).
- ▶ **DetailsFields**—added here are make up the detail rows for your report.

For this example, add `JobTitle` to the Page area, skip the Group area, add all the other fields to the Details area (your window should now look something like the one in Figure 53.13), and then click Next. Choose a color theme for your report, click Next, and, on the Completing the Wizard step, name your report `EmployeesByJobTitle`, check the Preview Report check box, and finally click Finish. Your completed report opens in Report Designer (RD) with its Preview pane (or the Output tool window) in focus.

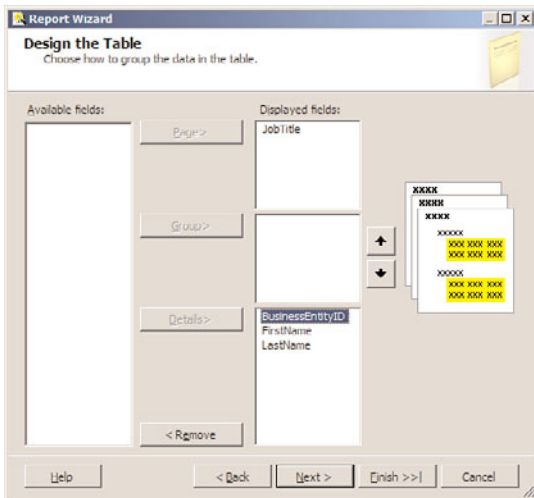

FIGURE 53.13 Field selections using the BIDS Report Wizard.

Switch to the Preview pane (if not already there) and examine the final report. Notice the toolbar across the top which enables pagination, skipping to a particular report page, refreshing the report (rerunning the report query), printing, page layout, page setup, and export features. If you're wondering why the page numbers are listed as 1 of 2?, the

reason is that each report page is rendered *on demand* (new in SSRS 2008); therefore, the total page quantity is not known unless you move through all pages or skip to the last page (using the toolbar or keyboard shortcuts).

Flip through the pages of your report. Notice how each new `JobTitle` value generates a new page, with the employees who have that `JobTitle` listed on that page. To understand the report settings behind this implementation, click on the Design tab (at the top of the surface) to switch to Design mode. Notice the Row Groups and Column Groups panes docked below the Report Designer surface.

The sample report has a single grouping on the `JobTitle` column. To see how this is set up, under Row Groups, click the black drop-down arrow at the right of the item named `list1_JobTitle` (this is the autogenerated name given to the group). Take note of the menu actions you can perform:

- ▶ **Add Group**—Allows creation of nested and adjacent groups
- ▶ **Add Total**—Creates a summary total row based on the selected group
- ▶ **Delete Group**—Deletes the selected group
- ▶ **Group Properties**—Shows the Group Properties window, from which you can configure formatting, rendering, sorting, filtering, and other advanced options related to the selected group

Click the Group Properties menu item; then click the General tab at the left of the screen. Notice the group expression, `[JobTitle]`, which indicates the field being grouped. Notice how your report's page breaks (which are forced on a per-`JobTitle` value basis) are controlled via the Page Breaks tab. Sorting (by `JobTitle`) is controlled on the Sorting tab. You can also change a number of other options using the remaining tabs.

On the left side of BIDS, notice the (new with SSRS 2008) Report Data Toolbox window. It provides a hierarchical view of everything related to your report, including data sources, datasets, report dataset fields, built-in fields, report parameters, and images. Expand the `Built-In Fields` node. These fields provide essential data frequently used in reports. You can drag any field to your report, where it will be instantiated as a text box control whose content is expressed by the simple expression pertaining to the field name (that is, `[FieldName]`). Simple expression syntax is covered earlier in the section "New Simple Expression Syntax."

Working with the Tablix

Returning to the report area of the designer, click anywhere on the report itself near the table. Notice how the GUI changes to a raised appearance? This indicates that your report is using the new Tablix control. The Tablix replaces the `Table`, `Matrix`, and `List` controls, providing all their functionality in one. It offers three *data region templates* (`Table`, `Matrix`, and `List`) that you drag from the Toolbox tool window onto the report. Take a moment to open the Toolbox to view these and the other standard controls.

The Tablix offers several important visual clues as to how your report data is organized with the control. Within its inner border, the innermost grouping for your report is always

indicated by a dark orange bracket. On its outside (gray) border, groupings are indicated by dark gray brackets, which may be nested depending on your report. Because the Tablix is so important to report development, let's examine it a bit further.

Using the Solution Explorer, right-click your project's Reports folder, select Add, New Item, and then select Report. Drag the Table data region template from the Toolbox onto your new report. Create a dataset (use the query in Listing 53.1) and click OK. Your new table-styled Tablix is bound to your new dataset. Let's explore this new control a bit.

Stretch out the Tablix to fit the report; then mouse over its right-most bottom cell. (If you have any difficulty in selecting the Tablix itself [to move or resize it], simply click the upper-left corner of its border; the Tablix changes its state to reveal its grab handles.) Notice the tiny table icon that appears in its upper-right corner. If you click it, you can select the field you want to display in that cell.

A simpler method for setting up a tabular report is to drag each field you want to display from your dataset in the Report Data window to the Header area of each column in the report. To add additional columns, simply right-click any column and select Insert Column; then choose Left or Right. Click on any cell in the bottom row of your Tablix. Notice how the (gray) outer border contains three horizontal lines? This indicates that the data bound to that row represents your *detail group*, meaning that the row data will repeat once per row (see Figure 53.14; notice the black arrow in the bottom-left corner).

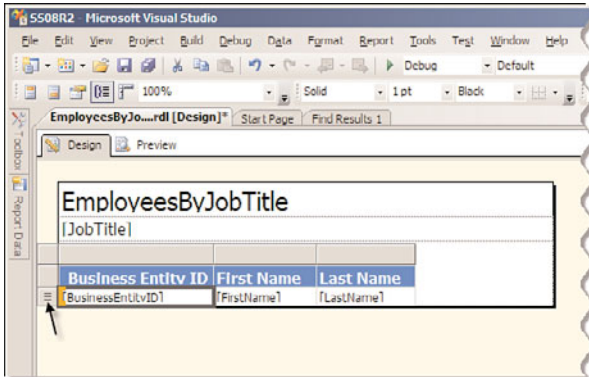

FIGURE 53.14 Detail group row on the table data region of a Tablix.

Right-click any column border's header and then click Tablix Properties. Here, you are presented with a range of options for how to format your Tablix: you can control its name, ToolTip, source dataset, dataset filtering and sorting, page breaks, row and column header repetition rules, and visibility.

Understanding Expressions

You've seen some simple expressions (covered in the earlier section "New Simple Expression Syntax"). Now it's time to delve a bit deeper into complex expressions. Almost every property of every reporting control can have its value determined at runtime as the

result of an expression (either simple or complex). You write expressions using VB .NET code. This means you can derive the value of almost any writable report property from contextual report data, built-in or custom function output, .NET assembly method output, or static content. This is no small statement (no pun intended). Table 53.3 shows some examples of complex expressions.

TABLE 53.3 SSRS Complex Expression Examples

Complex Expression	Explanation
<code>=Avg(CInt(Fields!FieldName.Value))</code>	Converts runtime dataset values from <code>FieldName</code> to integer and then sums those values
<code>"Page " & CStr(Globals!PageNumber) & " of " & CStr(Globals!TotalPages)</code>	Displays a string such as "Page N of N", using global values (use this in a header or footer row, or outside a data region)
<code>=IIf(IsDate(Fields!FieldName.Value), "Yes", "No")</code>	If the context value of <code>FieldName</code> is a valid date, returns the string "Yes"; otherwise returns "No"
<code>=CLng(First(Fields!FieldName.Value, "DataSetName")) << 3</code>	Casts the first row's value of <code>FieldName</code> in <code>DataSetName</code> to a long integer and then left-bit-shifts that value by 3

53

You don't even have to remember these examples to get started; the Report Designer's Expression Editor makes it easy to build complex expressions on your own. You can launch the Expression Editor, shown in Figure 53.15, in two ways:

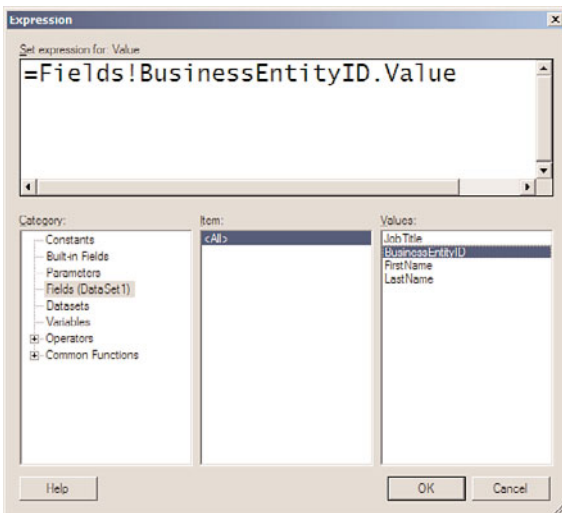

FIGURE 53.15 Using the BIDS Expression Editor.

- ▶ Right-clicking any cell (or another single control) within your report's Tablix (or any other control) and then selecting Expression.
- ▶ Selecting the value column for any writable property in the Properties tool window and then clicking its drop-down box and selecting <Expression...>.

The top half of the Expression window contains the evaluation area where you type your expressions. It offers IntelliSense (with limited autocompletion) and instant syntax checking. The bottom-left side of the Expression window (labeled Category) offers a complete list of various expression building blocks, including constants, built-in fields, parameters, dataset fields, variables, operators, and built-in functions, grouped by type.

Most complex expressions (those that contain something more than a static value) begin with the equal sign and are built up from there. To use any of these items in your expression, simply click on a Category on the left and then double-click the item you want to add to your expression listed under Item, or, in the case of dataset fields, click on the field in a third list box that appears (named Values). What's even nicer is that as you single-click through each item under Item, the Expression window provides a description and usage example on the right.

Report Design Fundamentals

Every report has three main parts: a body, header, and footer (you can view the header and footer and control their visibility settings by right-clicking an outer edge of the report on the design surface). A report body can be a collection of static controls, such as text boxes and lines, but most useful reports contain at least one data-bound control, meaning that the control is wired up to a dataset; its contents usually repeat in some fashion relative to the number of rows in the dataset. Notice that the header and footer cannot contain data-bound controls. Data-bound controls themselves may contain either data-bound or non-data-bound controls.

Table 53.4 summarizes all the controls in the Toolbox, with their data-binding requirements and some typical uses.

TABLE 53.4 Reporting Services Controls Summary

Control	Data-Bound	Purpose	Notes
Tablix	Yes	Displays tables, matrices, and lists via data region templates; supports multiple hierarchical groupings and header, footer, and detail rows.	Is new in SQL Server 2008; subsumes Table, Matrix, and List controls from SQL Server 2005 (not displayed in the Toolbox).
Table	Yes	Displays tabular data, allowing grouping of rows.	Is now a Tablix data region template.
Matrix	Yes	Displays multidimensional data, allowing grouping of both rows and columns (useful for cross-tab data, that is, data having a variable number of columns).	Is now a Tablix data region template.

TABLE 53.4 Reporting Services Controls Summary

Control	Data-Bound	Purpose	Notes
List	Yes	Displays report content in a simple repeating fashion (once per row); by default, repeats all contained items (this is tweakable per control).	Is now a Tablix data region template.
Chart	Yes	Provides enhanced graphical display of source data in a wide variety of formats; is great for visualizing results; supports financial reporting, accounting, asset tracking, and so on; supports multiple series of values; provides 2D or 3D display (with or without perspective); internally uses Dundas brand charts.	Provides several new styles and rendering options (including 3D); see “What’s New in SSR S2008” for details.
Gauge	Yes	Provides graphical display of KPI or other single data value; is great for data dashboards.	Is new in SSRS 2008.
Indicator	Yes	Illustrates that a data value falls within a finite set of conditions, values, or thresholds.	Is new in SSRS 2008 R2.
Data Bar	Yes	Displays a small, single-bar chart within a cell.	Is new in SSRS 2008 R2.
Sparkline	Yes	Displays a small chart that quickly illustrates a trend in the data.	Is new in SSRS 2008 R2.
Map	Yes	Renders geospatial and related analytical data; includes support for Bing map tiles; uses SQL geometry or geography data types; can also use ESRI spatial vector data files.	Is new in SSRS 2008 R2.
Rectangle	No	Enables you to lay out reports or other controls; is good for static grouping.	Is useful when displaying adjacent controls.
Line	No	Has primarily visual uses (layouts).	Is useful for styling.
Image	No	Displays images, either embedded within the report, culled from field data, URLs, or deployed as resources stored within the SSRS catalog. Support formats: PNG, GIF, JPG, X-PNG.	Gives a report a professional look.

TABLE 53.4 Reporting Services Controls Summary

Control	Data-Bound	Purpose	Notes
Subreport	No	Displays another report on a report; parameters passed to a subreport enable drill-through (that is, from one report to the next); uses subreports to chunk reports into reusable blocks.	Allows your current dataset to supply values to a subreport as parameters.
Text Box	No	Displays textual data; supports internationalization.	Each Tablix data region cell contains a single text box by default.

Using the Data Visualization Controls: Sparkline, Indicator, and Data Bar

In the next few examples, we examine the new controls that come with SSRS 2008 R2, starting with Sparklines.

As mentioned earlier, a Sparkline is a small, easy-to-understand chart that you usually place inside the text box cell of a grouping row in a Tablix. Sparklines make it easy to see trends in data at a glance. Most types of Sparklines can be converted to full chart controls when necessary (except for 3D charts). In the following example, we add a Sparkline to a new report.

As you've done before, right-click your Reports folder in Solution Explorer and then click Add New Report. As you follow the steps of the Report Wizard, select your shared data source (pointing to the AdventureWorks2008R2 database) and then enter the T-SQL shown in Listing 53.2 for your report query.

LISTING 53.2 T-SQL Code for a Sparkline Report

```

SELECT
    h.BusinessEntityID,
    e.Gender,
    p.LastName,
    h.Rate,
    h.RateChangeDate
FROM HumanResources.EmployeePayHistory h
JOIN HumanResources.Employee e
ON e.BusinessEntityID = h.BusinessEntityID
JOIN Person.Person p
ON e.BusinessEntityID = p.BusinessEntityID
ORDER BY h.BusinessEntityID, h.RateChangeDate

```

This query illustrates changes in hourly pay rates for all employees over their entire term with the company.

Continuing with the Report Wizard, choose the Tabular report style and then add all the columns generated by the query to the detail area of the report (at the Design the Table Wizard step). Select any color theme, name your report `RateChangesByEmployee`, and preview it in BIDS. Switch back to Design view and take the following actions using the Report Designer surface:

1. Click the left edge of your table to select its last row.
2. Using the Row Groups pane (below your report), click the black arrow for your grouping (named `table1_Details_Group` by default); then click Group Properties.
3. On the General tab, under Group Expressions, click the Add button.
4. In the Group On box, select `[BusinessEntityID]`.
5. On the Filters tab, click the Add button.
6. In the Expression box, type the following: `[Count(BusinessEntityID)]`.
7. Change the Data Type drop-down to Integer, change the Operator value to `>`, enter the number 1 in the Value combo box, and then click OK.
8. Click the top edge of your table to select the Gender column; then right-click and select Insert Column, Right.
9. Show the Toolbar tool window. Then click and drag a Sparkline control into the text box of the empty cell in the column you just created.
10. Click your new Sparkline control. On the Select Sparkline Type dialog, select the second Area chart from the left and click OK.
11. Click your Sparkline control again; then click the green plus sign above the Values box, select the Rate field, and then click OK.
12. Returning to the table, change the expressions for the Rate and Rate Change Data columns to `[First(Rate)]` and `[Last(Rate)]`, respectively.
13. Change the header text for the Rate and Rate Change Data columns to Starting Rate and Final Rate, respectively.
14. Preview the report; the result should look something like that shown in Figure 53.16.

In the next example, we examine the Indicator control, new with SSRS 2008 R2. Listing 53.3 illustrates the T-SQL for this report. In this report, you use the indicator as an icon representing the shift worked by a distribution of employees.

LISTING 53.3 T-SQL Code for an Indicator Report

```
SELECT
    e.BusinessEntityID,
    p.FirstName,
    p.LastName,
    s.ShiftID
FROM HumanResources.Shift s
JOIN HumanResources.EmployeeDepartmentHistory h
ON s.ShiftID = h.ShiftID
```

```

JOIN HumanResources.Employee e
ON e.BusinessEntityID = h.BusinessEntityID
JOIN Person.Person p
ON p.BusinessEntityID = e.BusinessEntityID
WHERE e.OrganizationLevel = 3
AND e.BusinessEntityID BETWEEN 40 AND 108
ORDER BY p.LastName

```

ID	Gender	Last Name	Starting Rate	Final Rate
4	M	Walters	0.6200	29.0462
16	M	Bradley	24.0000	37.5000
167	M	Johnson	6.5000	9.5000
170	M	Li	6.5000	9.5000
172	M	Ingle	6.5000	9.5000
174	M	Martin	6.7500	9.5000
175	M	Koch	6.5000	9.5000
176	M	Lawrence	6.5000	9.5000
177	M	King	6.5000	9.5000
178	M	Frum	6.5000	9.5000
224	M	Vong	0.6200	16.0000
231	F	Norman	39.0600	60.0962
250	F	Word	9.8600	30.0000

FIGURE 53.16 Sparkline report in Preview mode.

Add a new report by following the Report Wizard steps for a tabular report (just as in the Sparkline report example), using the T-SQL in Listing 53.3 for your query. Name your report `EmployeeShifts`, open it on the Report Designer surface, and take the following actions:

1. Click the cell that reads `[ShiftID]`. Then right-click it and choose `Delete` to delete the text box in that cell.
2. Show your `Toolbar` tool window; then click and drag an `Indicator` control into the cell where you just deleted the text box.
3. On the ensuing `Select Indicator Type` dialog, choose a set of icons that appeals to you and then click `OK`.
4. Click your new indicator control. Then, under the `Values` box, where it reads `(Unspecified)`, click the black drop-down arrow and then select `ShiftID`.
5. Preview your report; the result should look something like that in Figure 53.17.

For our next example, we utilize the new `Data Bar` control. In this simple report, we illustrate quantities sold of bicycle parts. Add a new report by following the Report Wizard steps for a tabular report (just as in the Sparkline example), using the T-SQL in Listing 53.4 for your query. Name your report `QuantitiesSold`.

Business Entity ID	First Name	Last Name	Shift ID
62	John	Campbell	▲
40	JoLynn	Dohney	●
78	Reuben	D'sa	▲
47	Andrew	Hill	◆
108	Jinghan	Lin	◆
93	Kok-Ho	Loh	▲
55	Taylor	Maxwell	●
102	Zheng	Mu	▲
87	Cristian	Petculescu	●
71	Michael	Ray	●

FIGURE 53.17 Indicator report in Preview mode.

LISTING 53.4 T-SQL Code for a Data Bar Report

```

SELECT TOP 15
    p.ProductID as ID,
    p.Name,
    p.ListPrice,
    SUM(d.OrderQty) as TotalSold
FROM Production.Product p
JOIN Sales.SalesOrderDetail d
ON d.ProductID = p.ProductID
GROUP BY p.Name, p.ListPrice, p.ProductID
ORDER BY SUM(d.OrderQty) DESC

```

Follow these steps to add a data bar visualization to your report:

1. Click the cell that reads [TotalSold]. Then right-click it and choose Delete to delete the text box in that cell.
2. Show your Toolbar tool window; then click and drag a Data Bar control into the cell where you just deleted the text box.
3. On the ensuing Select Data Bar Type dialog, choose a data bar style that appeals to you and then click OK.
4. Click your new data bar control. Then, under the Values box, where it reads (Unspecified), click the black drop-down arrow and then select TotalSold.
5. Preview your report; the result should look something like that shown in Figure 53.18.

Deploying Reports

When you are happy with your reports' content and layout, to make them available to others, you deploy (also known as *publish*) them to the SSRS catalog using BIDS or Report Manager, where they are stored. When you publish a report, its content is validated and compiled to an internal format in which it is saved. (If the report contains code, it is compiled into .NET assemblies.)

ID	Name	List Price	Total Sold
712	AWC Logo Cap	8.9900	[Bar]
870	Water Bottle - 30 oz.	4.9900	[Bar]
711	Sport-100 Helmet, Blue	34.9900	[Bar]
715	Long-Sleeve Logo Jersey, L	49.9900	[Bar]
708	Sport-100 Helmet, Black	34.9900	[Bar]
707	Sport-100 Helmet, Red	34.9900	[Bar]
864	Classic Vest, S	63.5000	[Bar]
873	Patch Kit/8 Patches	2.2900	[Bar]
884	Short-Sleeve	53.9900	[Bar]

FIGURE 53.18 Data Bar report in Preview mode.

Once in the catalog, reports can be managed, secured, and delivered to end users in a variety of formats, including HTML, Excel, PDF, TIFF, Word, CSV, Atom, and XML. When they are deployed, various delivery, caching, and execution options are made available, as are scheduling and historical archiving, covered later in this chapter.

To deploy a report, you must first specify a Report Server URL in the properties of your BIDS project (for example, `http://[servername]:[port]/ReportServer`). Note that this URL must point to the web service virtual directory, not the main `http://[servername]:[port]/Reports` directory, which is only for Report Manager. On the Properties window, you can also specify the catalog folder for your shared data sources, shared datasets, and report parts, and whether they are to be overwritten upon redeployment, as well as your target catalog folder for reports and the startup report for your project. Figure 53.19 illustrates the project deployment settings for our example.

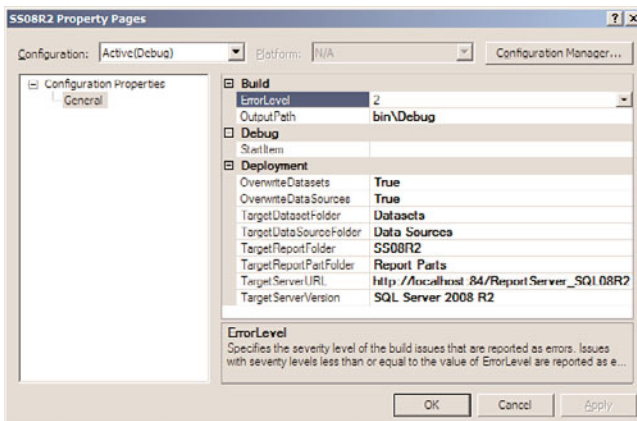

FIGURE 53.19 Deployment settings for a Report Server project in BIDS.

When your reports are successfully deployed, authorized users can execute them using Report Manager or any other SSRS-integrated tools. To deploy from BIDS, right-click your Report Server project name in the Solution Explorer and then select Deploy. You might need to first authenticate (once per user session) to the Report Server because it is secured.

Using Report Manager

Report Manager is organized hierarchically as a folder tree. Using it, you can create, delete, rename, secure, and organize all your deployed reporting objects, as well as the folders that contain them. The root Report Manager folder is simply known as Home, from which all other report objects in the tree descend. Permissions (known as *role assignments*) are inherited from parent item to child, and they may be overridden at any level.

Take some time now to explore Report Manager. To do this, navigate to the URL you configured earlier in the chapter (it should be something like `http://[servername]:[port]/Reports`). The layout of Report Manager is fairly straightforward: site configuration links are at the top right, where you can modify settings, get help, and (if you have personal folders enabled) view your subscriptions. The main site navigation enables you to create folders and data sources, launch Report Builder, upload a file to the SSRS catalog, and change the permissions for the current folder (in this case, Home).

If you've created all the sample reports so far, below the main navigation you find icons representing the folders to which you deployed your report items from BIDS. These folders correspond to the deployment folders you configured using the Properties page of your report project. If you hover your cursor over any folder, the outline of a drop-down box appears. If you click the drop-down, you get the following menu choices (provided you have adequate permissions): Move, enabling you to move the item; Delete, to delete it; Security, to set its permissions; and Manage, to view or change its properties. If you click the name of the item itself, the default action for that type of item is executed. Every deployed item in Report Manager has a hover menu and primary link. The options offered by each menu are item specific. Figure 53.20 illustrates how to work with Report Manager.

Navigate around your folders and view the properties for various items, such as your shared data source, shared dataset, and reports. Next, click the Details View link on the right side of the toolbar. Notice the new main navigation buttons that appear, allowing you to move and delete deployed items easily. If your SSRS content is still sparse, a great way to get started with Report Manager content is to download and install the sample reports for AdventureWorks2008R2 from www.codeplex.com.

Continuing with Report Manager, click the Site Settings link and then click on the General tab and configure a different name for your site (notice the company name displayed at the top of Figure 53.20). On this page you can also control the execution timeout limit for all reports, the number of report snapshots that SSRS stores by default, and the ClickOnce URL to launch Report Builder (you can use this to launch a different version of Report Builder than the default, version 3.0). Snapshots are covered in more detail in the section "Execution Snapshots."

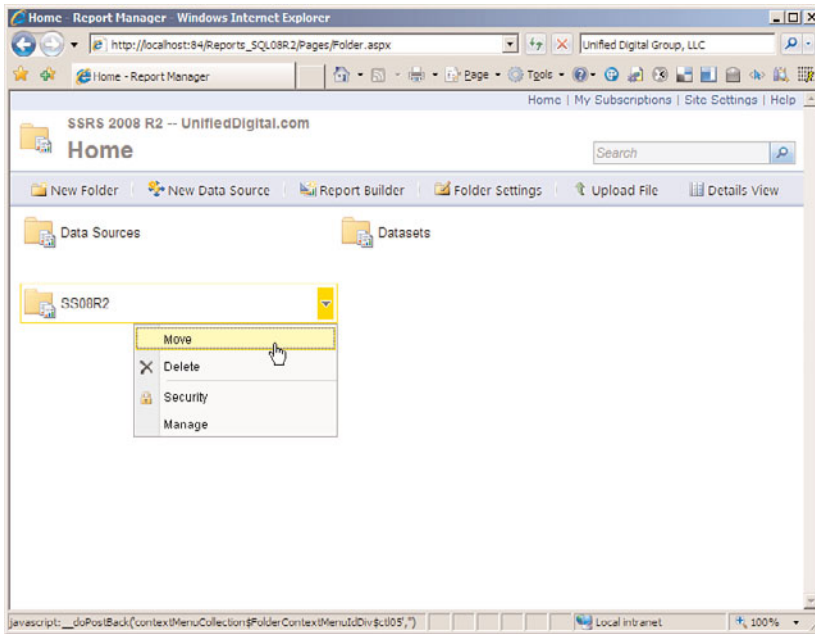

FIGURE 53.20 Working with Report Manager.

The Security tab in the settings area provides a straightforward means of adding and removing site users and changing role assignments. The Schedules tab enables you to set up schedules that you can later apply to report execution and delivery jobs. This chapter covers a few of these management tasks in greater depth in the section “Management and Security.”

Using Tables and Hierarchies in Reports

Now that you’ve had a quick tour of Report Manager, it’s time to go a little deeper into our report development examples.

Let’s say you want to represent an organizational hierarchy in a report (a fairly common task). Using the BIDS Solution Explorer, create a new report by selecting Add New Item (don’t use the Report Wizard this time) and naming it `EmployeeHierarchy.rdl`. Drag a Table data region from the Toolbox onto the report; then use the query in Listing 53.5 for its dataset (which is named `DataSet1` by default). Note that the `OrganizationNode` column in this query is of type `hierarchy_id` (covered in Chapter 42).

LISTING 53.5 T-SQL Code for a Hierarchical Data Report

```

SELECT
    e.JobTitle,
    e.BusinessEntityID,
    e.OrganizationNode.ToString() as OrganizationNode,
    e.OrganizationNode.GetAncestor(1).ToString() as ParentOrganizationNode,
    p.FirstName,
    p.LastName
FROM Person.Person p
JOIN HumanResources.Employee e
ON p.BusinessEntityID = e.BusinessEntityID
ORDER BY p.BusinessEntityID

```

Add six new columns to your table control; then, using the Report data tree, drag each dataset field onto the report. Next, using the Row Groups pane, click the Details drop-down box and then select Add Group, Parent Group. In the ensuing Tablix Group dialog, select ParentOrganizationNode in the Group By drop-down box, check the Add Group Header check box, and then click OK (this group is named Group1 by default). Next, using the Row Groups pane again, click its Group1 drop-down box; then select Add Group, Child Group. In the ensuing Tablix Group dialog, select OrganizationNode in the Group By drop-down box, check the Add Group Header check box, and then click OK. In Design mode, your report should look something like the one shown in Figure 53.21.

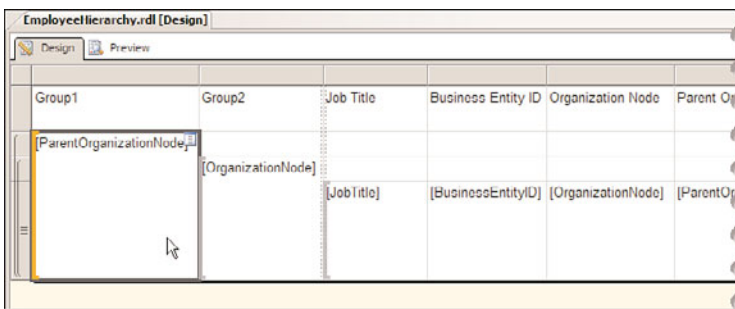

FIGURE 53.21 A hierarchically grouped report in Design mode.

Adding Interactivity

The next step is to add drill-down interactivity. To do this, select the final row in your Tablix by clicking on its gray border at the left edge of the table. Next, right-click the same border and then select Row Visibility. On the ensuing Row Visibility dialog, select Hide using the When the Report Is Initially Run radio button. Check the Display Can Be Toggled by This Report Item check box; then select Group1 in the drop-down box (see Figure 53.22).

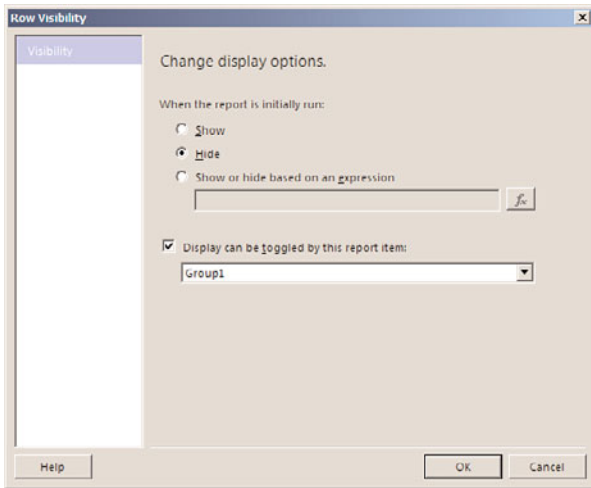

FIGURE 53.22 Changing detail row visibility in a hierarchically grouped report.

Save and preview the report. The result should resemble the report shown in Figure 53.23.

Group1	Group2	Job Title	Business Entity ID	Organization Node	Parent Organization Node	First Name	Last Name
+	/	Chief Executive Officer	1	/		Ken	Sanchez
+	/ /	Vice President of Engineering	2	/ /	/	Terri	Duffy
	/ /	Marketing Manager	16	/ /	/	David	Bradley

FIGURE 53.23 Hierarchically grouped report with toggle in Preview mode.

By clicking the + and - signs, your users can now expand and collapse the hierarchy.

Now that you've built a number of reports using BIDS, it's time to learn how to work with the other primary reporting tool, Report Builder 3.0.

Designing Reports Using Report Builder

Report Builder (RB) is a report authoring application that enables advanced users to design and publish their own reports. With this release of SQL Server, users can generate reports using three different versions of Report Builder (although we recommend using only version 3.0 for new work) and are free to use data generated by any T-SQL query from any supported data source, data from report models (built by a database administrator), and mapping sources.

Report Builder

Report Builder simplifies both the data-retrieval and the layout-design phases of report building for nondevelopers, although it still helps to have a developer around for configuration and advanced tasks.

NOTE

You cannot work in RB1 with reports developed in RB3, nor can you work in RB1 with BIDS 2008 report models. RB3 supports all the Toolbox controls described in Table 53.4, and the report authoring experience is similar to the experience of using BIDS, although a number of new wizards facilitate the process very nicely for nondevelopers. RB1 is essentially unchanged from previous editions of SQL Server. RB2 is similar in design and usage to RB3 (although RB3 has a few new features we cover shortly); however, because RB1 and RB2 may not be supported in future releases, they are not covered in this chapter.

RB Versions

SSRS 2008 comes bundled with Report Builder 3.0 (RB3) as a ClickOnce application. If you need Report Builder 1.0 or 2.0, you can still (as of this writing) download either one from Microsoft. Using a main navigation button on Report Manager, you launch RB3 by clicking the Report Builder link on the main menu. You may also install RB3 on a user workstation as a standalone application you launch via the Windows Start menu.

Installing RB3

When installing the standalone version of RB3, you encounter two options screens:

- ▶ **Feature Selection**—Gives you a choice of file installation location.
- ▶ **Default Target Server**—Prompts you to enter the URL to your installation of the SSRS web services (shown in Figure 53.24). When RB3 is installed, you can modify this option by clicking the Office button at the top left of the main UI and then click Options to open the screen shown in Figure 53.25.

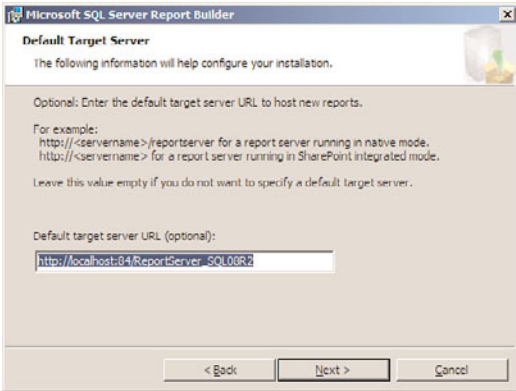

FIGURE 53.24 Report Builder 3.0 Default Target Server screen.

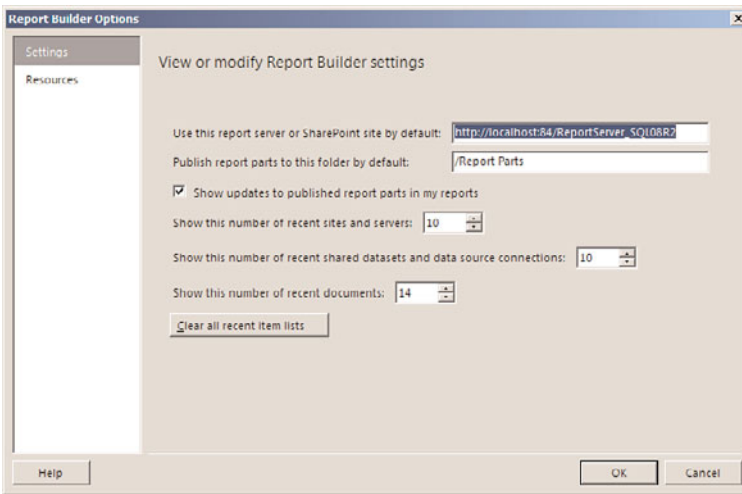

FIGURE 53.25 Report Builder 3.0 Options screen.

By default, the executable program (MSReportBuilder.exe) is located in the following folder:

%PROGRAMFILES%\Microsoft SQL Server\Report Builder 3.0

You can run this program via the menu shortcut located in the Windows Programs menu under

Programs\Microsoft SQL Server 2008 R2 Report Builder 3.0

Getting Started with RB3

When you run the RB3 application the first time, the main window appears as shown in Figure 53.26.

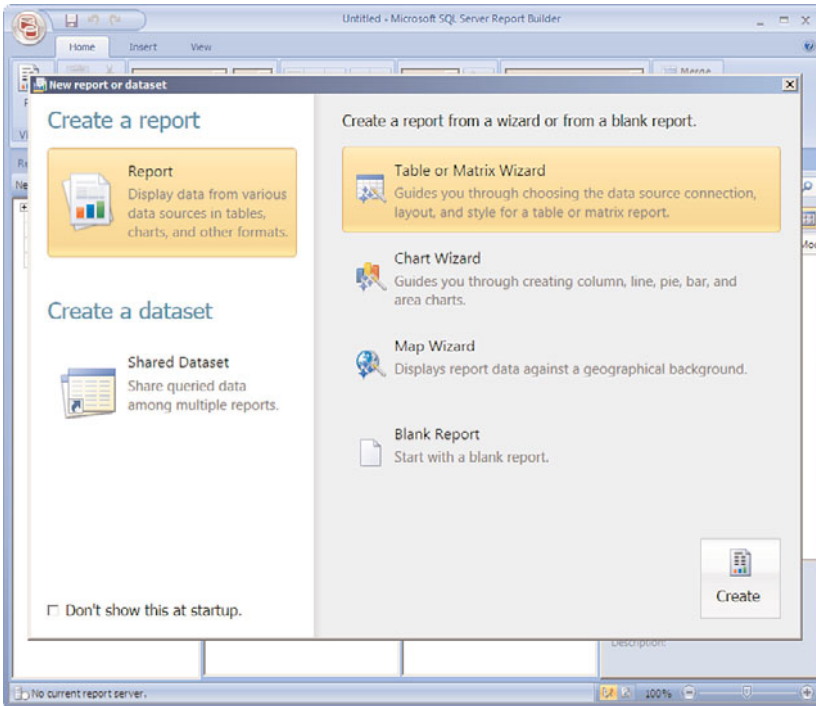

FIGURE 53.26 Report Builder 3.0 first run UI (new item screen).

As you can see, RB3 comes with a number of new wizards that make it easy for you to create reports that use tables, matrices, charts, and maps, as well as create datasets and blank reports (you learn how to use the Map Wizard a bit later in the section “Working with Maps”).

If you’ve been following along with all the examples in this chapter, you’ll notice that the RB3 UI includes many of the same features as the BIDS Report Designer, including the Report Data tool window (which you can use just as you would with BIDS to work with data sources, datasets, built-in and custom fields, images, and parameters), Row Groups and Column Groups designer panes, rulers, Properties window, and right-click menus. Of course, the big difference is the implementation of the Office Ribbon bar and associated wizards, which make it very easy to build your report. Plus, with RB3, you also get the new Report Part Gallery (report parts are covered in the section “Using Report Parts”).

Take a few minutes to explore the different sections of RB3's Ribbon bar. Table 53.5 summarizes all its features.

TABLE 53.5 RB3 Ribbon Bar Features by Tab

Features	Uses	Tab	Tab Group
Run report	Execute your report against the target server	Home	Views
Cut, copy, paste	Move report items	Home	Clipboard
Styling	Format report text, paragraph, and border styling	Home	Font, Paragraph, Border
Numeric formatting	Style numbers displayed in reports	Home	Number
Control positioning, cell structure	Change z-order index and relative alignment of report controls; merge and split cells	Home	Layout
Report controls that use data regions	Insert Tablix data regions (Table, Matrix, and List) into reports; includes wizards for easy generation	Insert	Data Regions
Graphical data-bound report controls	Insert Chart, Gauge, Map, Data Bar, Sparkline, and Indicator controls into reports; includes some wizards for easy generation	Insert	Data Visualizations
Non-data-bound report controls	Insert Text Box, Image, Line, and Rectangle controls into reports	Insert	Report Items
Subreport control	Insert Subreport controls into reports	Insert	Subreports
Header & footer	Control visibility of report header and footer	Insert	Header & Footer
Visibility settings	Toggle visibility of all designer tool windows and panes, including the (new with R2) Report Part Gallery	View	Show/Hide
Design	Return to Design mode when running a report	Run (appears on the Ribbon whenever you run a report)	Views
Zoom	Zoom in or out	Run	Zoom

TABLE 53.5 RB3 Ribbon Bar Features by Tab

Features	Uses	Tab	Tab Group
Page navigation	Move from page to page and back, refresh report, stop execution	Run	Navigation
Printing	Manage print setup and layout options	Run	Print
Exporting	Export a report to a file in any of the supported formats	Run	Export
Parameters, Table of Contents (TOC)	View the document map (the report's table of contents), and any report parameters	Run	Options
Searching	Locate text within the report	Run	Find

Let's start using the RB3 designer surface. To begin, click to highlight the text that reads Click to Add Title; then enter Sales by Product. Click the Save button at the top left. Notice how the ensuing Save As Report dialog actually shows you the folders as they are organized in your Report Server catalog (illustrated in Figure 53.27). This dialog provides a view of the server folder hierarchy, not your local file system as you might expect. Double-click an appropriate folder, enter a report name, and then click Save.

FIGURE 53.27 Viewing SSRS folders using Report Builder 3.0's Save As dialog.

Returning to the designer, click the Insert Ribbon bar menu item; then click the Chart button and select Chart Wizard. On the first step of the Chart Wizard, select the radio button to create a new dataset. On the next step, click the Browse button and navigate to your shared data sources folder. Then select the shared data source that you created and

deployed in a previous example. Click Next and then set up the appropriate credentials to access your instance of SQL Server. Then click Next.

The UI in the next step (Design a Query) is built to visually represent in a logical structure the tables, views, and stored procedures in your selected database. On the left, database objects are grouped by schema name. On the right, the fields you select from these objects are added to your query, as well as the appropriate relationships and any filters you want to apply to your data.

Using the Database View panel, expand the Sales schema node; then expand the Tables node and make the following selections: from SalesOrderHeader, check the boxes next to the SalesOrderID and OrderDate columns. From SalesOrderDetail, check SalesOrderID, ProductID, and OrderQty. Now, scroll up to the root of the tree and expand the Production schema node. From the Product table, check the ProductID and Name columns. Click the Run Query exclamation point button. Your Design a Query window should now look something like the one in Figure 53.28.

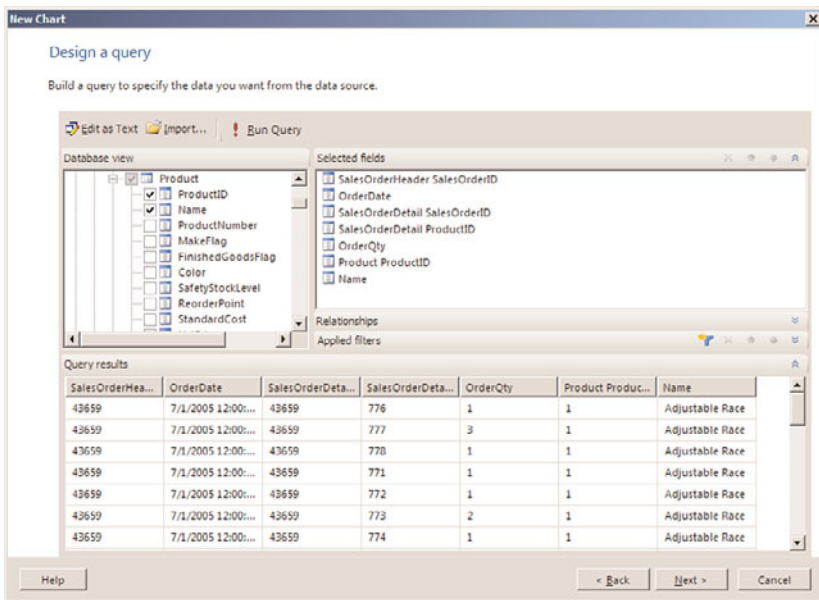

FIGURE 53.28 Report Builder 3.0's Design a Query window in Graphical mode.

When you click Next, a dialog pops up, telling you that the relationship between SalesOrderDetail.ProductID and Product.ProductID could not be detected. This makes sense because the relationship is only implied in the physical model. Accept the dialog or cancel it (either choice does the same thing); then click the Edit as Text button to view the T-SQL being generated. Add a JOIN clause to the query and the other statements shown in Listing 53.6 to make your T-SQL match. When finished, click the exclamation point button again to make sure your query is correct (as shown in Figure 53.29); then click Next.

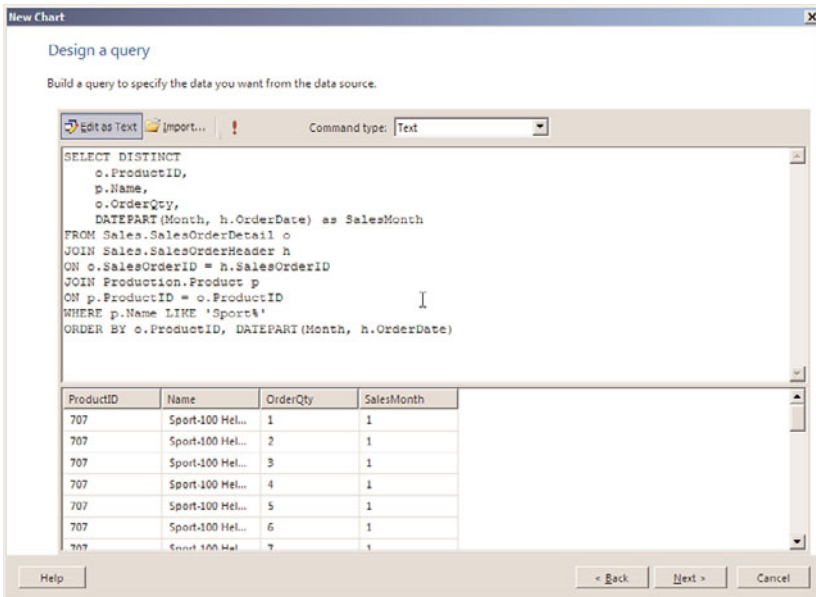

FIGURE 53.29 Report Builder 3.0's Design a Query window in T-SQL Edit mode.

LISTING 53.6 T-SQL Code for a Report Builder 3.0 Chart Report

```
SELECT DISTINCT
  o.ProductID,
  p.Name,
  o.OrderQty,
  DATEPART(Month, h.OrderDate) as SalesMonth
FROM Sales.SalesOrderDetail o
JOIN Sales.SalesOrderHeader h
ON o.SalesOrderID = h.SalesOrderID
JOIN Production.Product p
ON p.ProductID = o.ProductID
WHERE p.Name LIKE 'Sport%'
ORDER BY o.ProductID, DATEPART(Month, h.OrderDate)
```

On the ensuing Choose a Chart Type screen, select Column and then click Next. On the Arrange Chart Fields screen, drag and drop SalesMonth from the Available Fields list box to the Categories panel; then drag and drop Name to the Series panel and OrderQty to the Values panel and click Next. Select a chart style; then click Finish. Stretch out your chart a bit on the designer and then double-click it to edit the following text items: chart title, categories axis text, and series axis text. Now, right-click the chart control, select 3D

Effects, and then check the Enable 3D check box. Click OK, save, and then run the report. The result is shown in Figure 53.30.

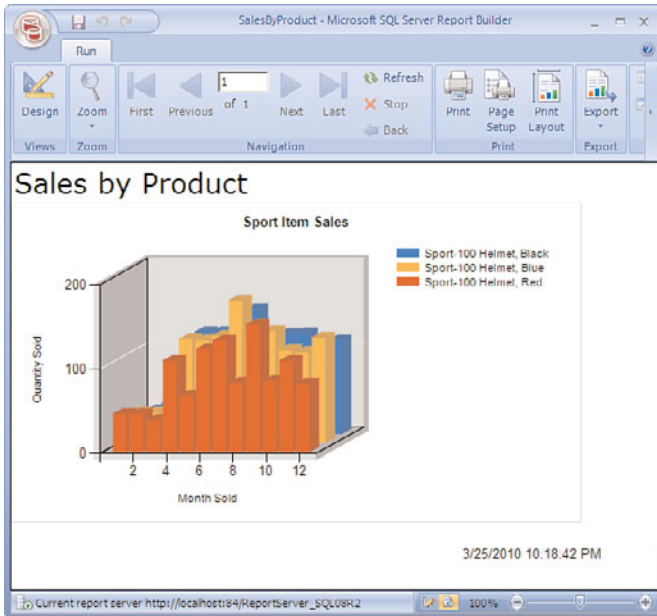

FIGURE 53.30 Rendered 3D chart report using Report Builder 3.0.

Using Report Parts

Best practices dictate that you use shared data sources and shared datasets to achieve maximum reuse and centralized distribution of your report data. Report parts take this a step further, enabling you to deploy the charts, tables, gauges, and other data visualization controls you create on one report to be reused on any other report. You no longer have to rely on using subreports to create reusable chunks of report functionality, although report parts do not render subreports obsolete; they still have their place in the Toolbox.

You can start using this new feature by publishing the report parts that live in the chart example you just completed. Using RB3, click on the Office button (top left of the application UI) and then select Publish Report Parts. On the ensuing Publish Report Parts dialog, click the first button to publish all report items (those that may become report parts) or click the second button to review your report parts before publication. The report controls that may become report parts are charts, data bars, Sparklines, gauges, indicators, images, lists, maps, matrices, report parameters, rectangles, tables, and shared datasets. As illustrated in Figure 53.31, the Select Report Parts to Publish step lists the publishable items, and you may check any combination of those you would like to publish. Check both the dataset and chart. Checking the dataset's check box automatically turns the report's (formerly embedded) dataset into a shared dataset on deployment. Click the Publish button; then click Close.

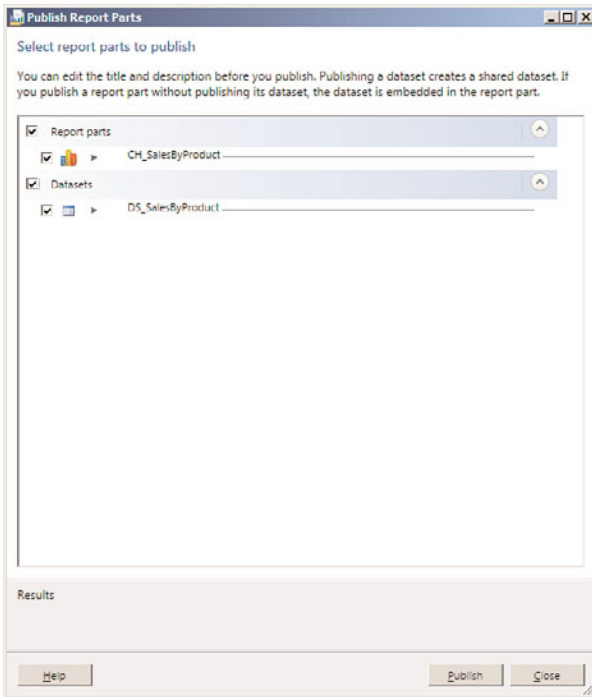

FIGURE 53.31 Selecting report parts to publish using RB3.

When publication is complete, return to the main designer and click on the Report Part Gallery tool window tab, located at the far right (docked with the Properties window). Click its magnifying glass icon to search for all published report parts (excluding datasets; they are not displayed in the gallery). Notice how the results grid displays a thumbnail of the chart you just created (shown in Figure 53.32). You (or any other privileged user) can now drag your chart from the Report Part Gallery onto the designer surface and reuse it. Keep in mind that anyone can reuse report parts as-is or modify them at will (provided he or she has the appropriate permissions).

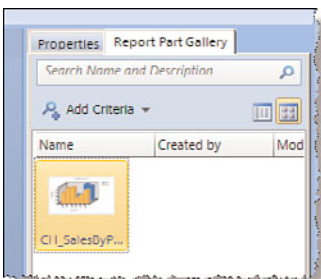

FIGURE 53.32 Using the Report Part Gallery in RB3.

After you modify a report part, you can then choose to republish it with your changes, overwriting the current version of the same. Note that this does not change the instances of the report part that live on other reports; those reports continue to use the version of the report part they dragged from the gallery when those reports were designed. In contrast, any new report that uses that report part for the first time gets your updated version from the gallery.

When the report's designer who used your report part (in its original state) opens the report at some future date in RB3, RB3 checks the SSRS catalog to see whether the report has been updated since the report was last opened. Because you updated and overwrote the original version of the chart, the designer is presented with the option to either accept your latest changes or continue using the version of the chart he or she originally added to the report. The designer can also check at any time to see whether any updated versions of the report parts on his or her report are available by clicking the Office button and selecting Check for Updates. An interactive information bar appears just below the Ribbon, indicating whether any report parts used in the current report have available updates. It is then up to the designer to accept or ignore any new versions.

Returning to report building, let's keep the momentum going by quickly creating a map report.

Working with Maps

To create a map report, start by clicking the Office button and then selecting New. On the ensuing New Report or Dataset screen, click the Map Wizard button; then click Create at the bottom right. Click Next. Then, on the Choose a Source of Spatial Data screen, select the SQL Server Spatial Query radio button. Then click Next. On the following screen, select the Add a New Dataset radio button and then click Next. Select the shared data source you created earlier and then click Next. On the Design a Query screen, click the Edit as Text button and then paste the following into the text area: EXEC Person.GetSampleSpatialData. Before proceeding to the next step, launch SSMS, connect to your data source, open new query window, and execute the T-SQL shown in Listing 53.7. Click the exclamation point button and then click Next.

LISTING 53.7 T-SQL Code for a Report Builder 3.0 Map Report

```
use AdventureWorks2008R2
go
CREATE PROC Person.GetSampleSpatialData
AS
DECLARE @T TABLE
(
    Quantity int,
    StateProvinceName nvarchar(50),
    StateProvinceCode char(2),
    Location geography
)
```

```

INSERT @T
SELECT
    SUM(d.OrderQty) Quantity,
    s.Name,
    s.StateProvinceCode,
    NULL
FROM Sales.SalesOrderHeader h
JOIN Sales.SalesOrderDetail d
ON h.SalesOrderID = d.SalesOrderID
JOIN Sales.SalesTerritory t
ON t.TerritoryID = h.TerritoryID
JOIN Person.Address a
ON a.AddressID = h.ShipToAddressID
JOIN Person.StateProvince s
ON s.StateProvinceID = a.StateProvinceID
WHERE t.CountryRegionCode = 'US'
GROUP BY s.StateProvinceCode, s.Name

UPDATE @T
    SET Location = a.SpatialLocation
FROM @T as t
JOIN Person.StateProvince s
ON s.StateProvinceCode = t.StateProvinceCode
JOIN Person.Address as a
ON a.StateProvinceID = s.StateProvinceID

SELECT * FROM @T

```

Execute your new stored procedure in your query window. Examining the dataset, you can see that it has four fields:

- ▶ **Quantity**—Contains the sum of all product orders for each state
- ▶ **StateProvinceName**—Contains the full English name of each state
- ▶ **StateProvinceCode**—Contains the two-letter code for each state
- ▶ **Location**—Contains SQL geography data-typed point data for each state

The Map Wizard is aware of which fields in your underlying query contain spatial data—data stored in a geography (in this case) or geometry-typed column. In our stored procedure, we pull spatial data from `Address.Location`, so we can use those locations as points on our map of the United States. This meets the spatial data requirement for the map control.

At the top of the Choose Spatial Data and Map View Options screen, notice how the Location column has already been selected as the spatial field that the map control will use. It also recognizes that Location holds point rather than line or polygonal values.

Check the check box near the bottom that reads Add a Bing Maps Layer; then select Road in the Tile Type drop-down. Integration with Bing Maps will surely give your reports a visual edge over the competition. Notice the new reporting term used on this check box, *layer*. You can think of maps as collections of z-ordered layers of information. You can add layers to illustrate regions, points, place names, pictures, icons, roads, terrain, perspective, or just about anything else you can conceive of.

Click Next; then, on the Choose Map Visualization screen, click the Bubble Map button and then click Next. On the ensuing Choose the Analytical Dataset screen, select the Choose an Existing Dataset radio button and then click on your dataset (usually, it is named DataSet1). Our *analytical* data illustrates relative numbers of product sales by state; that is, we are relating relative integer values to points in space. Click Next, and, on the ensuing Choose Color Theme and Data Visualization screen, pick a color theme you like (Ocean looks nice). Then make sure the Use Bubble Sizes check box is checked and that the Data field shown in the drop-down contains the simple expression [Sum(Quantity)]. This field is taken directly from the sample dataset. Check the Use Bubble Colors check box, ensure that the data field expression is the same as before, ([Sum(Quantity)]), and then pick a color you like and click Finish.

When you return to the RB3 UI, change the title text for the report to something more meaningful and then run the report. Afterwards, save the report and then look at it using Internet Explorer in Report Manager. No doubt, your users will be very impressed with the result, illustrated in Figure 53.33.

Returning to RB3, switch back to Design mode and then click twice on your report's map control. The Map Layers dialog (appearing against the right edge of the map) functions much like the Layers palette you may have worked with in Adobe Photoshop. It enables you to perform the following tasks:

- ▶ Show or hide layers
- ▶ View layer properties
- ▶ Add new layers (either using a wizard or manually)
- ▶ Delete layers
- ▶ Reorder layers (around the z-index)
- ▶ Zoom in or out on the map (especially useful when using Bing Map layers)
- ▶ Nudge the map in any direction

Using the context menu for each layer in the Map Layers dialog, you can also do the following:

- ▶ Add or delete layers
- ▶ Add or remove a map legend or title
- ▶ Show or hide the distance or color scale

- ▶ Cut, copy, or refresh a layer
- ▶ Set up rules for how point colors or sizes are displayed

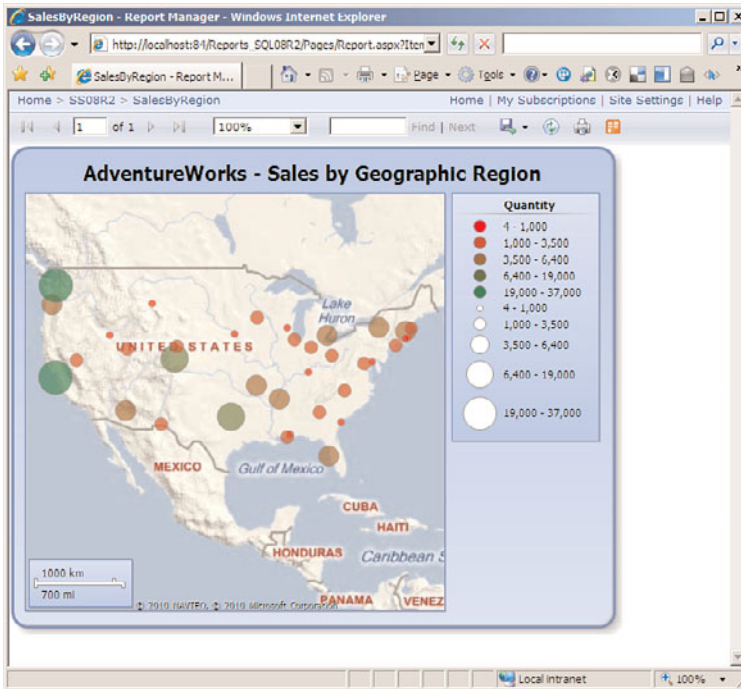

FIGURE 53.33 Viewing a map report designed with RB3 in Report Manager.

We mentioned earlier that maps can also consume nonrelational data sources, such as ESRI spatial data files. A few great public sources of a plethora of these are available:

- ▶ From the U.S. Centers for Disease Control and Prevention, at the following URL: <http://www.cdc.gov/epiinfo/shape.htm>
- ▶ From the U.S. Census Bureau, at the following URL: http://arcdata.esri.com/data/tiger2000/tiger_download.cfm

Let's take a quick look at a sample map report that uses an ESRI shape file for a country. First, obtain an ESRI shape file of your choice and launch RB3. Then, on the start screen, click Map Wizard and click the Create button. On the Choose a Source screen, select the ESRI Shapefile radio button, click Browse to locate your shapefile (it will have a .shp extension), and then click Next. On the Choose Spatial Data screen, add a Bing Maps layer, zoom the map to your desired size, and then click Next. Choose Basic Map on the next screen and then click Next. Choose a color theme and then click Finish. Change the

title text for your map using the designer surface and then run your report. It's that simple! The result is illustrated in Figure 53.34.

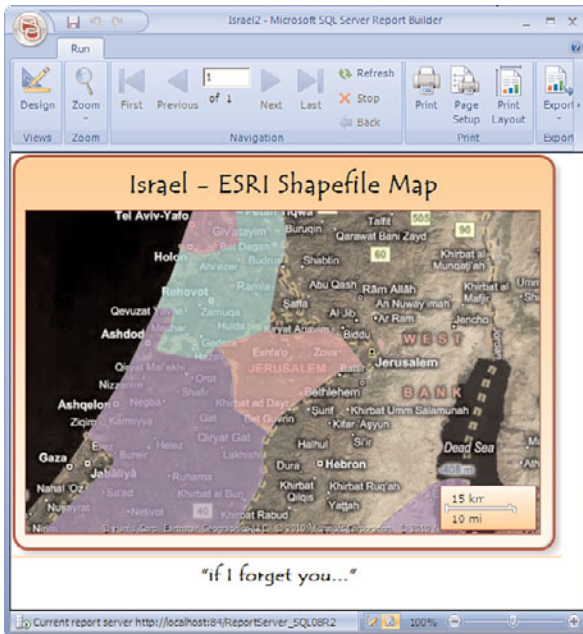

FIGURE 53.34 A map report using an ESRI shapefile of Israel, designed with RB3.

Working with Report Models

Although the chart and map control examples used here rely on mid-level T-SQL queries, you can develop reports using a technology that doesn't require your end users to know anything about SELECT statements, foreign keys, or the physical structure of a database. To make this possible, you build what's known as a *report model (RM)*—an abstraction of a database schema (also known as a *semantic model*) that allows users to work with tables in logical terms, navigating the relationship hierarchies, instead of writing queries. Under the hood, SSRS translates the model elements you add to your reports into native database queries. Other useful features of RMs include column- and row-level security, as well as drill-through link generation for related entities. When the RM is deployed, business users can use it to design their own ad hoc reports with RB3.

You design RMs with BIDS, either through an autogeneration process or by using the revamped Model Designer. To get started, launch BIDS and create a new Report Model Project (located under the Business Intelligence Projects list on the Add New Project dialog). In Solution Explorer, notice your new project's three main folders: Data Source, Data Source Views, and Report Models. Let's create one of each.

Right-click the Data Sources folder; then select Add New Data Source. On the Data Source Wizard's first screen, leave the first radio button selected; then click the New button and

connect to your local instance of AdventureWorks2008R2. After defining and testing your connection, click OK and then click Next. Name the data source whatever you like; then click Finish. Your data source is ready for use.

The next step is to create a Data Source View (DSV). RMs require the use of a DSV to access the subset of tables and views you define. You can include all tables and views if you like, but keep in mind that the more you expose, the more complex your model, the longer it takes to generate, the more confused your business users might be. Keep it simple.

Right-click the Data Source Views folder in Solution Explorer and select Add New Data Source View. On the ensuing wizard screen, select the data source you just created and then click Next. The Select Tables and Views screen allows you to define the tables and views available to your RB3 users. For this example, move the following tables from left to right using the arrow button and then click Next: Product(Production), ProductReview(Production), and ProductModel(Production). Name your DSV something like AW08_ProductBasics (rather than the default database name) and then click Finish.

TIP

To be brought into a model, your underlying tables (defined in your DSV) must have primary keys. RB3 uses primary keys to figure out what represents a logical unit in the table. Primary keys are not added to RMs during model generation (using BIDS) by default.

Now, all that's left is to create your RM. Right-click the Report Models folder in Solution Explorer and select Add New Report Model. Accept the default selection of your new DSV and then click Next. On the following screen (Select Report Model Generation Rules), you can tweak the *entities* (that is, tables), *attributes* (columns), *roles* (relations), and aggregates that will be created in your new RM (notice the logical modeling terminology used). Accept the defaults and click Next. On the following screen, you can accept the default behavior of updating the model statistics and click Next. On the last screen, name your model AW08_ProductBasicsModel and then click Next. When the model generation progress bars are all complete, click Finish. Your new RM opens in the BIDS Model Designer. Click F4 to reveal the Properties tool window.

Take a moment to explore the design surface. Notice the tree on the left that lists your model's entities. Click on the Product entity node. In the detail area on the right, notice the attributes that BIDS generated for the Product. Each attribute has an icon indicating its type: check boxes for Boolean-valued attributes, the letter *a* for strings, a calendar icon for DateTime values, a bracketed group for aggregate results (three vertical dots next to a curly brace), and a pound sign for numeric or scalar values.

Notice also how some attributes, such as Weight, are expandable nodes. The child nodes under these are *variation attributes*, which are based on their parent field. They rely on expressions, such as MIN(Weight), where Weight is the parent attribute and the value of the child Min Weight attribute is the lowest weight. Here's another example: for our DateTime fields, we have variation attributes for the parent Sell Start Date attribute,

including Start Sell Day, Start Sell Year, Start Sell Month, and Start Sell Quarter (shown in Figure 53.35).

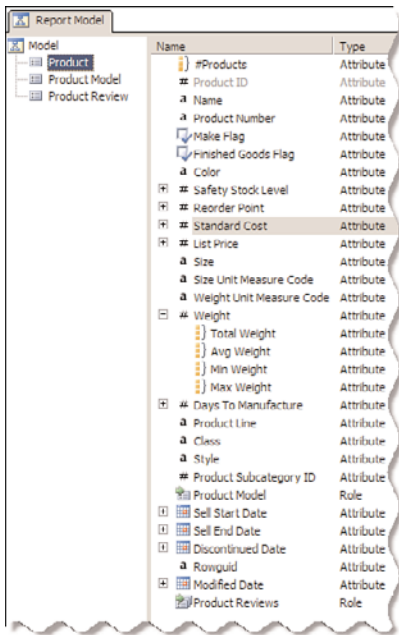

FIGURE 53.35 Viewing an entity's attributes with Model Designer.

Click on the Start Sell Day attribute and view its properties in the Properties tool window. Next, click on the ellipses button for its Expression property. This launches the Formula Designer, which is very much akin to the Expression Editor you learned about in previous examples, albeit much simplified.

The Formula Designer has two tabs on the left: one for selecting the model object you want to work with and another containing all manner of functions to run against your model object. On the right, you have a simplified formula editor, which allows for some basic operations in your expression, including math, string concatenation, and grouping.

Returning to the Model Designer, scroll down the detail area for your Product entity, until you see Product Reviews and Product Model. These *roles* represent your table relationships. Click either role and view its properties. Notice the Binding, Cardinality, and RelatedRole properties, which store the relationship's foreign key information, cardinality, and the name of the other participating role.

If you right-click any object in the detail area, you can regenerate that model object by selecting Autogenerate. This capability is useful if you make a mistake in a formula or simply want to start fresh. You can also change the order of the objects in the model (by selecting Move Up or Move Down), delete or rename the object.

Deploying and Managing Report Model Objects

Now that you're familiar with how RMs work, it's time to deploy our example. Right-click your project name in the Solution Explorer and select Properties. Ensure that the value of TargetServerURL points to the location of your SSRS web services. Ensure that the TargetModelFolder and TargetDataSourceFolder are the ones where you want these objects to be deployed from your project and then click OK. Right-click your project again; then click Deploy.

Launch Report Manager in your browser and then navigate to the folder where you deployed your RM (this is usually Models). Click on your new model (AW08_ProductBasicsModel) and view its properties. If you want to hide certain objects within the RM from certain users, click the Model Item Security link; then click the check box labeled Secure Individual Model Items Independently for This Model. Then, using the now-enabled tree control, click the item you want to secure and set permissions using the radio buttons below the tree. Users who are denied access to model objects won't even see the entities in RB3. Even more, if they run existing model-based reports that reference these entities, the columns to which they lack access are automatically filtered out by the query generation layer.

Working with Report Models in RB3

Now that your RM is deployed, it's time to launch RB3 again to create a simple report that uses it. Start RB3, and when it opens (on the New Report or Dataset window), click the Table or Matrix Wizard button and then click Create. On the following screen, select the Create a Dataset radio button and then click Next. On the Choose a Connection screen, click the Browse button; then navigate to your new Models folder in the SSRS catalog. Click to select your model (AW08_ProductBasicsModel), click Open, and then click Next (see Figure 53.36).

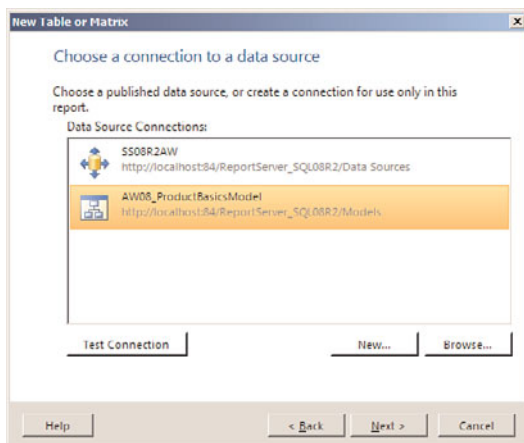

FIGURE 53.36 Selecting your report model as an RB3 data source.

As you can see, the Query Designer (QD) also supports building a query from an RM. After you add a field, if you click the Edit as Text button, you see that the QD generates a Semantic Model Query Language (SMQL) XML document for RMs rather than a T-SQL query. The RM itself is described by a Semantic Model Definition Language document, and this is the same SMDL used by the Entity Framework.

The QD's explorer pane includes the same Entities and Fields areas found on the BIDS Model Designer surface. The QD also offers a helpful search feature to locate RM objects, an advanced viewing mode, as well as the capability to create and add new fields to the RM on the fly.

Drag and drop the following fields into the Design area (top right): Product.Product Number, ProductModel.Name, ProductReview.Rating (a variation attribute of ProductReview.Total Rating), ProductReview.Review Date, and ProductReview.Reviewer Name. Click the Run button (the exclamation point) to verify that your results resemble those shown in Figure 53.37 and then click Next. On the Arrange Fields screen, drag any one of the fields into the Values pane and then click Next. Accept the defaults on the ensuing screen, click Next, choose a color theme, and then click Finish.

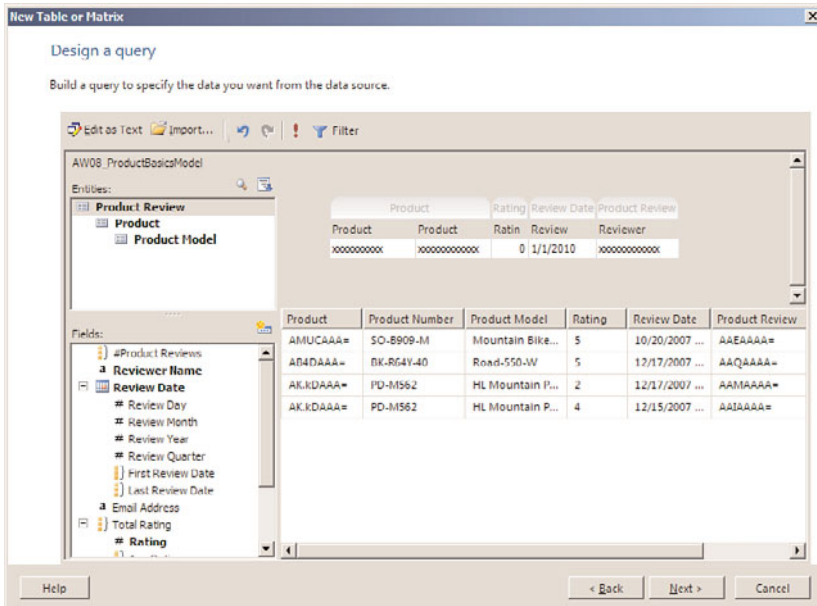

FIGURE 53.37 Building a report model SMQL query using Query Designer.

For clarity, Listing 53.8 provides a T-SQL version of the query you just built using the RM.

LISTING 53.8 T-SQL Representation of the Sample Report Model SMQL Query

```

SELECT
    p.ProductNumber,
    m.Name,
    r.Rating,
    r.ReviewDate,
    r.ReviewerName
FROM Production.Product p
JOIN Production.ProductReview r
ON r.ProductID = p.ProductID
JOIN Production.ProductModel m
ON p.ProductModelID = m.ProductModelID

```

Returning to RB3, notice your new dataset in the Report Data pane. Using the design surface, click once on the auto-created Tablix control, click its drag handle, and then press the Delete key to remove it. On the Insert tab of the Ribbon bar, click the List control button; then draw a list data region on the design surface where the table used to be.

Click in the middle of the list to reveal its Tablix borders, right-click its detail group row (this row has three horizontal lines in its middle), and then select Tablix Properties. On the General tab, under Dataset Name, use the drop-down to select DataSet1 (the default name of the RM-based dataset you just created), then click OK. Returning to the Insert Ribbon bar menu, click on the Textbox control button and draw a text box across the top third of your list control. Click once on the empty area of your list, right-click your new text box, and select Expression. For the value of the expression, enter the following and then click OK:

```

="Product: " & Fields!Product_Number.Value & " (" & Fields!Product_Model.Value &
")" & vbCrLf & "Reviewer: " & Fields!Reviewer_Name.Value & vbCrLf & "Review Date: "
& Fields!Review_Date.Value

```

Returning to the Insert Ribbon bar menu, click the Gauge control button; then draw a gauge that occupies the bottom two thirds of the list control. Select the 180 Degrees North radial style gauge and then click OK. Right-click the gauge and select Gauge Panel, Scale Properties. On the Radial Scale Properties dialog, set the Minimum drop-down value to 0 and the Maximum to 5; then click OK. Right-click the gauge again and select Gauge Panel, Pointer Properties. In the Value drop-down, enter the simple expression [Rating] and then click OK.

Right-click the designer surface (outside the boundary of the report); then click Remove Page Footer. Change the title for your report. Then, using the Line control from the Insert Ribbon menu, draw a line at the bottom of your list (just below your gauge) to separate list item repetitions during report execution. Your design surface should now resemble the one shown in Figure 53.38.

FIGURE 53.38 RB3 design surface with gauge report.

Save your report to the SSRS catalog and then click Run. Your rendered report should resemble the one shown in Figure 53.39.

FIGURE 53.39 Rendered RB3 gauge report.

Report Builder and Report Model Security

Security is not limited to running reports in RB3. When you save a report to the catalog, users can access it through Report Manager. A user who has permissions to view a report but doesn't have permissions to one of its fields simply will not see that column when running the report. This powerful feature is called *column subsetting* and is specific to reports using RMs.

Several resources are independently secured when you run reports in the Report Server:

- ▶ You can secure the report itself, by setting permissions on the report or inheriting permissions from the parent folder or the parent's parent, and so on, all the way up to the Report Server root folder.
- ▶ You can secure the model in the Report Server; this is similar to the way reports are secured. If a certain user is not granted permissions to a model, he or she can't see the model when RB3 starts and can't build or run reports based on it.
- ▶ You can secure the items in the model—for example, entities, fields, and relationships—in addition to securing the model itself.

Keep in mind the following security override rules for models:

- ▶ If a certain user has permissions to manage the model, this overrides the permissions set for any model items in the report. For instance, if Bob is given content manager permissions on a model, Bob sees all entities and fields in that model, regardless of the security set for model items.
- ▶ Local administrators on the Report Server machine have special permissions in SSRS: they can view and change security for any resource stored in the Report Server.

Enabling Report Builder

RB3 relies on having a Report Server available. It uses the Report Server to load data models, run reports, and save and load them from the server. On the other hand, like all the other SQL Server 2008 services, SSRS is locked down by default. The following sections describe the changes you need to make to enable RB3 functionality.

Granting Execute Report Definitions: A Global Permission

To start, launch Report Manager, go to Site Settings, and click the Security link on the left of the page. The list of permissions that appears contains pairs of Windows users or groups and Report Server security roles. (A security role is a collection of permissions.) Click New Role Assignment and add your user or group to the System User role. This permission is required to run reports in RB3.

Setting Model Permissions

To run reports against a model, users need Browser permissions to that model. To set permissions, in Report Manager, locate your model, click the Security link on the hover menu, click Edit Item Security, click OK on the confirmation dialog, and add your server principal to the Browser role.

In addition, if you want your users to see the Report Manager home folder, you need to add their principals to the **Browser** role in the home folder. Because permissions are inherited, unless inheritance is specifically broken, the members of that group then have permission to the entire content of the Report Server.

To remove permissions on a specific folder, navigate to it using Report Manager, select **Security** on its hover menu, click **Edit Item Security**, and then remove the respective role assignments.

Management and Security

SSRS provides a set of useful tools for managing and securing all reporting objects. The following sections discuss tools and the overall security model in detail.

Securing Reports

As we've seen in previous examples, SSRS has a built-in, role-based security system. All operations done on the server are subject to permissions. Access to SSRS is controlled through security roles and role assignments.

A *security role* is a collection of permissions—for example, the permission to create reports in a folder, the permission to view a certain report or a folder.

A *role assignment* is a set of permissions represented by the role given to a principal on a certain report or folder in the Report Server catalog. For example, the permissions on a folder called **Data Sources** contain the **local administrators** group with all permissions contained in the **Content Manager** role.

Permissions on folders are inherited to all items present in that folder, unless security inheritance is intentionally broken and the item is given its own permissions.

Built-in Roles and Permissions

SSRS comes with a set of built-in roles. Each role is a collection of permissions, normally used in tandem to enable a functional scenario. Following are some of the built-in roles:

- ▶ **Browser**—This role is a collection of read-only permissions that is useful for navigating the Reporting Services namespace and viewing reports and resources.
- ▶ **Content Manager**—This role is similar to an administrator on the part of the Report Server where it is granted. A person who has the **Content Manager** role can view and change any reports, folders, data sources, and resources and can read and set security settings in the folders where he or she has that permission.
- ▶ **Publisher**—This role is useful for report authors who need to create and change reports, folders, and data sources in a specified folder.
- ▶ **Report Builder**—This role can be used for granting permissions needed for editing Report Builder reports.

- **My Reports**—This security role is normally given to each user in his or her own My Reports folder. It gives each user of the Report Server his or her own place to publish documents on the server.

The security roles system is fully customizable. You can change or even delete existing roles, and you can also create new ones. To view and modify these roles, you use SSMS. Connect the Object Explorer to your SSRS instance and then navigate to the **Security, Roles** node. View the Properties page for any role definition to manage its permissions.

Local administrators on the Report Server machine are granted **Content Manager** permissions at the root of the SSRS catalog, and no one else has any permissions. To make the Report Server accessible to users, you need to explicitly grant permissions on the folders you want to make available to them.

System Roles and System Permissions

So far we have talked about permissions only on items in the Report Server namespace: reports, folders, and data sources. The Report Server also contains a set of server-wide roles and permissions. They are called *system roles*, and you can access them using SSMS as described previously.

As mentioned earlier, system roles are collections of permissions, such as **View Shared Schedules** or **Execute Report Definitions**. These permissions are not specific to a certain folder or part of the namespace but are global to the entire Report Server installation. A site permission is a collection of these roles assigned to users or groups. Out of the box, local administrators on the Report Server box are, by default, given the permissions contained in the **System Administrator** role.

To open your system to users, you add Windows users and groups to the site security. As with normal roles, you can change or delete the built-in system roles, or you can create other system roles.

Subscriptions

An important advantage to having reports available on a Report Server is that you can use its subscription features to *push* reports to users.

You can create subscriptions using Report Manager. Start by publishing a report to the catalog. Start Report Manager, click the **Details View** link, hover over a report of your choice, and then click **Subscribe**.

The first step in the Subscription dialog is to choose a delivery mode. There are three built-in delivery methods: email, file share, and null. The null delivery, as its name suggests, doesn't deliver anywhere; however, you can use it as a way to periodically load reports into the Report Server cache. For details, see the section "Report Execution Options," later in this chapter.

NOTE

The email delivery extension requires SMTP configuration via RSCM. Subscriptions and cache refresh plans rely on SQL Server Agent, so it must be running.

For this example, choose Windows File Share as the delivery method and fill in the file name, path, render format, server credentials, and overwrite options. The next step is to pick a schedule. You can set a schedule just for this report subscription, or you can use a shared schedule for several subscriptions. Five recurrence patterns are available for subscriptions: Hourly, Daily, Weekly, Monthly, and Once.

If your report has parameters, you also need to decide which parameter values to supply when the report is executed as part of the subscription.

One restriction in creating subscriptions is that report data sources must rely on stored credentials, whether Windows or database credentials. Integrated security and prompted credentials are not compatible with subscriptions because the actual user isn't around at runtime.

Data-Driven Subscriptions

Another way to customize report delivery is through data-driven subscriptions. A dynamic or data-driven subscription is very useful for delivering parameterized reports to a number of recipients whose email addresses are stored in a database, for instance. Unlike with a regular subscription, the recipient's settings—such as the To or CC address, the title of the email, and the parameters of the report being run—can all be based on a SQL Server query. For example, using the AdventureWorks2008R2 sample database, let's say you want to send quarterly human resources information reports to all managers at the company.

Suppose you have created a Human Resources report that takes a parameter, the login ID of an employee. If that employee is a manager, the report displays a list of all employees reporting to him or her, together with the person's title, the base pay rate, vacation hours, and sick leave hours.

You start the Data-Driven Subscription Creation Wizard using Report Manager by clicking the New Data-driven Subscription button on the Subscription tab for your Human Resources report. Type a name (such as Send quarterly HR reports to managers) and select the email delivery extension for the subscription. Then click Next.

On the data source page, use the shared AdventureWorks2008R2 data source you created earlier. Enter the query shown in Listing 53.9, which selects email addresses and login IDs for all managers.

LISTING 53.9 T-SQL for a Data-Driven Report Subscription

```
SELECT DISTINCT
    pe.EmailAddress,
    e2.LoginID
FROM HumanResources.Employee e
JOIN HumanResources.Employee e2
ON e2.OrganizationNode = e.OrganizationNode.GetAncestor(1)
JOIN Person.Person p
ON p.BusinessEntityID = e2.BusinessEntityID
JOIN Person.EmailAddress pe
```

```
ON pe.BusinessEntityID = e2.BusinessEntityID
ORDER BY pe.EmailAddress
```

Next, bind `EmailAddress` to the `To` field in the email and `LoginID` to the `LoginID` parameter of the `Human Resources` report. The last step is to choose a schedule for this subscription.

Subscription and Delivery Architecture

Let's look at what happens under the covers when a subscription is created. The meta-data for the subscription is validated and stored in the Report Server catalog database. A SQL Agent job is created, and the schedule specified in the subscription is saved in the SQL Agent job.

When the time comes, the SQL Agent job fires, inserting a so-called "event" row in the Report Server catalog. The Report Server matches the event with the information about the subscribers and sends notifications to the subscribers. The notifications are processed in the Report Server Windows service; the report is run and delivered to its target.

This architecture allows SSRS to scale very well with the number of subscribers and events. Because the events are recorded in the catalog database, it also allows for a scale-out configuration, so you can have a number of services process notifications in parallel, thus achieving greater scalability.

Report Execution Options

Another very useful feature of SSRS is the capability to cache report content and dataset data, to display data as of a certain date, to display historical snapshots of those data, to refresh those snapshots, and to do so on a scheduled basis. The following sections describe these capabilities.

Live Reports and Sessions

By default, when a report is deployed on the server, it is configured to be run live, or on demand. Every time a user clicks a report link in Report Manager, the report queries are executed. The report is processed, filters are applied, sorting is performed, and expressions are evaluated. Finally, the report is rendered to the desired format and returned to the user. The binary result of report execution is stored in a format-independent fashion in the Report Server's temporary database (`ReportServerTempDB`). This result is known as a *session snapshot*. When you page through a report or export it to a different format, the session snapshot is used to perform these operations; this way, report queries do not have to be rerun.

A session snapshot is tied to a specific user, is typically associated with a browser session, and is generally short lived (on the order of minutes).

Cached Reports

Let's assume (safely) that report queries take a relatively long time to run and the data to be displayed doesn't change very often. In that case, you can set execution options to cache the report. To do so, in Report Manager, view any report's properties (hover over it and select `Manage`); then click the `Processing Options` tab at the left of the page. Select

one of the caching option radio buttons (other than the default Do Not Cache Temporary Copies of This Report). When the first user accesses the report, it is executed (as described earlier), but the resulting snapshot will, from that point on, be saved and then shared across user sessions. When a second user clicks the report link, instead of the report running again, the user gets the snapshot that was generated when the first user ran it.

There are two ways to remove a snapshot from the cache:

- ▶ **After a certain number of minutes of inactivity**—This is a “sliding” expiration, meaning that as long as users navigate to the report, it is kept in the cache. If no one has requested the report for more than the specified number of minutes, the cache is expired, and the next report request causes a live execution, which starts another cache session, and so on.
- ▶ **On a schedule**—This is useful if the data is not valid after a certain date (for example, if sales information changes every two weeks), and you don’t want any cached report to show data older than this date .

Execution Snapshots

Snapshots are an extremely useful bit of functionality: they enable SSRS to fetch a report’s data, prerender the report ahead of its actual execution time, and then save that intermediate format for fast retrieval. If you configure your report to use snapshots, when the time comes for a user to run it, it will render very quickly because the data has already been culled from the report’s data sources and stored in ReportServerTempDB. The only downside is staleness of data, but you can adjust the snapshot creation interval to your customer’s liking.

If you don’t want your users to run reports against live data (for example, if the queries are prohibitively expensive or they make sense only for end-of-month sales and the report should be run only on the first day of each month for the data to be relevant), you can set the report settings to Execution Snapshot. The Report Server then runs the report on this schedule. Your users always get the data from this execution snapshot.

The main difference between execution snapshots and cached reports is that cached reports can run live if the cached data has expired; execution snapshots, on the other hand, are guaranteed to run only on the specified schedule .

Historical Snapshots

Historical snapshots are useful if you want to keep historical data for your reports. Say that you want to track all monthly sales reports from month to month. You can configure this on the Snapshot Options tab on the Report Properties window. You simply set the option Use the Following Schedule to Add Snapshots to Report History and then create a new or use an existing shared schedule.

To see historical snapshots, go to Report Manager, click the report, and then click the Report History tab. Notice the list of historical snapshots taken from the selected report (you can also create a new snapshot on demand on this screen). When you click a report on the list, you see the actual report data.

Cache Refresh Plans

Cache refresh plans (CRPs) are a new feature in SSRS 2008 R2. As the name implies, a CRP is a plan that controls when cached shared dataset or report data is to be automatically refreshed. To create a CRP, view any report or shared dataset in Report Manager; then hover it and click Manage. On the left, click Cache Refresh Options and then click the New Cache Refresh Plan button at the top of the page (if you already have a CRP, you can create a new CRP using the existing one as a baseline). You may get a confirmation dialog asking if it's okay to enable caching for the selected item. Answer in the affirmative. On the ensuing screen, enter a description for your new plan, create a new item-specific schedule, or use an existing shared schedule; then click OK (ensure that the SQL Agent service is running before doing so). If you are working with a shared dataset, your steps are complete. If you are working with a report that has one or more parameters, there is one more step to consider.

When caching a parameterized report, SSRS needs values supplied for all report parameters (at least, for those which do not except an empty value). A discrete set of cached report data is created for every unique combination of input parameter values you specify. Any errors in input render your CRP inactive .

User-Specific Data Limitations

Cached reports, execution snapshots, and history snapshots all have something in common: they each allow sharing of report data among users. This means that a given SSRS instance does not let you use these features with reports that contain user-specific data. Per-user references in the report include the usage of User!UserID in the report definition, the use of integrated security in the report data sources, and the Impersonate After Connection Is Made option for SQL Server data sources .

Performance and Monitoring

SSRS includes a number of performance and monitoring tools: the trace log, execution log, event log entries for system errors, and a set of performance counters. Also, to improve the product's quality, SSRS can send error reports to Microsoft if you opt-in during Setup or by using the SQL Server Error and Usage Reporting Tool.

SSRS Trace Log

Similar to the SQL Server Database Engine, SSRS writes detailed trace and error information, useful for troubleshooting, to a log file, namely:

```
%PROGRAMFILES%\Microsoft SQL Server\MSRS10_5.[InstanceName]\Reporting
  Services\LogFiles\ReportServerService_[timestamp].log
```

The log file contain three types of events: errors, warnings, and informational messages. Each entry begins with a prefix that includes the current time stamp, the process and

thread used, the type of event, and the message itself. Note that SSRS automatically deletes trace files older than a certain number of days.

Execution Log

If the level of detail provided in the `ReportServerService` log file is insufficient for your needs, you can take tracing to the next level by downloading (from www.codeplex.com) a T-SQL user database creation script, SQL Server Integration Services (SSIS) package, and a set of reports.

The SSIS package extracts execution data captured in `ReportServer.dbo.ExecutionLogStorage` to a new user database. To monitor execution, you can periodically run the package. Then you can use the provided reports to discover which reports your users most commonly run, which take the most time or are the biggest, or how many of them have succeeded or failed.

SSRS 2008 R2 also includes three new views (since SSRS 2005) in the `ReportServer` database: `dbo.ExecutionLog`, `dbo.ExecutionLog2`, and `dbo.ExecutionLog3`. The first is essentially a copy of the table removed (from this SSRS edition) by the same name. The other two are similar, except that they include a new `AdditionalInfo xml` column joined from the `ExecutionLogStorage` table. `ExecutionLog3` has two columns renamed from `ExecutionLog2` (`ReportPath` is now `ItemPath`, `ReportAction` is now `ItemAction`, reflecting the fact that not just reports are accessed and/or executed).

As with trace log files, SSRS deletes execution log table entries older than two months. You can adjust the trace level for execution logging by changing settings in the `ReportingServicesService.exe.config` file.

For more complete information, see the MSDN article “Querying and Reporting on Report Execution Log Data.”

Windows Event Log

SSRS writes configuration or internal server errors to the application event log. It also writes a number of informational messages (for example, when there are changes to the configuration files). The event log entries are marked with `Report Server*` as the source.

Performance Counters

SSRS defines a number of performance counters that you can use to measure the performance of your system. There are two performance counter categories: `MSRS 2008 R2 Web Service` and `MSRS 2008 R2 Windows Service`. You see a number of counters for each service and an instance for each instance of Reporting Services running on that machine. For more details, see the “Monitoring Report Server Performance” topic in Books Online.

Summary

This chapter describes the components included in SSRS as well as the product's overall architecture. Specifically, it discusses report development, deployment, administration, security, and delivery.

If you use SSRS, you will no doubt come to appreciate what it has to offer: its power and simplicity, its open and extensible architecture, and its rich feature set. Today it is easier than ever to unlock the data from database systems and make it available to business users.

In the next chapter, "Managing Linked and Remote Servers," you learn how to administer linked and remote servers.

This page intentionally left blank

CHAPTER 54

Managing Linked and Remote Servers

As your databases grow in size, complexity, or geographic distribution, you might need to spread your data across multiple servers and locations. You might also need to bring together disparate data that is not all on one server or is not all in the same type of data container (Access, Excel, text files, and other RDBMSs) to fulfill a business need. SQL Server has long had the capability to perform server-to-server communication. This can be done using remote server or linked server capabilities. In versions of SQL Server prior to 7.0, the only option was to use Remote Procedure Calls (RPC) and remote servers. An RPC is the execution of a stored procedure on a local server that actually resides on a remote server. This capability allows you to retrieve or modify data that resides on a different SQL Server. The main drawback, however, is that you cannot join between tables residing on more than one server using RPCs, nor can you selectively choose the columns of information you want to retrieve from the remote server. You get whatever the stored procedure on the remote server is defined to return. Linked servers to the rescue! As linked server capabilities were introduced (with SQL Server 7.0 onward), using the remote servers approach became fairly obsolete because of their inherent limitations. In fact, remote servers are supported in SQL Server 2008 for backward compatibility only. Microsoft has clearly stated that remote servers are being deprecated in the next release of SQL Server.

SQL Server 2008 provides the capability to link together servers (of the same or different data containers), allowing you to join information together across servers or simply access data on another server. Access to the remote tables can be to another SQL Server or to any other data source with an OLE DB provider. You can also define distributed

partitioned views that can pull data together from multiple servers into a single view. For end-user queries that use these views, it appears as if the data is coming from a single local table. For more information on distributed partitioned views, see Chapter 27, “Creating and Managing Views.”

This chapter provides an overview of linked servers in SQL Server 2008 along with a brief discussion of remote servers. As mentioned earlier, remote servers and RPCs are legacy features that are still supported for backward compatibility. In other words, you can still set up and use remote servers and RPCs, but linked servers are much easier to set up and provide greater functionality. Keep in mind that Microsoft is also telling folks to convert any remote server implementations they currently have to linked server implementations. Deprecating remote servers was also announced in SQL Server 2005; however, due to the outcry from many customers, it was not dropped in SQL Server 2008. You can likely count on it not surviving another major release, though.

What’s New in Managing Linked and Remote Servers

With SQL Server 2008, there are no significant changes to the linked servers’ capabilities, and there are virtually no changes in the remote servers area. Of the few changes for linked servers, the following are the most significant:

- ▶ Remote servers are being deprecated, and this means system stored procedures such as `sp_addserver`, `sp_remotoption`, `sp_helpremotelogin`, and `sp_addremotelogin` will go away.
- ▶ System variable `@@REMSERVER` and server-wide settings such as `SET REMOTE_PROC_TRANSACTIONS` will also go away.
- ▶ The system stored procedure was introduced, such as `sp_setnetname` to associate a remote or linked server name with the network name of the server that is remote (not local).
- ▶ More DATA providers are now certified with Microsoft. This includes flat files, DB2, Informix, and Oracle providers used with linked servers.
- ▶ A bit more tightening has been done on the login/account delegation model that linked servers utilize.
- ▶ For remote servers, RPCs are disabled, by default, with SQL Server 2005 and SQL Server 2008. This greatly enhances the default security of your SQL Server out of the box.

Managing Remote Servers

Remember that remote servers are supported in SQL Server 2008 for backward compatibility only. (Remote servers are being deprecated!) By definition, a *remote server* is a server you access as part of a client process without opening a separate, distinct, and additional *direct* client connection. SQL Server can manage the communication between servers using Remote Procedure Calls (RPCs). Essentially, the “local” SQL Server to which the

client is connected opens another connection to the “remote” server and submits a remote stored procedure request to the remote server. Execution results are passed back to the local server, and they are then passed back to the originating client application (see Figure 54.1).

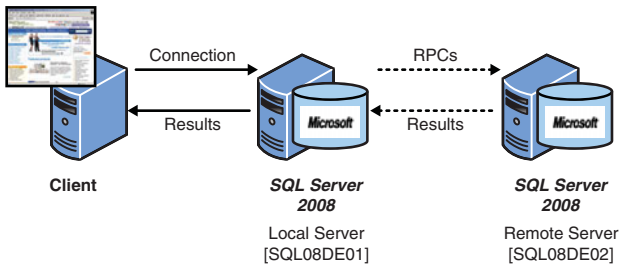

FIGURE 54.1 The remote server is accessed through the local server. The client has to maintain only a single connection to the local server.

You call a remote procedure the same way you call a local procedure; the only difference is that you need to fully qualify the name of the procedure with the name of the server. This fully qualified procedure name includes the server name node, database/catalog name node, database owner node, and remote stored procedure name itself. The local SQL Server recognizes this as a remote procedure, establishes the connection to the remote server, and executes the stored procedure (remotely). Following is the syntax for a fully qualified remote procedure call execution:

```
EXECUTE remote_server_name.db_name.owner_name.procedure_name
```

Here's an example:

```
EXECUTE [DBARCH-LT2\SQL08DE02].[UnleashedRemoteDB].[dbo].[Top10Customers]
```

Remote servers are more limited in functionality and a bit more time-consuming to set up than linked servers. The following are the basic steps involved in setting up remote servers:

1. Define the local and remote servers on both servers.
2. Configure each server for remote access.
3. Create logins to be used with the remote servers.
4. Create the login mappings from the local server to the remote server.
5. Grant execute permissions for the remote login.

If you are connecting between multiple SQL Server 2008, SQL Server 2005, SQL Server 2000, or SQL Server 7.0 servers, it is best to set them up as linked servers and not just

remote servers. However, if you need to execute Remote Procedure Calls only or are on a pre-SQL Server 7.0 server, you need to set up remote servers as described here.

Before we look at an example of a local server connecting to a remote server, let's first set up a database, create a sample table, and create a stored procedure to execute on the remote server. You can grab the `CustomersPlusSQLTable.sql` SQL script for this purpose from the CD for this book. The `CustomersPlusSQLTable.sql` script contains a `create` database statement that creates a database named `UnleashedRemoteDB`, creates a table named `CustomersPlus` in this database, and populates the table with about 89 rows of test data. You should go ahead and grab the script now and execute it on the target remote server (`SQL08DE02` in this example). You need to edit the `create` database statement (`FILENAME` parameter) for your own environment. While you are executing this script, go ahead and grab the three other scripts you will also need to complete this remote server section: `LocalServerSQL.sql`, `RemoteServerSQL.sql`, and `RPCexecution.sql`.

Remote Server Setup

You can assume that the local server is called `SQL08DE01` and the remote server is called `SQL08DE02` (as shown in Figure 54.1). First, you need to use `sp_addserver` to add the remote server name to the system table in the master database if it's not defined already. But first, let's see what servers are already defined at the local server. To do so, you run `sp_helpserver` from the local server (`SQL08DE01`). This provides you with the complete list of local and remote servers known to this server:

```
EXECUTE sp_helpserver
go
name          network_name  status
            id collation_name connect_timeout query_timeout
-----
DBARCH-LT2\SQL08DE01  DBARCH-LT2\SQL08DE01  rpc, rpc out, use
            remote collation  0 NULL 0 0
```

You can also see the same information by doing a simple `SELECT` against the `sys.servers` system view:

```
SELECT * FROM sys.servers
```

Generally, you don't need to execute `sp_addserver` for the local server. This is usually taken care of during SQL Server installation. The local server has an ID of `0`. If you need to add the entry for the local server, you can specify the `local` flag as the second argument:

```
exec sp_addserver [DBARCH-LT2\SQL08DE01], local
```

You need to execute `sp_addserver` for each of the remote servers you will access from the local server. The SQL script `LocalServerSQL.sql` that you just got from the CD contains

these commands. For example, on the local server (SQL08DE01), you execute the following command to add SQL08DE02:

```
EXECUTE sp_addserver [DBARCH-LT2\SQL08DE02]
```

Then, to see this new entry, you again execute `sp_helpserver`, as follows:

```
EXECUTE sp_helpserver
go
name                network_name  status
            id  collation_name  connect_timeout  query_timeout
-----
-----
DBARCH-LT2\SQL08DE01  DBARCH-LT2\SQL08DE01  rpc,rpc out,use
                    0  NULL  0  0
DBARCH-LT2\SQL08DE02  DBARCH-LT2\SQL08DE02  rpc,rpc out,use
                    1  NULL  0  0
```

You now see the newly added remote server entry (with an ID of 1 in this example).

To drop a remote server entry, you need to execute `sp_dropserver`. For example, on the local server (SQL08DE01), you execute the following command to drop the SQL08DE02 remote server entry:

```
EXECUTE sp_dropserver [DBARCH-LT2\SQL08DE02]
```

If the local server is a 7.0 or later version of SQL Server, you can add the remote servers by using `sp_addlinkedserver`:

```
EXECUTE sp_addlinkedserver [DBARCH-LT2\SQL08DE02]
```

This command sets up the server for remote stored procedure execution and for direct data access. (You learn more on this later in this chapter, in the section “Linked Servers.”)

Now, on the remote server ([DBARCH-LT2\SQL08DE02]), you need to define the local server ([DBARCH-LT2\SQL08DE01]) that will be connecting to it. The SQL script `RemoteServersSQL.sql` that you just got from the CD contains these commands:

```
EXECUTE sp_addserver [DBARCH-LT2\SQL08DE01]
```

You also need to verify that each server (both the local and remote servers) allows remote connections. This is the SQL Server 2008 default but can easily be verified by looking at the properties for each server from SQL Server Management Studio. By default, remote access is automatically enabled during setup to support replication. Figure 54.2 shows the current configured values of the remote server connection entry, indicating that remote connections to this server are allowed (checked) for the DBARCH-LT2\SQL08DE02 remote SQL Server. You need to double-check both servers (local and remote).

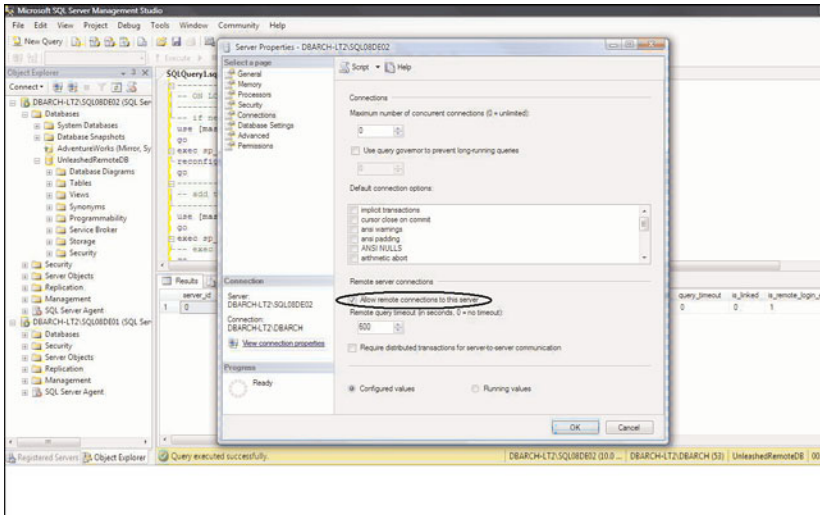

FIGURE 54.2 Allowing SQL Server remote connections (this check box has been circled).

You can also configure this remote connection access by using `sp_configure`. The proper syntax is as follows:

```
EXECUTE sp_configure 'remote access', 1
reconfigure
```

After enabling remote access, you need to shut down and restart each server.

Now you need to follow the basic rule of allowing only a named SQL login the capability to execute a remote stored procedure. In this way, you can tightly control the permissions and execution of that stored procedure from wherever the remote execution request originates from. You start by creating the logins you want to use to connect to the local SQL Server (SQL08DE01 in this example) and the same login name on the remote SQL Server (SQL08DE02 in this example). You can do this by using Microsoft SQL Server Management Studio (new login) or by using a `CREATE LOGIN SQL` command, as follows (on the local server, which is SQL08DE01 in this example):

```
-- FROM THE LOCAL SERVER ONLY--
CREATE LOGIN ForRPC WITH PASSWORD = 'password',
CHECK_EXPIRATION = OFF, CHECK_POLICY = OFF,
DEFAULT_DATABASE = master
go
```

This SQL Server login will connect from the client application. Note that your environment might want to enforce various password policies, conventions, and expiration dates.

Next, you create the corresponding SQL login on the remote server (and make that login a user in the database where the remote procedure is located). Again, this can be done by

using Microsoft SQL Server Management Studio (new login) on the remote server (SQL08DE02 in this example) or by using the `CREATE LOGIN` and `CREATE USER SQL` commands as follows:

```

--- FROM THE REMOTE SERVER ONLY ---
CREATE LOGIN ForRPC WITH PASSWORD = 'password',
CHECK_EXPIRATION = OFF, CHECK_POLICY = OFF,
DEFAULT_DATABASE = UnleashedRemoteDB
go
USE [UnleashedRemoteDB]
GO
CREATE USER [ForRPC] FOR LOGIN [ForRPC]
GO

```

Notice that you also identify the default database for this remote login to be the database created earlier in this example (UnleashedRemoteDB test database). You also make the login a user within that database.

Now you must set up login mappings on the remote server and possibly on the local server. Basically, remote server login mappings must be set up on the remote server to map the incoming login for an RPC connection from a specified server to a local login (on the remote server). In other words, you need to define how to map the logins from the server making the remote procedure request (SQL08DE01) to the environment on the server receiving the request (SQL08DE02). Also, the trusted option of `sp_remoteoption` is not supported in SQL Server 2005 or SQL Server 2008. This change was made to close a huge security hole in prior SQL Server versions.

Although you are technically setting things up on the remote server (SQL08DE02), when you are doing things on the remote server, it is typically referred to as the local server, and the local server (SQL08DE01) is treated as the remote server. It's easiest to think about this situation from the point of view of where you are standing (at the local server versus the remote server). Then it will make a lot more sense.

Following is the syntax for the `sp_addremotelogin` command:

```

EXECUTE sp_addremotelogin remote_server_name
    [, local_login_name [, remote_login_name]]

```

For example, on the remote server (SQL08DE02), you execute the following command to map the newly created login on SQL08DE01 to the same login on SQL08DE02:

```

EXECUTE sp_addremotelogin [DBARCH-LT2\SQL08DE01], ForRPC, ForRPC

```

This is the simplest mapping method. It presumes that the logins are the same on both servers, and it maps login to login. To see the complete list of resulting mappings, you simply execute `sp_helpremotelogin`:

```

EXECUTE sp_helpremotelogin
go

```

server	local_user_name	remote_user_name options
DBARCH-LT2\SQL08DE01	ForRPC	ForRPC

TIP

If users from the remote server need access on your server, don't forget to add them with the `CREATE LOGIN` statement *first*.

The login to which you map the remote logins determines the permissions the remote users will have on the local server. If you want to restrict the procedures that the remote users can execute, you need to be sure to set the appropriate permissions on the procedure for the login to which they are mapping. To set execute permissions for the RPC named `Top10Customers` to the SQL login of `ForRPC`, you use the following:

```
GRANT EXECUTE ON [UnleashedRemoteDB].[dbo].[Top10Customers] TO ForRPC
go
```

That's it! You are now ready to execute an RPC via the local server as soon as you connect to the local server with the just-created `ForRPC` SQL login credentials. The SQL script name `RPCexecution.sql` contains the remote stored procedure execution statement. You simply log in to the local server (`SQL08DE01` in this example) using the `ForRPC` SQL login and execute the fully qualified remote stored procedure as follows:

```
-- FROM LOCAL SERVER - SQL08DE01 in our example --
use [master]
go
EXECUTE [DBARCH-LT2\SQL08DE02].[UnleashedRemoteDB].[dbo].[Top10Customers]
go
```

As you can see, setting up remote servers can be a bit confusing and a tedious process. You have to perform setup tasks on both the local and remote servers. In addition, the mapping of logins severely limits what types of servers can be accessed. Login mappings are performed at the remote server instead of the local server, which works fine if the remote server is a SQL Server machine, but how do you perform this task in another database environment that doesn't have user mappings? How do you tell an Oracle database to which Oracle user to map a SQL Server user? When you understand how linked servers are set up and what expanded capabilities they provide, you won't want to use remote servers unless you absolutely have to, which should be only when you need to execute RPCs on pre-7.0 SQL Servers.

Linked Servers

Linked servers enable SQL Server-based applications to include most any other type of data source to be part of a SQL statement execution, including being able to directly reference remote SQL servers. They also make it possible to issue distributed queries, updates, deletes, inserts, commands, and full transactions on heterogeneous data sources across your entire company (network). SQL Server essentially acts as the master query manager. Then, via OLE DB providers and OLE DB data sources, any compliant data source is easily referenced from any valid SQL statement or command. For each data source, either they are directly referenced, or SQL Server creates provider-specific subqueries issued to a specialized provider. This is very close to being a federated data management capability across most heterogeneous data sources.

Unlike remote servers, linked servers have two simple setup steps:

1. Define the remote server on the local server.
2. Define the method for mapping remote logins on the local server.

All linked server configurations are performed on the local server. The mapping for the local user to the remote user is stored in the local SQL Server database. In fact, you don't need to configure anything in the remote database. Using linked servers also allows SQL Server to use OLE DB to link to many data sources other than just SQL Server.

OLE DB is an API that allows COM/.NET applications to work with databases as well as other data sources, such as text files and spreadsheets. This capability lets SQL Server have access to a vast amount of different types of data as if these other data sources were local SQL Server tables or views. This is extremely powerful.

Unlike Remote Procedure Calls (and remote servers only), linked servers also allow distributed queries and transactions.

TRULY A LINKED SERVER

Keep in mind that when you define linked servers, SQL Server really keeps these data resources linked in many ways. Most importantly, it keeps the schema definitions linked. In other words, if the schema of a remote table on a linked server changes, any server that has links to it also knows the change (that is, gets the change). Even when the linked server's schema comes from something such as Excel, if you change the Excel spreadsheet in any way, that change is automatically reflected back at the local SQL Server that has defined that Excel spreadsheet. This is extremely significant from a metadata and schema integrity point of view. This is what is meant by “completely linked.”

Distributed Queries

Distributed queries access data stored in OLE DB data sources. SQL Server treats these data sources as if they contained SQL Server tables. Basically, via a provider such as OLE DB, the data source is put in terms of recordsets. Recordsets are the way SQL Server needs to see any data. The Microsoft SQL Native Client OLE DB provider (with `PROVIDER SQLNCLI`) is the official OLE DB provider for SQL Server 2008. You can view or manipulate data through this provider by using the same basic Data Manipulation Language (DML) syntax as for T-SQL for SQL Server (`SELECT`, `INSERT`, `UPDATE`, or `DELETE` statements). The main difference is the table-naming convention. Distributed queries use a four-part table name syntax for each data source as follows:

```
linked_server_name.catalog.schema.object_name
```

The following distributed query accesses data from a sales table in an Oracle database, a region table in a Microsoft Access database, and a customer table in a SQL Server database—all with a single SQL statement:

```
SELECT s.sales_amount
FROM access_server...region AS r,
oracle_server..sales_owner.sale AS s,
sql_server.customer_db.dbo.customer AS c
where r.region_id=s.region_id
and s.customer_id=c.customer_id
and r.region_name='Southwest'
and c.customer_name='ABC Steel'
```

All these data sources are on completely different physical machines. But with linked servers and distributed queries, you might not ever realize this.

Distributed Transactions

With SQL Server distributed transactions, it is now possible to manipulate data from several different data sources in a single transaction. Distributed transactions are supported if the OLE DB provider has built in the XA transactional functionality. For example, suppose two banks decide to merge. The first bank (let's call it OraBank) stores

all checking and savings accounts in an Oracle database. The second bank (let's call it SqlBank) stores all checking and savings accounts in a SQL Server 2008 database. A customer has a checking account with OraBank and a savings account with SqlBank. What would happen if the customer wanted to transfer \$100 from the checking account to the savings account? You can handle this task by using the following code while maintaining transactional consistency:

```
BEGIN DISTRIBUTED TRANSACTION
-- One hundred dollars is subtracted from the savings account.
UPDATE oracle_server..savings_owner.savings_table
SET account_balance = account_balance - 100
WHERE account_number = 12345
-- One hundred dollars is added to the checking account.
UPDATE sql_server.checking_db.dbo.checking_table
SET account_balance = account_balance + 100
WHERE account_number = 98765
COMMIT TRANSACTION;
```

The transaction is either committed or rolled back on both databases.

Adding, Dropping, and Configuring Linked Servers

The next few sections show how to add, drop, and configure linked servers through system stored procedures. All these configuration options can also be done very easily with SQL Server Management Studio. The following sections occasionally describe that capability but focus on the SQL commands method because you will usually use this method in real-life production systems.

sp_addlinkedserver

Before you can access an external data source through SQL Server, it must be registered inside the database as a linked server. Essentially, you must capture (register) the connection information and specific data source information within SQL Server. After it is registered, the data source can simply be referenced within the SQL statement by a single logical name. You use the `sp_addlinkedserver` stored procedure for this registering purpose. Only users with the `sysadmin` or `setupadmin` fixed server roles can run this procedure.

SQL Server 2008 ships with a number of OLE DB providers, including providers for Oracle, DB2, Informix, Access, and other SQL Server 6.5/7.0/2000/2005 databases, as well as databases that can be reached through ODBC and JDBC. SQL Server also comes with OLE DB providers for Microsoft Excel spreadsheets and Indexing Service and a whole bunch more. Microsoft puts each of these providers through extensive testing to certify them. We have found that sometimes a provider isn't available on the 64-bit version of SQL Server 2008 yet. So, as a precaution, check the list of 64-bit providers *before* you upgrade your SQL Server to the 2008 64-bit version. If you are not using a Microsoft-certified provider, however, you might still be able to use that provider if it is compliant with the OLE DB provider specifications.

TIP

When a linked server is created using `sp_addlinkedserver`, a default self-mapping is added for all local logins. This means that for non-SQL Server providers, SQL Server authenticated logins may be able to gain access to the provider under the SQL Server service account. If you want, you can issue the `sp_droplinkedserverlogin` command to remove these mappings.

Figure 54.3 depicts the overall technical architecture of what is being enabled via linked servers and providers. There is a SQL Server 2008 side set of provider DLLs, along with a client-side provider that communicates directly with the data sources. Clients usually connect to SQL Server 2008 via the native `SQLNCLI` provider (OLE DB) or via the ODBC provider.

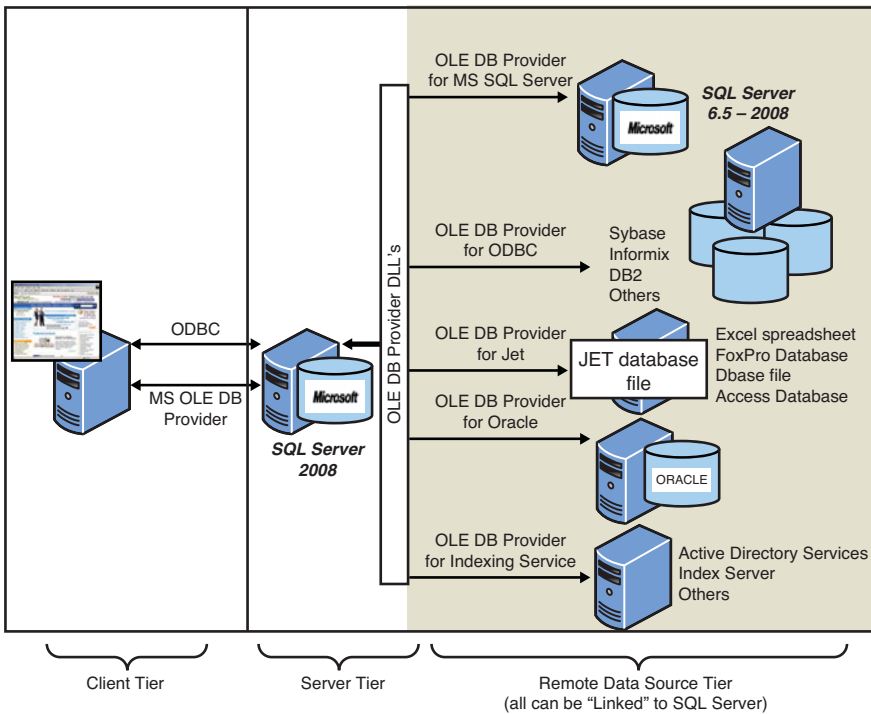

FIGURE 54.3 Linked servers provider architecture.

This provider architecture allows data sources to be accessed from within SQL Server 2005 with the highest degree of efficiency and integrity possible.

Some of the arguments for `sp_addlinkedserver` are needed only for certain OLE DB providers. Because of the number of different options and settings available, you should

always double-check the documentation for the OLE DB provider to determine exactly which arguments must be provided and what strings are to be specified. Following is the `sp_addlinkedserver` procedure:

```
sp_addlinkedserver [@server =] 'server'
    [, [@srvproduct =] 'product_name']
    [, [@provider =] 'provider_name']
    [, [@datasrc =] 'data_source']
    [, [@location =] 'location']
    [, [@provstr =] 'provider_string']
    [, [@catalog =] 'catalog']
```

Following are the elements of this syntax:

- ▶ **server**—The name of the linked server that will be added (@server parameter).
- ▶ **product_name**—The product name of the OLE DB provider (@srvproduct parameter). If this argument is set to 'SQL Server', only the @server argument is required. For all other OLE DB providers delivered with SQL Server, you can ignore this parameter.
- ▶ **provider_name**—The unique programmatic identifier (PROGID). This value must match the PROGID in the Registry for the particular OLE DB provider (@provider parameter). The following are the OLE DB providers delivered with SQL Server and the corresponding values for the *provider_name* argument:

OLE DB Provider	Value (PROGID)
SQL Server	SQLNCLI (OLE DB provider)
SQL Server	SQLOLEDB
Access DB/Jet	Microsoft.Jet.OLEDB.4.0 (32-bit only)
Excel spreadsheets	Microsoft.Jet.OLEDB.4.0 (32-bit only)
ODBC	MSDASQL
DB2	DB2OLEDB
Oracle	MSDAORA (32-bit only)
Oracle, Version 8 or later	OraOLEDB.Oracle (32-bit only)
File system	MSIDXS (through Indexing Service)

- ▶ **data_source**—A data source that points to the particular version of the OLE DB source (@datasrc parameter). For example, for setting up an Access linked server, this argument holds the path to the file. For setting up a SQL Server linked server, this argument holds the machine name of the linked SQL Server. Following are the OLE DB providers delivered with SQL Server and the corresponding values for this argument:

OLE DB Provider	Value
SQL Server	Network name of the SQL Server
Access DB/Jet	Full pathname to the file
Excel spreadsheet	Full pathname to spreadsheets
ODBC	System DSN or ODBC connection string
Oracle	SQL*Net alias
Oracle, Version 8 or later	Alias for the database
DB2	Catalog name of the database
File System	Indexing Service catalog name (Indexing Service)

- ▶ **location**—The location string, possibly used by the OLE DB provider (@location parameter).
- ▶ **provider_string**—The connection string, possibly used by the OLE DB provider (@provstr parameter).
- ▶ **catalog**—The catalog string, possibly used by the OLE DB provider (@catalog parameter).

The SQLNCLI native SQL provider uses the same OLE DB provider code, so it is considered the same provider as SQLOLEDB. There are also many other “certified” providers, such as an Analysis Services data mining model provider, an Analysis Services OLAP provider, XML providers, SSIS (DTS) providers, PostgreSQL providers, and even data replication providers. Figure 54.4 shows the entire list of providers available within the Linked Servers node of SQL Server Management Studio.

The following example adds an Oracle linked server called 'ORACLE_DATABASE' that connects to the database specified by the SQL*Net string 'my_sqlnet_connect_string':

```
EXEC sp_addlinkedserver @server='ORACLE_DATABASE',
@srvproduct='Oracle', @provider='MSDAORA',
@datasrc='my_sqlnet_connect_string'
```

The next example creates a linked server reference for an Access database called CustomersPlus.mdb. As you can see in Figure 54.5, this Microsoft Access database is an Access 2000 file format database.

The following example adds an Access database linked server entry called 'ACCESS_DATABASE_CUSTOMERS' that establishes a connection to the database 'CustomersPlus.mdb' stored in the C:\temp directory:

```
EXECUTE sp_addlinkedserver @server='ACCESS_DATABASE_CUSTOMERS',
@srvproduct='Access',
@provider='Microsoft.Jet.OLEDB.4.0',
```

FIGURE 54.4 Linked server providers supplied by Microsoft with SQL Server 2008.

54

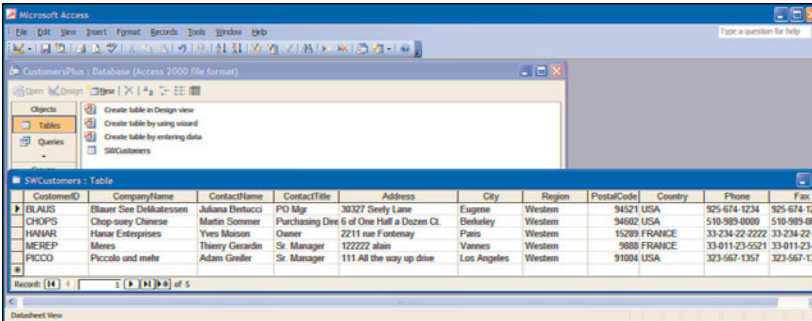

FIGURE 54.5 The **CustomersPlus.mdb** Microsoft Access database.

The CustomersPlus.mdb is available on the CD included with this book. For this example, copy this Access database file from the CD onto the same server machine on which you have SQL Server installed. The Microsoft Access client provider also needs to be present on this machine (which it will be you have installed Microsoft Office on the system). You can now reference this linked server directly from a SQL statement. `sp_addlinkedserver` and all other SQL statements for this linked server set of examples are also on the CD for this book in the script file `LinkedServerSQL.sql`. Here is a small sample of SQL code that selects all values from this Access database linked server entry:

```
SELECT CustomerID, ContactName, City, Country
FROM ACCESS_DATABASE_CUSTOMERS...SWCustomers
```

ORDER BY ContactName

Go

```
CustID ContactName      City      Country
-----
PICCO  Adam Greifer        Los Angele USA
CHOPS  Martin Sommer      Berkeley  USA
MEREPE Thierry Gerardin    Vannes   FRANCE
BLAUS  Juliana Bertucci     Eugene    USA
HANAR  Yves Moison         Paris     FRANCE
```

(5 row(s) affected)

Note that you can see the fully qualified link server reference as the table name.

Here’s an example that adds a “SQL Server” linked server that resides on the 'DBARCH-LT2\SQL08DE01' machine:

```
EXECUTE sp_addlinkedserver @server='DBARCH-LT2\SQL08DE01',
@srvproduct='SQL Server'
```

Then you select data from a table on that linked server:

```
-----
-- Selecting data from the Linked Server directly --
-----
SELECT TOP 10
    [CustomerID]
    ,[CustomerName]
    ,sum([YTDSalesTotal]) as 'YTD Sales'
FROM [DBARCH-LT2\SQL08DE01].[Unleashed].[dbo].[HotCustomerPlus]
GROUP BY [CustomerID]
        ,[CustomerName]
ORDER BY 3 desc
go
```

CustomerID	CustomerName	YTD Sales
85	Roadway Bicycle Supply	188509.608000
599	Westside Plaza	178835.169285
433	Thorough Parts and Repair Services	168182.664000
205	Rally Master Company Inc	146097.433161
546	Field Trip Store	135208.616867
193	Perfect Toys	134068.411416
697	Brakes and Gears	125784.511476
448	Action Bicycle Specialists	122380.103796
506	Great Bikes	122283.656936
230	Global Bike Retailers	115936.910796

(10 row(s) affected)

This example adds an Excel 8.0 spreadsheet as a linked server:

```
/* Set up of an Excel linked server */
EXEC sp_addlinkedserver
    'ExcelSW', /* linked server name you want to use*/
    'Jet Excel', /* product name - can be anything */
    'Microsoft.Jet.OLEDB.4.0', /* OLE provider name */
    'd:\SWCustomers.xls', /* datasource name */
    NULL, /* location not needed in this case */
    'Excel 8.0', /* Provider string if needed */
    NULL /* catalog name if needed */
go
```

This example adds an ODBC data source as a linked server called 'ODBC_with_DATA_SOURCE'. The ODBC connection string must be registered on the local server to use this linked server:

```
EXEC sp_addlinkedserver
    @server='ODBC_with_DATA_SOURCE',
    @srvproduct='ODBC',
    @provider='MSDASQL',
    @datasrc='My_ODBC_connection_string'
```

This example adds an ODBC data source as a linked server called 'ODBC_with_PROVIDER_STRING'. Unlike with the previous example, an ODBC data source does not need to exist. The information normally stored as an ODBC data source is stored in the provstr argument:

```
EXEC sp_addlinkedserver
    @server='ODBC_with_PROVIDER_STRING',
    @srvproduct='ODBC',
    @provider='MSDASQL',
    @provstr='DRIVER={SQL Server}; SERVER=MyServer; UID=sa;PWD=;'
```

Following is an example of a distributed query that accesses multiple tables via linked servers:

```
SELECT substring(CustomerID,1,5) as 'CustID',
       substring(ContactName,1,18) as ContactName,
       substring(City,1,10) as 'City',
       substring(Country,1,15) as 'Country'
FROM [Linked ExcelSW]...[SWCustomers$]
UNION
SELECT substring(CustomerID,1,5) as 'CustID',
       substring(ContactName,1,18) as ContactName,
       substring(City,1,10) as 'City',
       substring(Country,1,15) as 'Country'
```

```

FROM ACCESS_DATABASE_CUSTOMERS...SWCustomers
go
CustID ContactName      City      Country
-----
BLAUS  John Monroe      Concord  USA
BLAUS  Juliana Bertucci  Eugene   USA
CHOPS  Martin Sommer   Berkeley USA
HANAR  Yves Moison      Paris    FRANCE
MEREPE Thierry Gerardin Vannes   FRANCE
PICCO  Adam Greifer     Los Angele USA

```

(6 row(s) affected)

In this example, you unite customers from the Access database with customers from the Excel spreadsheet, all as a single SQL statement within SQL Server.

sp_linkedservers

To see the linked servers defined within a SQL Server instance, you simply use `sp_linkedservers`:

```

EXEC sp_linkedservers
Go

```

The `sp_linkedservers` execution provides the list of all linked servers on this SQL Server:

```

SRV_NAME                SRV_PROVIDERNAME        SRV_PRODUCT  SRV_DATASOURCE
-----
ACCESS_DATABASE_CUSTOMERS Microsoft.Jet.OLEDB.4.0 Access C:\temp\CustomersPlus.mdb
DBARCHLT\SQL08DE04      SQLNCLI                  SQL Server  DBARCHLT\SQL08DE04

```

```

Linked ExcelSW          Microsoft.Jet.OLEDB.4.0 Jet Excel
C:\TEMP\SWCustomers.xls

```

(3 row(s) affected)

Since the introduction of SQL Server 2005, you can also get the same information via system views set up for this purpose. In this case, you can query the system catalog view `sys.servers` directly to get your information on linked servers:

```

select server_id,
       substring(name,1,26) as 'name',
       substring(product,1,10) as 'Product',
       substring(provider,1,24) as 'Provider',
       substring(data_source,1,25) as 'Source'
from sys.servers
order by server_id

```

```

go
id  name                                Product  Provider                                Source
-----
0   DBARCHLT\SQL08DE04                    SQL Server  SQLNCLI                                DBARCHLT\SQL08DE04
3   ACCESS_DATABASE_CUSTOMERS             Access     -Microsoft.Jet.OLEDB C:\temp\
CustomersPlus.mdb
4   Linked ExcelSW                         Jet Excel  -Microsoft.Jet.OLEDB C:\TEMP\
SWCustomers.xls

(3 row(s) affected)

```

sp_dropserver

To unregister linked servers, you can use `sp_dropserver`. Only members of the `sysadmin` and `setupadmin` fixed server roles can execute this stored procedure:

```
sp_dropserver [@server =] 'server' [, [@droplogins =] {'droplogins' | NULL}]
```

The elements of the syntax are as follows:

- ▶ **server**—The linked server that will be unregistered.
- ▶ **droplogins**—An argument that specifies the logins associated with the server should be dropped. If this argument is not specified, the server is dropped only if logins do not exist for this linked server.

The following example unregisters Oracle, Access, and SQL Server databases:

```

EXECUTE sp_dropserver @server='ORACLE_DATABASE', @droplogins='droplogins'
EXECUTE sp_dropserver @server='ACCESS_DATABASE_CUSTOMERS'
EXECUTE sp_dropserver @server='DBARCH-LT2\SQL08DE01',@droplogins='droplogins'

```

sp_serveroption

You can configure linked servers by using `sp_serveroption`. This affects how distributed queries behave at the linked server provider level. In other words, the options you set with the `sp_serveroption` procedure are for a particular linked server entry only. Only users with the `sysadmin` or `setupadmin` fixed server roles can run this procedure, which has the following syntax:

```

sp_serveroption [[@server =] 'server']
[,[@optname =] 'option_name']
[,[@optvalue =] 'option_value']

```

The elements of the syntax are as follows:

- ▶ **server**—The linked server affected by this option.
- ▶ **option_name**—The name of the option to be configured. The valid option names follow:

Option Name	Description
'collation compatible'	If <code>optvalue</code> is set to <code>TRUE</code> , SQL Server assumes that the linked server has the same character set and collation sequence. Set this option to <code>TRUE</code> only if you are sure the character sets and collation are identical.
'connect timeout'	The length of time, in seconds, to wait before timing out the connection attempt to the linked server. If set to <code>0</code> , this option uses the <code>sp_configure</code> default value.
'data access'	If <code>optvalue</code> is set to <code>TRUE</code> and if the OLE DB provider supports them, distributed queries are allowed. If <code>optvalue</code> is set to <code>FALSE</code> , distributed queries are disabled on this linked server.
'lazy schema validation'	If <code>optvalue</code> is set to <code>TRUE</code> , the check of the schema for remote tables will be skipped at the beginning of the query.
'query timeout'	Length of time, in seconds, to wait before timing out queries against linked server. If set to <code>0</code> , this option uses the <code>sp_configure</code> default value.
'rpc'	If the <code>optvalue</code> is set to <code>TRUE</code> , this option allows RPCs from the linked server.
'rpc out'	If the <code>optvalue</code> is set to <code>TRUE</code> , this option allows RPCs to the linked server.
'use remote collation'	If the <code>optvalue</code> is set to <code>TRUE</code> , this option uses the collation of remote columns for SQL Server data sources or the specified <code>collation name</code> for non-SQL Server sources. If set to <code>FALSE</code> , this option uses the local server default collation.
'collation name'	If <code>use remote collation</code> is set to <code>TRUE</code> and the linked server is not a SQL Server, this option specifies the name of the collation to be used on the linked server. Use this option when the OLE DB data source has a collation that matches one of the SQL Server collations.

- **option_value**—The value of this option. Valid values are `TRUE` (or `ON`) and `FALSE` (or `OFF`), a non-negative integer for the `connect timeout` and `query timeout` options, or a collation name for the `collation name` option.

The following example disables distributed queries to the `ORACLE_DATABASE` linked server:

```
EXECUTE sp_serveroption @server='ORACLE_DATABASE',
@optname='data access', @optvalue='FALSE'
```

The following example enables Remote Procedure Calls to the SQL_SERVER_DB linked server:

```
EXECUTE sp_serveroption @server='SQL_SERVER_DB',
@optname='rpc out', @optvalue='TRUE'
```

To set the query timeout to 60 seconds for the SQL Server data source, you execute the following command:

```
EXECUTE sp_serveroption 'DBARCH-LT2\SQL08DE01', 'query timeout', 60
```

To display the options currently enabled for a linked server, you use `sp_helpserver`:

```
EXECUTE sp_helpserver @server='DBARCH-LT2\SQL08DE01'
GO
name                network_name        status  id connect..
-----
DBARCH-LT2\SQL08DE01 DBARCHLT\SQL2005SUB rpc..    0  0  60
```

Mapping Local Logins to Logins on Linked Servers

For a user to gain access to a linked server, the linked server must validate the user for security reasons. The requesting server (that is, the local server) provides a login name and password to the linked server on behalf of the local server user. For this to work, you need to map the local logins with the linked server logins you are going to use. Remember that `sp_addlinkedserver` creates a default self-mapping for all local logins to the linked server. You use `sp_addlinkedsrvlogin` to specifically control the logins that you want to use the linked server.

sp_addlinkedsrvlogin

SQL Server provides the `sp_addlinkedsrvlogin` system stored procedure to map local logins to logins on the linked servers. This stored procedure can be executed by members of the `sysadmin` and `securityadmin` fixed server roles. Its syntax is as follows:

```
sp_addlinkedsrvlogin [@rmtsrvname =] 'rmtsrvname'
[,[@useself =] 'useself']
[,[@locallogin =] 'locallogin']
[,[@rmtuser =] 'rmtuser']
[,[@rmtpassword =] 'rmtpassword']
```

The elements in this syntax are as follows:

- **rmtsrvname**—The linked server that will use this login setting (`@rmtsrvname` parameter).

- ▶ **useself**—The setting that determines whether a user or group of users will use their own usernames and passwords to log in to the linked server (@useself parameter). There are two possible settings:
 - ▶ **'true'**—Local server logins use their own usernames and passwords to log in to the linked server. Consequently, the rmtuser and rmtpassword arguments are ignored. For example, the local jdoe user with a password of shrek would attempt to log in to the linked server with the jdoe username and shrek password.
 - ▶ **'false'**—Local server logins use the arguments specified in rmtuser and rmtpassword to log in to the linked server. For a linked server that does not require usernames and passwords (such as Microsoft Access), these arguments can be set to NULL.
- ▶ **locallogin**—The local logins affected by this mapping (@locallogin parameter). You can designate either an individual login or all local logins. To specify that all logins be affected, you pass a NULL to this argument.
- ▶ **rmtuser**—The username used to connect to the linked server if @useself is set to FALSE (@rmtuser parameter).
- ▶ **rmtpassword**—The password used to connect to the linked server if @useself is set to FALSE (@rmtpassword parameter).

As noted earlier, by default, after you run `sp_addlinkedserver`, all local logins automatically attempt to use their own usernames and passwords to log in to the new linked server. Essentially, SQL Server runs the following statement after `sp_addlinkedserver`:

```
EXECUTE sp_addlinkedsrvlogin @rmtsrvname='My_Linked_Server',
@useself='true', @locallogin=NULL
```

You can delete this default mapping by using `sp_droplinkedsrvlogin`, which is described in the next section.

In Windows Authentication mode, SQL Server submits the Windows username and password to the linked server if the provider supports Windows authentication and if security account delegation is available on both the client and server.

The following example connects all users to the 'ORACLE_DATABASE' linked server, using the 'guest' username and 'confio' password:

```
EXECUTE sp_addlinkedsrvlogin @rmtsrvname='ORACLE_DATABASE',
@useself='false', @rmtuser='guest', @rmtpassword='confio'
```

The following example connects all users to the 'DBARCH-LT2\SQL08DE01' linked server, using their own local usernames and passwords:

```
EXECUTE sp_addlinkedsrvlogin @rmtsrvname='DBARCH-LT2\SQL08DE01',
@useself='true'
```

The following example logs in the local 'RobinOrdes' user as the remote user 'R0rdes' with the 'new_orleans' password to the 'ORACLE_DATABASE' linked server:

```
EXECUTE sp_addlinkedsrvlogin @rmtsrvname='ORACLE_DATABASE',
@useself='false', @locallogin='RobinOrdes', @rmtuser='R0rdes',
@rmtpassword='new_orleans'
```

The following example logs in the Windows user 'Domain1\DonLarson' as the remote user 'DLarson' with the 'five_sons' password:

```
EXECUTE sp_addlinkedsrvlogin @rmtsrvname='ORACLE_DATABASE',
@useself='false', @locallogin='Domain1\DonLarson',
@rmtuser='DLarson', @rmtpassword='five_sons'
```

The following example connects all users to the 'ACCESS_DATABASE_CUSTOMERS' linked server without providing a username or password:

```
EXECUTE sp_addlinkedsrvlogin @rmtsrvname='ACCESS_DATABASE_CUSTOMERS',
@useself='false', @rmtuser=NULL, @rmtpassword=NULL
```

sp_droplinkedsrvlogin

You can delete mappings for linked servers by using `sp_droplinkedsrvlogin`. Members of the `sysadmin` and `securityadmin` fixed server roles can execute this stored procedure:

```
sp_droplinkedsrvlogin [@rmtsrvname =] 'rmtsrvname',
[@locallogin =] 'locallogin'
```

The elements of this syntax are as follows:

- ▶ **rmtsrvname**—The linked server that will lose this login mapping (@rmtsrvname parameter).
- ▶ **locallogin**—The local login that will lose the mapping to the linked server (@locallogin parameter). You can designate either an individual login or all local logins. To specify that all logins should be affected, you pass a `NULL` to this argument.

The following example removes the login mapping for the 'RobinOrdes' user to the 'ORACLE_DATABASE' linked server:

```
EXECUTE sp_droplinkedsrvlogin @rmtsrvname='ORACLE_DATABASE',
@locallogin='RobinOrdes'
```

The following example removes the default login mapping for all users using the 'SQL_SERVER_DB' linked server:

```
EXEC sp_droplinkedserver @rmtsrvname='SQL_SERVER_DB',
@locallogin=NULL
```

sp_helplinkedserver

To determine the current linked server login settings, you run the `sp_helplinkedserver` procedure, which has the following syntax:

```
sp_helplinkedserver [[@rmtsrvname =] 'rmtsrvname',]
[[@locallogin =] 'locallogin']
```

The elements of this syntax are as follows:

- ▶ **rmtsrvname**—The linked server that will have its login settings displayed.
- ▶ **locallogin**—The local login mappings that will be displayed.

The following example shows the `sp_helplinkedserver` output if no arguments are provided:

```
EXECUTE sp_helplinkedserver
GO
```

Linked Server	Local Login	Is Self Mapping	Remote Login
ACCESS_DATABASE_CUSTOMERS	NULL	1	NULL
DBARCHLT\SQL08DE04	NULL	1	NULL
Linked ExcelSW	NULL	1	NULL
ORACLE_DATABASE	NULL	0	guest
ORACLE_DATABASE	RobinOrdes	0	ROrdes

This example displays one line for each linked server login mapping. The first column (Linked Server) shows which linked server owns this mapping. The second column (Local Login) shows which user is affected by this mapping. If set to NULL, this mapping applies to all users who do not have specific mappings. The third column (Is Self Mapping) displays a 1 if the local username and password will be attempted on the remote server. If it displays a 0, the value in the last column (Remote Login) will be used to log in to the remote server. Note that the remote password is not listed for security reasons.

The next example shows the `sp_helplinkedserver` output if only the `rmtsrvname` argument is provided:

```
EXECUTE sp_helplinkedserver @rmtsrvname='ORACLE_DATABASE'
GO
```

Linked Server	Local Login	Is Self Mapping	Remote Login
ORACLE_DATABASE	NULL	0	guest
ORACLE_DATABASE	RobinOrdes	0	ROrdes

The output for this example is identical to that of the preceding example except that only the entries for the specified server are displayed:

The following example shows the `sp_helplinkedserverlogin` output if all arguments are provided:

```
EXECUTE sp_helplinkedserverlogin @rmtsrvname='ORACLE_DATABASE',
  @locallogin='RobinOrdes'
GO
```

Linked Server	Local Login	Is Self Mapping	Remote Login
ORACLE_DATABASE	RobinOrdes	0	R0rdes

Again, the output for this example is identical to that of the previous examples except that it is limited to the server and is user specified.

Obtaining General Information About Linked Servers

You can use both SQL Server Management Studio and the system stored procedures to gather information about linked servers and the referenced data sources. Following are some of the most-often-used system stored procedures:

- ▶ **sp_linkedservers**—This returns a list of linked servers defined on the local server.
- ▶ **sp_catalogs**—This displays a list of catalogs and descriptions for a specified linked server.
- ▶ **sp_indexes**—This shows index information for a specified remote table.
- ▶ **sp_primarykeys**—This returns the primary key columns for the specified table.
- ▶ **sp_foreignkeys**—This lists the foreign keys defined for the remote table.
- ▶ **sp_tables_ex**—This displays table information from the linked server.
- ▶ **sp_columns_ex**—This returns column information for all columns or a specified column for a remote table.
- ▶ **sp_helplinkedserverlogin**—This displays the linked server login mappings for each linked server.

For example, at query prototyping time, it is useful to see all the ways the linked server objects and columns are being referenced (especially when you're dealing with other data sources, such as Excel spreadsheets).

First, the exact linked object name is displayed via the `sp_tables_ex` system stored procedure. In this case, you would see the following for the `ACCESS_DATABASE_CUSTOMERS` linked server just created:

```
EXECUTE sp_tables_ex 'ACCESS_DATABASE_CUSTOMERS'
go
TABLE_CAT TABLE_SCHEM TABLE_NAME          TABLE_TYPE  REMARKS
-----
NULL      NULL           MSysAccessObjects ACCESS TABLE
NULL      NULL           MSysACEs       SYSTEM TABLE
NULL      NULL           MSysObjects    SYSTEM TABLE
NULL      NULL           MSysQueries    SYSTEM TABLE
NULL      NULL           MSysRelationships SYSTEM TABLE
NULL      NULL           SWCustomers    TABLE
```

Then you can see all the table columns of that linked server's data source by using the `sp_columns_ex` system stored procedure. The following command provides the column definitions for the `SWCustomers` Access table for the linked server `'ACCESS_DATABASE_CUSTOMERS'`:

```
EXECUTE sp_columns_ex 'ACCESS_DATABASE_CUSTOMERS'
go
TABLE_CAT TABLE_SCH TABLE_NAME          COLUMN_NAME  TYPE_NAME  SIZE
-----
NULL      NULL      MSysAccessObjects  Data        VarBinary  3992
NULL      NULL      MSysAccessObjects  ID          Long       10
NULL      NULL      SWCustomers        CustomerID  VarChar    255
NULL      NULL      SWCustomers        CompanyName VarChar    255
NULL      NULL      SWCustomers        ContactName VarChar    255
NULL      NULL      SWCustomers        ContactTitle VarChar    255
NULL      NULL      SWCustomers        Address     VarChar    255
NULL      NULL      SWCustomers        City       VarChar    255
NULL      NULL      SWCustomers        Region     VarChar    255
NULL      NULL      SWCustomers        PostalCode Double     15
NULL      NULL      SWCustomers        Country    VarChar    255
NULL      NULL      SWCustomers        Phone     VarChar    255
NULL      NULL      SWCustomers        Fax       VarChar    255
```

Executing a Stored Procedure via a Linked Server

Executing a stored procedure is possible via a linked server. The server hosting the client connection accepts the client's request and sends it to the linked server. The `EXECUTE` statement must contain the name of the linked server as part of its syntax:

```
EXECUTE servername.dbname.owner.procedure_name
```

The following example executes the `sp_helpserver` system stored procedure on the linked server `'DBARCH-LT2\SQL08DE01'`, which simply shows the server configuration information on that remote server:

```
EXEC [DBARCH-LT2\SQL08DE01].[master].[dbo].[sp_helpserver]
```

Setting Up Linked Servers Using SQL Server Management Studio

Although you can set up linked servers and login mappings by directly executing system stored procedures, you can also set them up easily through SQL Server Management Studio.

To create a “SQL Server” linked server, you follow these steps:

1. Open SQL Server Management Studio with a connection to a local server (DBARCHLT\SQL08DE05 in this example).
2. Expand the Server Objects node and then the Linked Servers node.
3. Right-click the Linked Servers node and choose New Linked Server.
4. You are presented with a properties page where you must specify all the connection properties for the linked server. For this example, create a SQL Server database linked server entry. As shown in Figure 54.6, provide the linked server name DBARCHLT\SQL08DE04T (or whatever your server and instance name might be) and click the SQL Server radio button. All the other fields are not needed (and are grayed out).

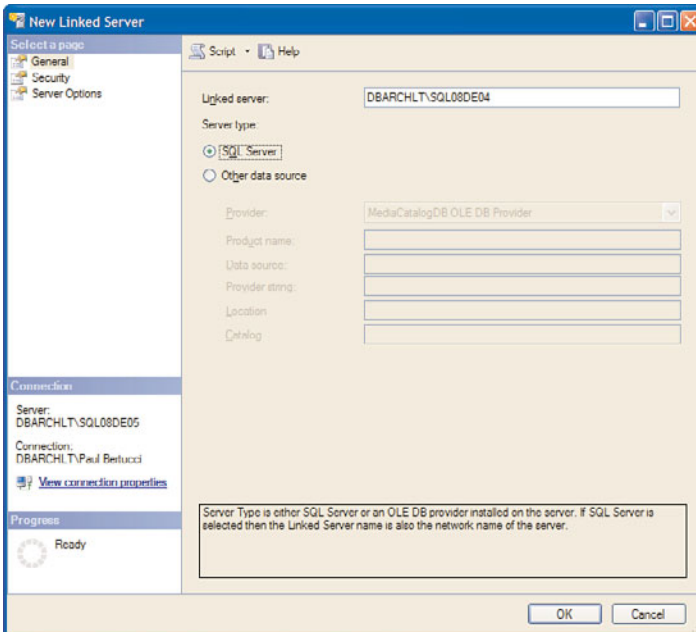

FIGURE 54.6 Creating a “SQL Server” linked server entry through SQL Server Management Studio.

5. After you finish the linked server specification, click OK. An entry is added under the Linked Server node in SQL Server Management Studio. You may receive an

error message complaining about not having the proper authentication for the linked server access. Not to worry; we'll fix that in a minute. The linked server can be used by a SQL query based on the default local logins being mapped to the linked server. However, you really want to control the access to this linked server.

- Right-click the newly created linked server entry and choose Properties. When the properties page comes up, select the Security entry on this page. Figure 54.7 shows explicitly a local login on the local server (DBARCHLT\Paul Bertucci) that you can use to impersonate your login at the linked server (where you are already a valid user on the linked server). Now, also indicate that for any logins not in this list, connections will be made using the login's current security context. This locks it down as tightly as you need it. Click OK, and you are ready to test the linked server.

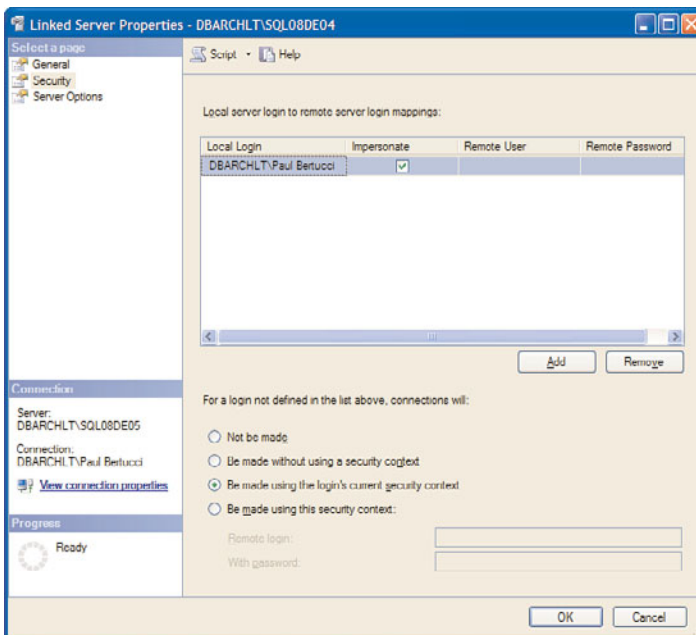

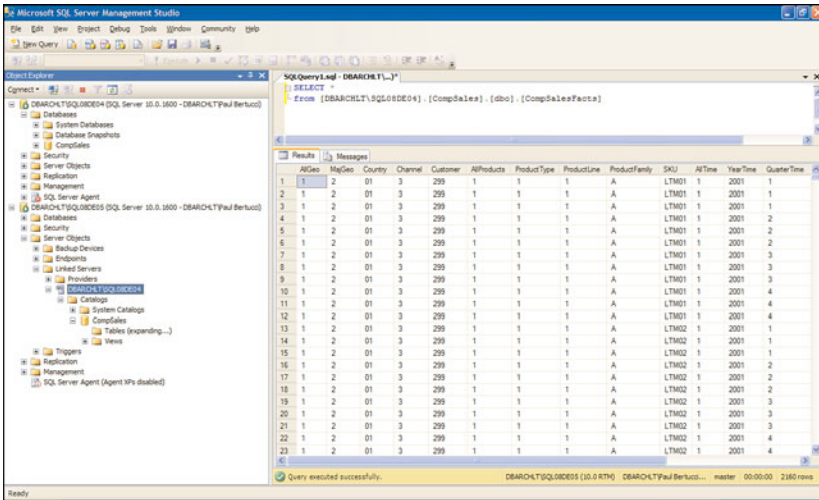

FIGURE 54.7 Specifying the security properties of a new linked server entry.

Figure 54.8 shows the successful execution of a query by user DBARCHLT\Paul Bertucci, using the linked server.

Figure 54.9 shows an example of creating an Access database linked server entry. As you can see, you specify the linked server name ACCESS_DATABASE_CUSTOMERS, click the Other Data Source radio button, pick Microsoft Jet 4.0 OLE DB Provider for Provider, specify Access for the Product Name entry, and supply the full path to the Access database for which you are trying to create the linked server entry (c:\temp\CustomerPlus.mdb). There is no need to specify a provider string for this type of linked server entry. When you click the OK button at the bottom, this linked server is ready to use for a SQL query.

54

FIGURE 54.8 Execution of a SQL query by user **DBARCHLT\Paul Bertucci**, referencing the new linked server entry.

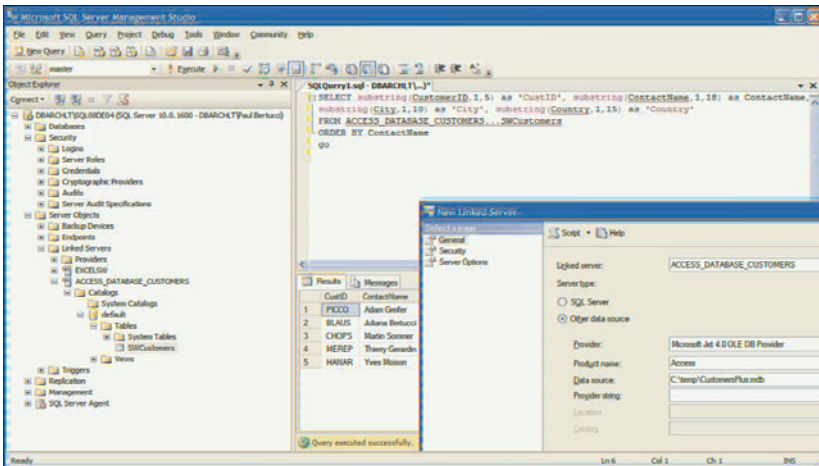

FIGURE 54.9 Creating an Access database linked server through SQL Server Management Studio.

You are now ready to charge ahead in the realm of using linked servers for everyday purposes. As you can see in Figure 54.10, linked servers can take their place in your SQL Server data access layer alongside any traditional SQL table. This capability expands your data access horizons much further than you could have reached before.

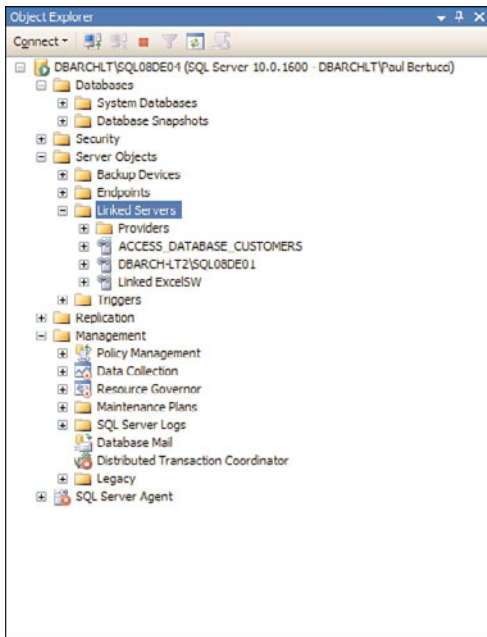

FIGURE 54.10 Several different linked servers from SQL Server Management Studio.

Summary

In this chapter, you saw the difference between the more common linked servers and the old type of remote servers. You also learned how distributed queries and transactions work with linked servers. Specifically, you learned how to set up, configure, and gather information on linked servers by using the system stored procedures, including `sp_addlinkedserver`, `sp_dropserver`, `sp_serveroption`, `sp_linkedserver`, `sp_table_ex`, `sp_column_ex`, `sp_addlinkedsrvlogin`, `sp_droplinkedsrvlogin`, and `sp_helplinkedsrvlogin`. Finally, you learned how to configure linked servers through SQL Server Management Studio and tighten up the security access around the use and execution of linked servers. These foundational skills are the cornerstone of helping your organization expand its reach to data, no matter where it resides.

Keep in mind that although linked servers provide a method to access data in other data sources beyond SQL Server, at times you might need to work with data in a data source that cannot be linked. In these rare circumstances, you can still use BCP to import data files that have been exported from other data sources into local SQL Server tables or create SSIS packages to periodically pull, push, and transform data to other locations.

CHAPTER 55

Configuring, Tuning, and Optimizing SQL Server Options

This chapter delves into what can be done with the SQL Server configurable options—particularly what can be improved that SQL Server isn't automatically tuning already. By setting the values of several key SQL Server configuration parameters, you can fine-tune SQL Server to provide excellent performance and throughput. Note that with each release of SQL Server, less needs to be tuned from a SQL Server configuration point of view. With the advent of self-tuning or self-configuring options, it is only a matter of time before most of your server tuning time will be spent elsewhere, such as with the operating system, disk systems, and network interfaces—and only because SQL Server can't reach there (yet). As you also see in Chapter 39, “Monitoring SQL Server Performance,” many SQL Server components can be monitored and tuned to yield high performance. Some of the options discussed here also surface in that chapter, from a monitoring point of view.

This chapter also covers one of Microsoft's hidden capabilities, the Database Engine Tuning Advisor. This tool can make table, partitioning, and index tuning recommendations to support certain workloads. Understanding the Database Engine Tuning Advisor as well as the SQL Server–configurable options can pay off rather quickly for you in your never-ending performance quest. This chapter also covers the newest feature for SQL Server 2008: the Data Collection services. It provides just a brief view of how the server options that you are adjusting can be easily viewed and interpreted by utilizing the right data collection set reports.

IN THIS CHAPTER

- ▶ What's New in Configuring, Tuning, and Optimizing SQL Server Options
- ▶ SQL Server Instance Architecture
- ▶ Configuration Options
- ▶ Fixing an Incorrect Option Setting
- ▶ Setting Configuration Options with SSMS
- ▶ Obsolete Configuration Options
- ▶ Configuration Options and Performance
- ▶ Database Engine Tuning Advisor
- ▶ Data Collection Sets

What's New in Configuring, Tuning, and Optimizing SQL Server Options

There are a few new configuration options in SQL Server 2008 R2. These new configuration options are user instance oriented (for SQL Server 2008 Express only), for FileStream, Compression, and are Access Check Cache options. However, you must be warned that there are options available that are not obsolete yet but have no effect (even if you set them). We identify them in this chapter as they come up.

SQL Server 2000 had a total of 36 options. With SQL Server 2005, the number of options nearly doubled, with a total of 64 (basic and advanced) active options. There are now 70 basic and advanced options in SQL Server 2008 R2. Not all are usable, and some apply only to certain OS platforms (64-bit) or SQL Server editions. Only 68 basic and advanced options appear on 32-bit-based platforms.

NOTE

You can't use Allow Updates, Open Objects, or the Set Working Set Size `sp_configure` options. They have become obsolete and have no effect in SQL Server 2008, even though they are still listed. The Web Assistant Procedures option doesn't exist anymore either. In addition, Microsoft has announced that all the `ft_crawl` and `ft_notify` options (`ft` = File Text) will be deprecated.

This chapter discusses the configuration options as well as the Database Engine Tuning Advisor (DTA) and some of the reports available via the Data Collection service within SQL Server Management Studio's (SSMS's) management options. Microsoft is improving in these areas, with new tuning analysis, improved recommendation reports, and now data collection reports that can give you an overall picture of how your SQL Server instance is performing.

SQL Server Instance Architecture

Figure 55.1 illustrates the address space architecture of an instance of SQL Server 2008 R2. When you fire up a SQL Server instance, two main areas are allocated: the code area and memory pool area. The code area is mostly static executable code of the SQL Server kernel; SQL Server .NET Library DLLs; Open Data Services code; the stack space; and a variable code area that contains distributed query OLE DB providers, OLE automation objects, and extended stored procedures as they are needed by user requests.

The memory pool area of SQL Server is the most dynamically changing part of an instance. Even now, the once-static system data structures and user connection structures (connection context) are controlled by user requests and dynamically allocate structures as they are needed. Then, there are the primary SQL Server databases `master`, `tempdb`, `msdb`, and `model`. There is another system database called a *resource database* that is present in each SQL Server instance. This read-only database contains system objects that are included with SQL Server. System objects are physically persisted in the resource database,

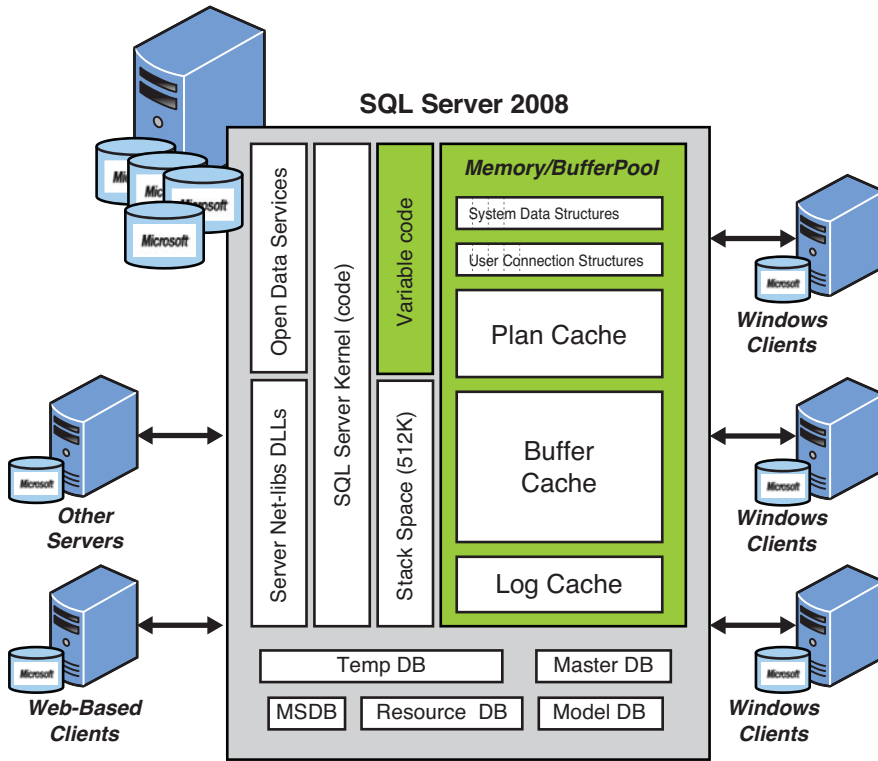

FIGURE 55.1 The SQL Server 2008 R2 instance architecture.

but they logically appear in the sys schema of every database and provide the results to system-level information such as server properties (SERVERPROPERTY) and object definitions (OBJECT_DEFINITION). Of these system-wide databases, tempdb has the most significance for performance because it is the heart of all internal tables, indexing, sorting, grouping, and other worktable activity for the entire SQL Server instance.

By default, SQL Server tries to keep the amount of virtual memory allocations on a computer at 4MB to 10MB less than the physical memory available. The rest of the memory pool area is divided into procedure cache, data cache (buffer cache), and log cache. SQL Server actively adjusts these for optimal performance. Previously, the system administrator had to do all this manually. Many of the configurable options directly relate to optimizing this address space. There is a caching framework that utilizes internal and external clocks to determine how the caches are managed; it is explained in Chapter 39.

Configuration Options

With SQL Server 2008, many options may affect the performance of individual SQL statements or the overall performance of a SQL Server instance. There are instance-wide configuration options (set using the sp_configure system stored procedure or with the server

properties dialog within SSMS), database-level options (set with `ALTER DATABASE`), database compatibility levels (using the `sp_dbcmtlevel` system stored procedure), batch-level options (using the `SET` command for things such as `SET ANSI_NULLS`), and statement-level options (such as table hints, query hints, and join hints). Always remember that a hint overrides a `SET` option, a `SET` option overrides a database option, and a database option overrides an instance-wide option.

For SQL Server 2008, this chapter discusses the instance-wide configurable options in two distinct categories: basic options and advanced options. The advanced options are a super-set of the basic options. As each option is discussed, this chapter notes whether it is self-configuring. A *self-configuring option* is an option that adjusts itself dynamically, according to the needs of the system. In most cases, this eliminates the need for setting the values manually. Sometimes you don't want to rely on certain self-configuring values, depending on how SQL Server is being used. This chapter identifies self-configuring values.

As you can see in Figure 55.2, SQL Server provides configuration parameters that the system administrator can set to maximize the performance of a system from the properties option within SSMS. You can set these and other SQL Server configuration parameters by using the `sp_configure` system stored procedure as well.

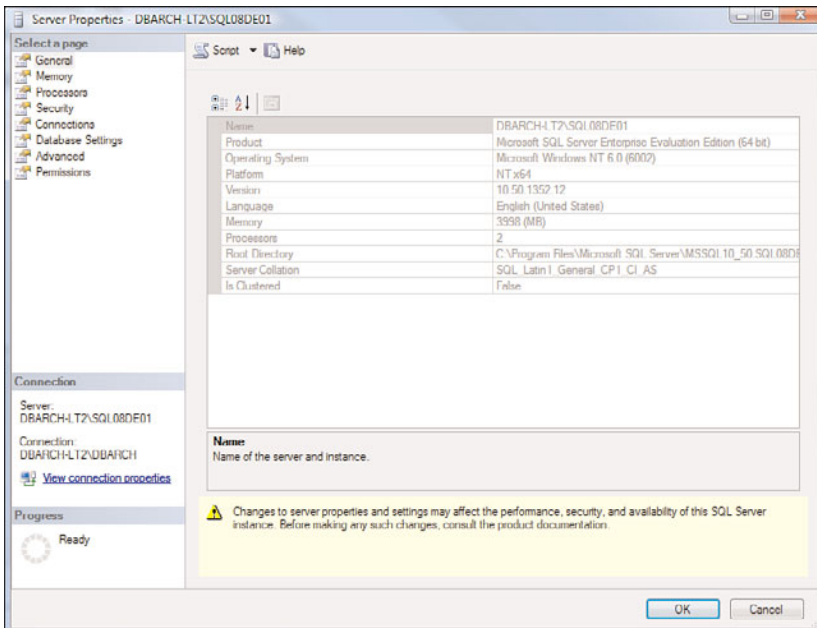

FIGURE 55.2 SQL Server 2008 Configuration Properties dialog from SSMS.

Now, the only questions that need to be answered are “What configuration options do I need to set that aren’t already fine?” and “How do I set them?”

To answer the “what” question, you first need to determine for what purpose the applications are using SQL Server. The answer must include understanding variables such as the number of potential connections to support, resources available on the box, size of the database, type of data accesses occurring, and workload being put on SQL Server. When you know all this, it is easy to determine the configuration option setting to adjust.

The following shows a generalization of the types of applications you might find in the real world that would be implemented using SQL Server 2008 and the general behavior they elicit:

- ▶ **Online transaction processing (OLTP)**—Mix of reads, writes, updates, and deletes. Large number of concurrent users.
- ▶ **Data warehouse**—Incremental loads (deltas), aggregation/transformation processing, then primarily read-only. Medium number of users.
- ▶ **Online analytical processing (OLAP)**—Big loads, then primarily read-only. Medium to large number of simultaneous users.
- ▶ **Mixed server**—Mix of reads, writes, updates, deletes, big loads, and big extracts. Large number of users.

This is not a complete list, just a generalized list. Because these configuration options are set at the SQL Server level, it is important to know the combined behavior of all application processing. For each SQL Server configuration option discussed in this chapter, we recommend an appropriate setting, based on these generalized application processing behavior types.

Now let’s answer the “How do I set them?” question. The next few sections describe all the types of configuration options available on SQL Server 2008. These sections show how to set these configuration options using both SSMS and the `sp_configure` system stored procedure. The rule is that you can certainly set a configuration option using SSMS, but you should keep an `sp_configure` version of that setting change as a backup in case you need to rebuild the entire server configuration from scratch. In addition, keeping an `sp_configure` version around in a file provides a great audit trail of what you did and why. If you simply execute `sp_configure` without parameters, you are given a list of options that can be addressed. When you have just installed a SQL Server instance, you can see only the basic configuration options.

SQL Server 2008 has 16 basic configuration options available:

```
exec sp_configure
go
name                minimum    maximum    config_value run_value
-----
allow updates       0          1          0            0
backup compression default 0          1          0            0
clr enabled         0          1          0            0
cross db ownership chaining 0          1          0            0
default language    0          9999       0            0
```

filestream access level	0	2	0	0
max text repl size (B)	-1	2147483647	65536	65536
nested triggers	0	1	1	1
remote access	0	1	1	1
remote admin connections	0	1	0	0
remote login timeout (s)	0	2147483647	20	20
remote proc trans	0	1	0	0
remote query timeout (s)	0	2147483647	600	600
server trigger recursion	0	1	1	1
show advanced options	0	1	0	0
user options	0	32767	0	0

By default, all SQL Server users have permission to run the `sp_configure` system stored procedure, but only users who have `sysadmin` and `serveradmin` fixed server roles (such as `sa`) can actually set the value of a parameter.

The proper syntax of the `sp_configure` command is as follows:

```
exec sp_configure [parameter_name [, parameter_value ]]
```

In this syntax, *parameter_name* is the name of the configuration parameter you want to set, and *parameter_value* is the value for the parameter. Both of these parameters are optional. Parameters set by `sp_configure` take effect at the server level.

Following is a brief explanation of the output of the `sp_configure` command. As you can see, the output consists of five columns:

- ▶ **Name**—This is the name of the configurable option.
- ▶ **Minimum**—This is the minimum legal value allowed for this parameter. Passing an illegal value causes SQL Server to return an error.
- ▶ **Maximum**—This is the maximum legal value allowed for this parameter. Passing an illegal value causes SQL Server to return an error.
- ▶ **Config_value**—This column reflects the values that will take effect the next time SQL Server is started. If you change static parameters, the new values are listed under this column.
- ▶ **Run_value**—This column reflects the values that SQL Server is currently using. If you change any dynamic parameters, the new values are listed in this column. At the time of SQL Server startup, `config_value` for all the parameters is copied into `run_value`. Immediately after restart, both columns (`run_value` and `config_value`) should display the same values, corresponding to each parameter.

If you specify a parameter name, SQL Server returns the current configuration value for that particular parameter, as in this example:

```
exec sp_configure 'clr enabled'
go
name                minimum    maximum    config_value run_value
```

```
-----
clr enabled                0          1          0          0
```

There are many more than 16 basic configuration options. In fact, there are 70 configuration options in total. They consist of the original 16 basic options plus 54 advanced options (including two for 64-bit processing). To see a complete list of all options, you turn on the `show advanced options configuration` option with the value 1.

In addition, when using `sp_configure` to change a setting, you use the `RECONFIGURE WITH OVERRIDE` statement to make the change take effect immediately. You can also choose to use just the `RECONFIGURE` statement. Depending on the configuration option, it may take effect immediately, or it may not take effect until the server has been restarted.

The following commands set the `show advanced options configuration` option and then retrieve the complete list of all configuration options:

```
exec sp_configure 'Show Advanced Options', 1      /* Advanced config options */
go
RECONFIGURE WITH OVERRIDE                        /* to have it take effect immediately */
go
sp_configure
go
name                minimum      maximum      config_value run_value
-----
access check cache bucket count    0          65536       0          0
access check cache quota           0          2147483647  0          0
Ad Hoc Distributed Queries          0          1           0          0
affinity I/O mask                  -2147483648 2147483647  0          0
affinity mask                      -2147483648 2147483647  0          0
affinity64 I/O mask                -2147483648 2147483647  0          0
affinity64 mask                    -2147483648 2147483647  0          0
Agent XPs                          0          1           1          1
allow updates                      0          1           0          0
awe enabled                        0          1           0          0
backup compression default         0          1           0          0
blocked process threshold (s)      0          86400       0          0
c2 audit mode                      0          1           0          0
clr enabled                        0          1           0          0
common criteria compliance enabled  0          1           0          0
cost threshold for parallelism     0          32767       5          5
cross db ownership chaining        0          1           0          0
cursor threshold                   -1         2147483647 -1         -1
Database Mail XPs                  0          1           0          0
default full-text language         0          2147483647 1033       1033
default language                   0          9999        0          0
default trace enabled              0          1           1          1
disallow results from triggers     0          1           0          0
```

EKM provider enabled	0	1	0	0

xp_cmdshell	0	1	0	0

Microsoft suggests that only very experienced SQL Server administrators change these advanced configuration options. In general, this is good advice because most of these options are set to where you might want them as you start out. As you learn more about your application and the other things happening in your SQL Server instance, you will change them more and more. You have been warned!

Earlier SQL Server 2008 R2 documentation also listed a configuration option, `enable_force_flush`, that wasn't present in the November Community Technology Preview (CTP) for R2. We're not sure whether we will see it very soon.

With SQL Server 2008, you can see all the configuration options and their current settings via system views. The `sys.configurations` view shows the option, a description, and the current value in use for each configuration option. The following example shows what you might expect to see if you query the `sys.configurations` view:

```
SELECT convert(varchar(10),value_in_use) AS 'Value in Use',
substring (name,1,30) AS 'Configuration Option',
substring (description,1,30) AS 'Description'
FROM sys.configurations
ORDER BY 2
```

Go

Value in Use	Configuration Option	Description
0	access check cache bucket coun	Default hash bucket count for
0	access check cache quota	Default quota for the access c
0	Ad Hoc Distributed Queries	Enable or disable Ad Hoc Distr
0	affinity I/O mask	affinity I/O mask
0	affinity mask	affinity mask
0	affinity64 I/O mask	affinity64 I/O mask
0	affinity64 mask	affinity64 mask
1	Agent XPs	Enable or disable Agent XPs
0	allow updates	Allow updates to system tables
0	awe enabled	AWE enabled in the server
0	backup compression default	Enable compression of backups
0	blocked process threshold (s)	Blocked process reporting thre
0	c2 audit mode	c2 audit mode
0	clr enabled	CLR user code execution enable
0	common criteria compliance ena	Common Criteria compliance mod
5	cost threshold for parallelism	cost threshold for parallelism
0	cross db ownership chaining	Allow cross db ownership chain
-1	cursor threshold	cursor threshold
0	Database Mail XPs	Enable or disable Database Mai
1033	default full-text language	default full-text language
0	default language	default language
1	default trace enabled	Enable or disable the default

0	disallow results from triggers	Disallow returning results fro
0	EKM provider enabled	Enable or disable EKM provider
0	filestream access level	Sets the FILESTREAM access lev
0	fill factor (%)	Default fill factor percentage
100	ft crawl bandwidth (max)	Max number of full-text crawl
0	ft crawl bandwidth (min)	Number of reserved full-text c
100	ft notify bandwidth (max)	Max number of full-text notifi
0	ft notify bandwidth (min)	Number of reserved full-text n
0	index create memory (KB)	Memory for index create sorts
0	in-doubt xact resolution	Recovery policy for DTC transa
0	lightweight pooling	User mode scheduler uses light
0	locks	Number of locks for all users
0	max degree of parallelism	maximum degree of parallelism
4	max full-text crawl range	Maximum crawl ranges allowed
2147483647	max server memory (MB)	Maximum size of server memory
65536	max text repl size (B)	Maximum size of a text field i
0	max worker threads	Maximum worker threads
0	media retention	Tape retention period in days
1024	min memory per query (KB)	minimum memory per query (kByt
0	min server memory (MB)	Minimum size of server memory
1	nested triggers	Allow triggers to be invoked w
4096	network packet size (B)	Network packet size
0	Ole Automation Procedures	Enable or disable Ole Automati
0	open objects	Number of open database object
0	optimize for ad hoc workloads	When this option is set, plan
60	PH timeout (s)	DB connection timeout for full
0	precompute rank	Use precomputed rank for full-
0	priority boost	Priority boost
0	query governor cost limit	Maximum estimated cost allowed
-1	query wait (s)	maximum time to wait for query
0	recovery interval (min)	Maximum recovery interval in m
1	remote access	Allow remote access
0	remote admin connections	Dedicated Admin Connections ar
20	remote login timeout (s)	remote login timeout
0	remote proc trans	Create DTC transaction for rem
600	remote query timeout (s)	remote query timeout
0	Replication XPs	Enable or disable Replication
0	scan for startup procs	scan for startup stored proced
1	server trigger recursion	Allow recursion for server lev
0	set working set size	set working set size
1	show advanced options	show advanced options
1	SMO and DMO XPs	Enable or disable SMO and DMO
0	SQL Mail XPs	Enable or disable SQL Mail XPs
0	transform noise words	Transform noise words for full
2049	two digit year cutoff	two digit year cutoff
0	user connections	Number of user connections all

0	user options	user options
0	xp_cmdshell	Enable or disable command shell

Dynamically changing configuration options are also updated so that their values are visible through the system views.

Fixing an Incorrect Option Setting

Setting a parameter value too high might cause SQL Server to crash during startup. For example, if you set the value of the memory option to a value that is higher than the physical memory on the machine, SQL Server does not start. In this case, you start SQL Server with the `-f` option, which causes SQL Server to start with the default parameter values (the same values used by the Setup program when you installed SQL Server). After SQL Server is running, you can change the incorrect value to the correct one and restart SQL Server without the `-f` option.

Setting Configuration Options with SSMS

As mentioned previously, you can set SQL Server configuration options by using SSMS. You simply invoke SSMS from the Microsoft SQL Server program group and right-click the Server folder. In Figure 55.2, you can see the SQL Server Properties pane, the different server categories of options that are available (General, Processors, Memory, and so on), and the selected option category properties that can be adjusted. Keep in mind that some of these options are not configuration options that correspond to `sp_configure` (for example, the Root Directory or Platform properties of the General Server Instance properties options). However, as you will see, Microsoft has done a nice job of organizing and presenting the option information. In addition, you can look at either the configured option value or the running values. If you are manipulating these, they may not be the same.

Not all 70 configuration options can be set from SMSS; only about half of them can. It's therefore best to get to know the `sp_configure` system stored procedure. Remember that you must have `sysadmin` and `serveradmin` fixed server roles to make changes.

All the `sp_configure` settings and options used in this chapter are included in a SQL script named `SQLConfigOptions.sql` that you can find on the CD for this book.

Obsolete Configuration Options

Many configuration options available in SQL Server 7.0 or SQL Server 2000 have become obsolete or do not function any longer. Some options, such as `time slice`, were introduced in SQL Server 7.0 and then immediately became obsolete.

The following configuration options are obsolete in SQL Server 2008:

- ▶ Allow Update (remains listed but cannot be set)

- ▶ `set working set size` (remains listed but has no effect)
- ▶ `Open Objects` (remains listed but has no effect)

From a historical perspective, one of the all-time favorite options in SQL Server 7.0 was `max async IO`. The reason that option became obsolete is that it is completely automated with SQL Server 2000, SQL Server 2005, and SQL Server 2008. Previously, `max async IO` was used to specify the number of simultaneous disk I/O requests that SQL Server 7.0 (and earlier versions) could submit to the Windows OS during a checkpoint operation. It invariably helped overall throughput on systems that used RAID devices that had extensive disk cache mechanisms. SQL Server 2008 adjusts these options automatically.

Configuration Options and Performance

The following sections explain essential information about many of the most significant SQL Server configuration options and their impact on SQL Server performance. Some of the options don't have performance implications and therefore may not be addressed in much detail—or at all. As part of each option's explanation, an indication of whether the option is advanced or basic is given, along with the option's default value and whether the option is self-configuring. Recommended values are usually indicated for the different types of generalized application processing that the SQL Server is used for (that is, OLTP, OLAP, data warehouse, and mixed). For some configuration options, there may not be recommended values, but perhaps there may be notes that further explain how they can be used. Remember that there are 70 configuration options; this chapter focuses on the essential ones in alphabetical order (how they are listed in SQL Server).

access check cache bucket count

Type: Advanced Option

Default Value: 0

When any database object is accessed by SQL Server, the access check is cached in an internal structure named `access check result cache`. The `access check cache bucket count` option controls the number of entries and number of hash buckets used for `access check result cache`.

Possible performance gains can be made by changing these options (in rare circumstances). In general, you should leave this one alone.

The following is an example of this option:

```
exec sp_configure 'access check cache bucket count', 0
go
RECONFIGURE
Go
```

access check cache quota

Type: Advanced Option

Default Value: 0

In conjunction with `access check cache bucket count` option, when SQL server accesses any database object, the access check is cached in an internal structure named `access check result cache`. The `access check cache bucket count` option, along with the `access check cache quota` option, controls the number of entries and number of hash buckets used for `access check result cache`.

Possible performance gains can be made by changing these options (in rare circumstances). But, in general, you should leave this one alone also.

The following is an example of this option:

```
exec sp_configure 'access check cache quota', 0
go
RECONFIGURE
Go
```

ad hoc distributed queries

Type: Advanced Option

Default Value: 0

SQL Server does not allow ad hoc distributed queries using `OPENROWSET` and `OPENDATASOURCE` against providers other than the SQL Native Client OLE DB provider. When the `ad hoc distributed queries` option is set to 0, SQL Server allows ad hoc access against other providers. When it is set to 1, SQL Server does not allow any ad hoc access.

Ad hoc distributed queries use the `OPENROWSET` and `OPENDATASOURCE` functions to connect to remote data sources using OLE DB. `OPENROWSET` and `OPENDATASOURCE` should be used only to reference OLE DB data sources that are accessed infrequently. For any data sources that will be accessed more than a few times, you should define a linked server. Enabling the use of ad hoc queries means that any authenticated login to SQL Server can access the provider. SQL Server administrators should enable this feature only for highly trusted providers that are safe to be accessed by any local login.

The following is an example of this option:

```
exec sp_configure 'Ad Hoc Distributed Queries', 1
go
RECONFIGURE
Go
```

affinity I/O mask

Type: Advanced option; requires a reboot of SQL Server to take effect

Default value: 0

In Windows Servers, multitasking sometimes requires that process threads move among different processors. This type of movement of processing threads can reduce Microsoft SQL Server performance under heavy system loads because each processor cache is repeatedly reloaded with data. Assigning processors to specific threads can improve performance by eliminating processor reloads; such an association between a thread and a processor is called *processor affinity*. SQL Server 2008 supports processor affinity by means of two affinity mask options: *affinity mask* (to deal with the processor affinity needs) and *affinity I/O mask* (to address I/O-related affinity). Affinity support for servers with 33 to 64 processors is available only on 64-bit operating systems.

The *affinity I/O mask* option binds SQL Server disk I/O to a specified subset of CPUs. In high-end SQL Server OLTP environments, this extension can enhance the performance of SQL Server threads issuing I/Os. This enhancement does not support hardware affinity for individual disks or disk controllers.

The value for *affinity I/O mask* specifies which CPUs in a multiprocessor computer are eligible to process SQL Server disk I/O operations. The mask is a bitmap in which the rightmost bit specifies the lowest-order CPU (0), the bit to its immediate left specifies the next-lowest-order CPU (1), and so on. To configure more than 32 processors, you set both *affinity I/O mask* and *affinity64 I/O mask*. When all bits are set to 0 (or *affinity I/O mask* is not specified), SQL Server disk I/O is scheduled to *any* of the CPUs eligible to process SQL Server threads.

The values for *affinity I/O mask* are as follows:

- ▶ A 1-byte *affinity I/O mask* value covers up to 8 CPUs in a multiprocessor computer.
- ▶ A 2-byte *affinity I/O mask* value covers up to 16 CPUs in a multiprocessor computer.
- ▶ A 3-byte *affinity I/O mask* value covers up to 24 CPUs in a multiprocessor computer.
- ▶ A 4-byte *affinity I/O mask* value covers up to 32 CPUs in a multiprocessor computer.

To cover more than 32 CPUs, you configure a 4-byte *affinity I/O mask* value for the first 32 CPUs and up to a value-byte *affinity64 I/O mask* value for the remaining CPUs.

A 1 bit in the *affinity I/O* pattern specifies that the corresponding CPU is eligible to perform SQL Server disk I/O operations; a 0 bit specifies that no SQL Server disk I/O operations should be scheduled for the corresponding CPU.

An example of the bitmask values for the first seven processors of an eight-processor system follows (with decimal values shown in parentheses):

Bitmask	Processors Used
00000001 (1)	0
00000011 (3)	0, 1
00000111 (7)	0, 1, 2
00001111 (15)	0, 1, 2, 3
00011111 (31)	0, 1, 2, 3, 4
00111111 (63)	0, 1, 2, 3, 4, 5
01111111 (127)	0, 1, 2, 3, 4, 5, 6

Because setting the SQL Server `affinity I/O mask` option is a specialized operation, it should be used only when necessary. When specifying the `affinity I/O mask` option, you must use it with the `affinity mask` configuration option. You should not enable the same CPU in both the `affinity I/O mask` switch and the `affinity mask` option. The bits corresponding to each CPU should be in one of the following three states:

- ▶ 0 in both the `affinity I/O mask` option and the `affinity mask` option
- ▶ 1 in the `affinity I/O mask` option and 0 in the `affinity mask` option
- ▶ 0 in the `affinity I/O mask` option and 1 in the `affinity mask` option

In SQL Server 2008, reconfiguring the `affinity I/O mask` option requires a restart of the SQL Server instance.

The following is an example of this option:

```
exec sp_configure 'affinity I/O mask', 1
go
RECONFIGURE
Go
```

`Affinity64 I/O mask` is available only in the 64-bit version of SQL Server.

affinity mask

Type: Advanced option

Default value: 0

When a server is experiencing a heavy load because other applications are running on the same server, it might be desirable to bind thread affinity to a processor.

`affinity mask` is a bitmapped field that provides SQL Server threads an affinity to processors. This is typically used in conjunction with the `affinity I/O mask` option just described. Starting from the least-significant digit, each bit that is set to 1 represents the processor on which SQL Server will spawn its threads. Processors are numbered from 0 to 7. An example of the bitmask values for the first seven processors of an eight-processor system follows (with decimal values shown in parentheses):

Bitmask	Processors Used
00000001 (1)	0
00000011 (3)	0, 1
00000111 (7)	0, 1, 2
00001111 (15)	0, 1, 2, 3
00011111 (31)	0, 1, 2, 3, 4
00111111 (63)	0, 1, 2, 3, 4, 5
01111111 (127)	0, 1, 2, 3, 4, 5, 6

You usually leave the eighth processor alone because many system processes—such as domain controllers—default to that processor.

For example, if you want to create the affinity for one SQL Server instance's threads to use four processors of an eight-processor system, you would set this bitmask to be 15 (00001111). As a result, SQL Server would spawn its threads only on those processors, thus reducing overall reloading of the processor cache. This can be especially evident during heavy system loads.

The following is an example of this option:

```
exec sp_configure 'affinity mask', 15
go
RECONFIGURE
Go
```

In general, the default affinity value is able to provide ample load balancing across processors. You should allocate CPUs based on your particular processing load and application types. `affinity64 mask` is available only on the 64-bit version of SQL Server.

Following is a general recommendation of what to specify based on the different application types you are running:

- ▶ **OLTP**—Use the default value, 0.
- ▶ **Data warehouse**—Potentially use 75% of available processors to maximize the huge data loads, large reporting, and number of users.
- ▶ **OLAP**—Use the default value, 0.
- ▶ **Mixed**—Use the default value, 0.

From SSMS, you select SQL Server Properties, open the Processor tab, and select the targeted processors in the Enable Processors section, as shown in Figure 55.3.

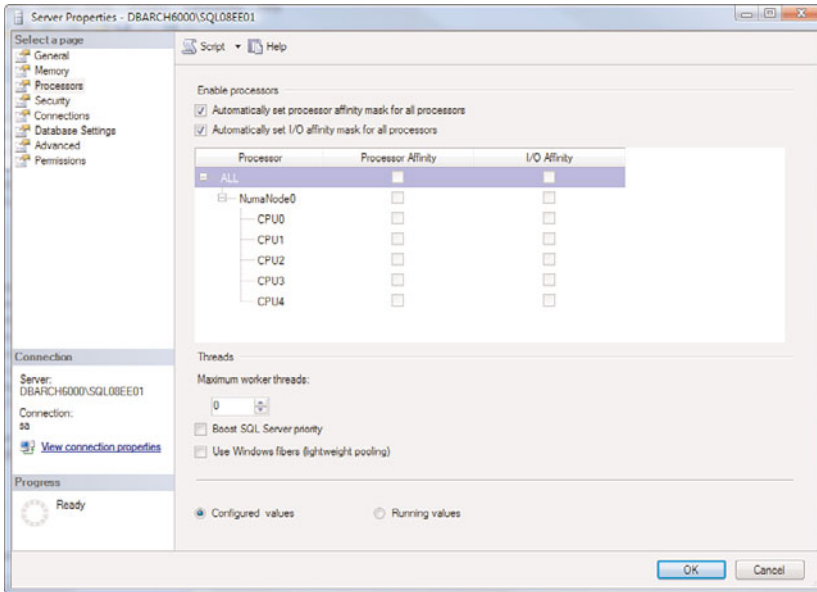

FIGURE 55.3 SQL Server 2008 processors' configurations from SSMS.

Agent XP

Type: Advanced

Default value: 0

The Agent XP option enables SQL Server 2008 Agent extended stored procedures for this server. If enabled, the SQL Server Agent is available in SSMS. If not enabled, the SQL Server Agent is not available in SSMS and cannot be used to start or stop the service. This option also supports direct execution of CLR assemblies. It is not optimized to do so; it just supports this.

A 0 value indicates that SQL Server Agent extended stored procedures are not available (the default). A value of 1 indicates that the SQL Server Agent extended stored procedures are available.

awe enabled

Type: Advanced; requires a reboot of SQL Server to take effect

Default value: 0

SQL Server can use the Advanced Windowing Extensions (AWE) API to support large amounts of physical memory. In fact, the specific amount of memory you can use

depends on your hardware configuration and operating system support. The amount of physical memory supported has increased with the introduction of Microsoft Windows Server operating systems:

- ▶ Windows Server Standard Edition supports physical memory up to 4GB.
- ▶ Windows Server Enterprise Edition supports physical memory up to 32GB.
- ▶ Windows Server Datacenter Edition supports physical memory up to 64GB.

The default of 0 for the `awe enabled` option tells SQL Server to use dynamic memory in standard 32-bit virtual address spaces. When you enable AWE, the SQL Server instance does not dynamically manage the size of the address space. The instance holds all memory acquired at startup until it is shut down, and memory pages come from the Windows nonpageable pool. This means that none of the memory of the instance can be swapped out. You end up with a great deal of activity occurring in memory only. This is potentially a fast Database Engine.

NOTE

Releases of SQL Server before SQL Server 2005 supported dynamic memory, which allowed SQL Server to automatically adjust memory usage when there was spare memory on the system. However, SQL Server was limited by the amount of memory available at startup. Starting with SQL Server 2005, this limit on startup memory availability is removed. SQL Server 2005 and 2008 support Hot Add Memory in Microsoft Windows Servers, which allows users to add physical memory without restarting the server.

Hot Add Memory requires SQL Server 2008 Enterprise Edition and is available only for 64-bit SQL Server and for 32-bit SQL Server when AWE is enabled. Hot Add Memory is not available for 32-bit SQL Server when AWE is not enabled. Hot Add Memory is available only for Windows Servers Enterprise and Datacenter Editions. It also requires special hardware supported by the hardware vendor.

`awe enabled` is usually used in conjunction with the `max server memory` option to control how much memory each SQL Server instance uses.

The following is an example of this option:

```
sp_configure 'awe enabled', 1
go
RECONFIGURE
Go
```

Following is a general recommendation of what to specify based on the different application types you are running:

- ▶ **OLTP**—If memory is available, set it to 1.
- ▶ **Data warehouse**—Not appropriate for this type.

- ▶ **OLAP**—If memory is available and you are not using OLAP file options, set it to 1.
- ▶ **Mixed**—If memory is available, set it to 1.

backup compression default

Type: Basic

Default value: 0

Starting with SQL Server 2008 Enterprise, you can use the `BACKUP Transact-SQL` statement to select the backup compression setting to use `WITH COMPRESSION` or `WITH NO_COMPRESSION`. However, when you install SQL Server 2008, the backup compression default is set to 0, which makes backup compression off by default. To change the default to `COMPRESSION`, you set the backup compression default to 1. To revert the default to `NO_COMPRESSION`, set the backup compression default back to 0.

From a performance point of view, compression can significantly increase CPU usage, and the additional CPU consumed by the compression process might impact concurrent operations. Therefore, you might want to create low-priority compressed backups in a session whose CPU usage is limited by the Resource Governor.

blocked process threshold

Type: Advanced

Default value: 0

The `blocked process threshold` option allows you to specify the threshold, in seconds, at which blocked process reports are generated. By default, no blocked process reports are produced. `blocked process threshold` uses the deadlock monitor background thread to walk through the list of tasks waiting for a time greater than or multiples of the configured threshold. This option is useful when debugging systems with many deadlock situations. However, there is a cost of overhead involved, so it should be used for only short periods of time.

c2 audit mode

Type: Advanced; requires a reboot of SQL Server to take effect

Default value: 0

C2 audit mode can be configured through SSMS or with the `c2 audit mode` option in `sp_configure`. This feature is still available. Selecting this option configures the server to record both failed and successful attempts to access statements and objects. This information can help you profile system activity and track possible security policy violations. The C2 security standard has been superseded by common criteria compliance features. Much of the detail-level auditing is now done with SQL Auditing (covered in the SQL Server Security chapters) and is far more robust than this feature. C2 audit mode data is saved in a file in the default data directory of the instance. If the audit log file reaches its size limit of 200MB, SQL Server creates a new file, closes the old file, and writes all new audit

records to the new file. This process continues until the audit data directory fills up or auditing is turned off. To determine the status of a C2 trace, you query the `sys.traces` catalog view. Be aware that C2 audit mode saves a large amount of event information to the log file, which can grow quickly. If the data directory in which logs are being saved runs out of space, SQL Server shuts itself down! If auditing is set to start automatically, you must either restart the instance with the `-f` flag (which bypasses auditing) or free up additional disk space for the audit log.

clr enabled

Type: Basic

Default value: 0

SQL Server 2008 supports direct execution of CLR assemblies. It is not optimized to do so; it just supports this capability.

A 0 value for `clr enabled` indicates that these CLR assemblies are not allowed to run on this SQL Server instance. A value of 1 allows this type of execution. The setting takes effect immediately after `sp_configure` is run, with no restart of the SQL Server instance required. When `RECONFIGURE` is run and the run value of the `clr enabled` option is changed from 1 to 0, all application domains containing user CLR assemblies are immediately unloaded. CLR assembly execution is not supported under lightweight pooling, so you must disable one of two options: `clr enabled` or `lightweight pooling`.

common criteria compliance enabled

Type: Advanced; requires a reboot of SQL Server to take effect

Default value: 0

The `common criteria compliance enabled` option enables three areas (or elements) of what is termed *common criteria*. The first is Residual Information Protection (RIP), which overwrites memory with a known pattern of bits before memory is reallocated to a new resource. This meets the RIP standard and contributes to improved security. The downside of this improvement is a slowing in performance. The second enables login auditing to occur. Each time a user successfully logs in to SQL Server, information about the last successful login time, the last unsuccessful login time, and the number of attempts between the last successful and current login times is made available. These login statistics can be viewed by querying the `sys.dm_exec_sessions` dynamic management view. And lastly, this option enables the behavior that a column-level `GRANT` should not override a table-level `DENY`. In other words, when enabled, a table-level `DENY` takes precedence over a column-level `GRANT`.

cost threshold for parallelism

Type: Advanced

Default value: 5

SQL Server 2008 supports parallel query execution. Before a query is executed, SQL Server's cost-based optimizer estimates the cost of execution for a serial plan (that is, a plan that uses a single thread). The option to set the cost threshold for parallelism allows you to specify a threshold in seconds; if the cost of the serial execution plan (in seconds) is greater than the value specified by this parameter, SQL Server considers a parallel query execution plan. A query does not become a candidate for parallel query execution simply based on this fact. Because parallel query execution is supported only on multiprocessor servers, the `cost threshold for parallelism` value is ignored for single-processor hardware. For an application that uses many complex queries, you should set this value to a lower number so that you can take advantage of the parallel query execution capabilities of SQL Server.

The following is an example of this option:

```
exec sp_configure 'cost threshold for parallelism', 2
go
RECONFIGURE
Go
```

The following is a general recommendation of what to specify based on the different application types you are running:

- ▶ **OLTP**—Use the default value, 5.
- ▶ **Data warehouse**—Many complex queries are candidates for parallelism. Set to a low value, such as 2 (seconds).
- ▶ **OLAP**—Use the default value, 5.
- ▶ **Mixed**—Use the default value, 5.

cross db ownership chaining

Type: basic

Default value: 0

You use the `cross db ownership chaining` option to configure cross-database ownership chaining for an instance of Microsoft SQL Server. This server option allows you to control cross-database ownership chaining at the database level or to allow cross-database ownership chaining for all databases. In other words, when this option is off for the instance, it is disabled for all databases. This server-wide option can be more selectively set at the individual database level. Our recommendation is to turn it off at the server instance level and

then explicitly allow cross-database ownership chaining using the SET clause of the ALTER DATABASE statement.

cursor threshold

Type: Advanced

Default value: -1

The `cursor threshold` option allows you to specify when SQL Server should generate a cursor result set asynchronously. If the optimizer estimates that the number of rows returned by the cursor is greater than the value specified by this parameter, it generates the result set asynchronously. The optimizer makes this decision based on the distribution statistics for each table that is participating in the join in the cursor.

To determine the optimal value for this parameter, you need to make sure that statistics are up-to-date (by running update statistics) for the tables used in the cursors. By default, SQL Server generates a cursor result set synchronously. If you are using a fair number of cursors that return a large number of result sets, setting this value to a higher value results in better performance. Setting this value to 0 forces SQL Server to always generate a cursor result set asynchronously.

The following is an example of this option:

```
exec sp_configure 'cursor threshold', 100000
go
RECONFIGURE
go
```

The following is a general recommendation of what to specify based on the different application types you are running:

- ▶ **OLTP**—Use the default value, -1.
- ▶ **Data warehouse**—A data warehousing environment is the largest potential user of this option due to the high volume of result rows returned by applications using data warehouses. Setting this value to 100,000 is a good starting point.
- ▶ **OLAP**—Use the default value, -1.
- ▶ **Mixed**—Use the default value, -1.

default full-text language

Type: Advanced

Default value: 1033

The `default full-text language` option is used to specify a default language value for full-text indexed columns. Linguistic analysis is performed on all data that is full-text indexed and is strictly dependent on the language of the data. The default value of this option is the language of the server.

The value of the default `full-text language` option is used when no language is specified for a column through the `LANGUAGE` option in the `CREATE FULLTEXT INDEX` or `ALTER FULLTEXT INDEX` statements. If the default `full-text language` option is not supported or the linguistic analysis package is not available, the `CREATE` or `ALTER` operation doesn't work, and SQL Server returns an `invalid language specified` error message. To see the list of linguistic analysis packages that are part of SQL Server 2008, you query the system view `sys.fulltext_languages`, as in this example:

```
SELECT * FROM sys.fulltext_languages
order by 2
Go
lcid      name
-----
1025     Arabic
1093     Bengali (India)
1046     Brazilian
2057     British English
1026     Bulgarian
1027     Catalan
3076     Chinese (Hong Kong SAR, PRC)
5124     Chinese (Macau SAR)
4100     Chinese (Singapore)
1050     Croatian
1043     Dutch
1033     English
1036     French
1031     German
1095     Gujarati
1037     Hebrew
1081     Hindi
1039     Icelandic
1057     Indonesian
1040     Italian
1041     Japanese
1099     Kannada
1042     Korean
1062     Latvian
1063     Lithuanian
1086     Malay - Malaysia
1100     Malayalam
1102     Marathi
0        Neutral
1044     Norwegian (Bokmål)
2070     Portuguese
1094     Punjabi
1048     Romanian
```

1049	Russian
3098	Serbian (Cyrillic)
2074	Serbian (Latin)
2052	Simplified Chinese
1051	Slovak
1060	Slovenian
3082	Spanish
1053	Swedish
1097	Tamil
1098	Telugu
1054	Thai
1028	Traditional Chinese
1058	Ukrainian
1056	Urdu
1066	Vietnamese

If setting to other than the default, the `sp_configure` command would look like this (when set to French):

```
exec sp_configure 'default full-text language', 1036
go
RECONFIGURE
Go
```

default language

Type: Basic

Default value: 0

The `default language` option specifies the language ID currently in use by SQL Server. The default value is 0, which specifies the U.S. English system. As you add languages on the server, SQL Server assigns a new ID for each language. You can then use these IDs to specify the default language of your choice. You can add languages by using the SQL Server Setup program. Adding a language allows SQL Server to display error messages and date/time values in the format that is appropriate for that language. You set this option in the Server Settings tab of the SQL Server Properties dialog.

You can override the default language for a login by using `sp_addlogin` or `sp_defaultlanguage`. The default language for a session is the language for that session's login, unless overridden on a per-session basis by using the ODBC or OLE DB APIs. To see the languages supported for your SQL Server instance, you use the system view `sys.syslanguages`.

```
SELECT langid, substring(name,1,20) AS name,
       substring(alias,1,20) AS alias,
       lcid
FROM sys.syslanguages
```

order by 3

Go

langid	name	alias	lcid
31	Arabic	Arabic	1025
27	Português (Brasil)	Brazilian	1046
23	British	British English	2057
20	Bulgarian	1026	
16	hrvatski	Croatian	1050
12		Czech	1029
4	Dansk	Danish	1030
7	Nederlands	Dutch	1043
0	us_english	English	1033
24	eesti	Estonian	1061
10	Suomi	Finnish	1035
2	Français	French	1036
1	Deutsch	German	1031
19		Greek	1032
13	magyar	Hungarian	1038
6	Italiano	Italian	1040
3		Japanese	1041
29		Korean	1042
25		Latvian	1062
26		Lithuanian	1063
8	Norsk	Norwegian	2068
14	polski	Polish	1045
9	Português	Portuguese	2070
15	română	Romanian	1048
21		Russian	1049
30		Simplified Chinese	2052
17		Slovak	1051
18	slovenski	Slovenian	1060
5	Español	Spanish	3082
11	Svenska	Swedish	1053
32		Thai	1054
28		Traditional Chinese	1028
22	Türkçe	Turkish	1055

Setting the default language to something other than the default would look like this (again, when set to French):

```
exec sp_configure 'default language', 2
go
```

RECONFIGURE

Go

You can change the language for a session during the session through the `SET LANGUAGE` statement. From SSMS, you can easily see the current default language and default full-text language settings, as shown in Figure 55.4.

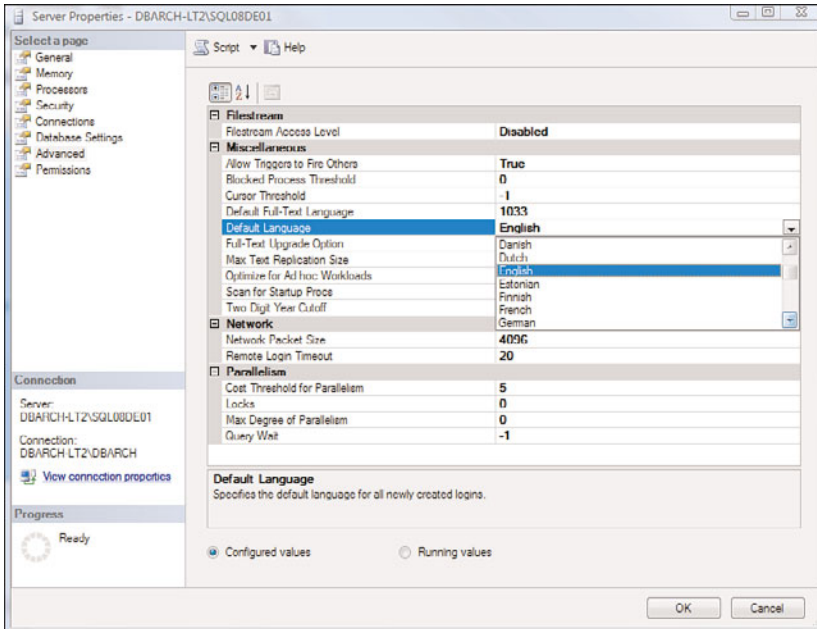

FIGURE 55.4 SQL Server 2008 language configuration from SSMS.

EKM provider enabled

Type: basic

Default value: 0

The `EKM provider enabled` option controls Extensible Key Management (EKM) device support in SQL Server. By default, this option is off. SQL Server 2008 Extensible Key Management enables third-party EKM/HSM vendors to register their modules in SQL Server. When registered, SQL Server 2008 users can use the encryption keys stored on EKM modules. This enables SQL Server to access the advanced encryption features these modules support, such as bulk encryption and decryption, and key management functions such as key aging and key rotation.

The following is an example of this option:

```
exec sp_configure 'EKM provider enabled', 1
go
RECONFIGURE
go
```

filestream_access_level

Type: **basic**

Default value: **0**

You use the `filestream_access_level` option to change the FILESTREAM access level. Before this option has any effect, the Windows administration settings for FILESTREAM must be enabled. You can also enable these settings when you are installing SQL Server or by using SQL Server Configuration Manager (SSCM) for a specific SQL Server instance. Setting the value to `0` disables this option. A value of `1` enables FILESTREAM for T-SQL access only. A value of `2` enables FILESTREAM for both T-SQL and Win32 streaming access.

FILESTREAM integrates the SQL Server Database Engine with an NTFS file system by storing `varbinary(max)` binary large object (BLOB) data as files on the file system. T-SQL statements can insert, update, query, search, and back up FILESTREAM data.

The following is an example of this option:

```
exec sp_configure 'filestream_access_level', 2
go
RECONFIGURE
```

fill factor

Type: **Basic**

Default value: **0**

The `fill factor` option allows you to define the percentage of free space on a data page or an index page when you create an index or a table. The value can range from `1` to `100`. Setting the value to `80` would mean each page would be 80% full at the time of the create index. SQL Server also allows you to specify the value of fill factor at the server level by providing a `fill factor` parameter.

The following is an example of this option:

```
exec sp_configure 'fill factor', 80
go
RECONFIGURE
Go
```

The following is a general recommendation of what to specify based on the different application types you are running:

- ▶ **OLTP**—This is a good candidate for leaving space free in pages due to the update, delete, and insert characteristics. Try 80% full value first and watch the page split activity.
- ▶ **Data warehouse**—Use the default value, 0.
- ▶ **OLAP**—Use the default value, 0.
- ▶ **Mixed**—Use the default value, 0, or about a 90% full value.

index create memory

Type: Advanced, self-configuring

Default value: 0

The `index create memory` option is used to control the amount of memory used by index creation sorts. It is a self-configuring option and usually doesn't need to be adjusted. However, if you are having problems with the creation of large indexes, you might want to try specifying a KB value here that will contain the sort portion of the `index create`.

The following is an example of this option:

```
exec sp_configure 'index create memory', 1000
go
RECONFIGURE
go
```

in-doubt xact resolution

Type: Advanced

Default value: 0

The `in-doubt xact resolution` option changes the behavior of the default outcome for transactions that the Microsoft Distributed Transaction Coordinator (MS DTC) is unable to resolve. This helps prevent MS DTC-related downtime and provides clarity to transaction outcomes across database servers. A value of 1 is a *presume commit* directive. In other words, any MS DTC in-doubt transactions are presumed to have committed. A value of 2 is a *presume abort* directive, which means any MS DTC in-doubt transactions are presumed to have aborted.

The following is an example of this option:

```
exec sp_configure 'in-doubt xact resolution', 2
go
RECONFIGURE
go
```

lightweight pooling

Type: Advanced

Default value: 0

Lightweight pooling is relevant to multiprocessor environments that have excessive context switching. By flipping the `lightweight pooling` switch, you might get better throughput by performing the context switching inline, thus helping to reduce user/kernel ring transitions. The `lightweight pooling` option actually causes SQL Server to switch to fiber mode scheduling. CLR execution is not supported under lightweight pooling. You can disable one of two options: `clr enabled` or `lightweight pooling`.

The following is an example of this option:

```
exec sp_configure 'lightweight pooling', 1
go
RECONFIGURE
go
```

The following is a general recommendation of what to specify based on the different application types you are running:

- ▶ **OLTP**—This is a good candidate for use on a multiprocessor machine.
- ▶ **Data warehouse**—This has a good potential for usage on a multiprocessor machine.
- ▶ **OLAP**—Use the default value, 0.
- ▶ **Mixed**—Use the default value, 0.

locks

Type: Advanced, self-configuring

Default value: 0

In versions of SQL Server prior to 2005, the DBA had to specify the number of locks available to SQL Server. If this parameter was set to a low value, a query requiring a large number of locks would fail at runtime. Setting it too high would result in wasting memory that otherwise could be used to cache data. SQL Server 2008 can handle locks dynamically if this parameter is set to the default value (0). SQL Server initially allocates 2% of memory available to SQL Server (or usually about an initial pool of 2,500 lock structures). As lock resource structures are consumed, the lock manager allocates more lock resources to the pool, to a maximum of 60% of the memory available on SQL Server. When the `locks` option is not set to 0, lock escalation occurs when the number of locks reaches 40% of the value specified for `locks`. Unless you are certain of the overall lock consumption of your application, you probably don't need to change this value.

The following is an example of this option:

```
sp_configure 'locks', 10000
go
RECONFIGURE
go
```

max degree of parallelism

Type: Advanced

Default value: 0

The `max degree of parallelism` option specifies the number of threads to be used for parallel query execution. On a single-processor server, this value is always ignored. For multiprocessor servers, a default value of 0 signifies that all the CPUs will be used for parallel query execution. When SQL Server 2008 runs on a machine that has more than one processor, it detects the best degree of parallelism. If you set this value to 1, all query plans are serialized. If the `affinity mask` option is on, parallel query execution takes place only on the CPUs for which the `affinity mask` bit is turned on. In that way, these two options can be used in conjunction. The application types assessment is the same as described for the `affinity mask` option.

The following is an example of this option:

```
sp_configure 'max degree of parallelism', 4
go
RECONFIGURE
go
```

max server memory and min server memory

Type: Advanced, self-configuring

Default values: 2147483647 and 0

The `max server memory` option specifies the maximum amount of memory (in megabytes) available to SQL Server. It is used in conjunction with `min server memory`, and they essentially establish upper and lower bounds for memory allocation. SQL Server uses this memory for user connections, locks, internal data structures, and caching of the data. This is the memory pool described earlier. The default value of 2147483647 for the `max server memory` option means that SQL Server performs dynamic allocation of memory from the operating system, based on available physical memory on the machine. The default value of 0 for the `min server memory` option means that SQL Server starts allocation memory as it is needed and then never goes below the minimum value after it is reached.

The SQL Server lazywriter process is responsible for making sure enough memory is available to SQL Server for the optimal number of buffers and Windows so that no excess paging occurs at the operating system level. The lazywriter process frequently checks physical memory available on the machine. If the memory available is greater than 5MB, lazywriter assigns excess memory to the SQL Server buffer cache.

You should watch the `Working Set` performance counter, which shows the amount of memory used by a process (SQL Server in this case). If this number is consistently below the amount of memory for which SQL Server is configured, SQL Server is configured for more memory than it needs. You can also adjust the `set working set size` configuration option.

If SQL Server is the only application running on a machine, you might want to perform static memory allocation. You need to be careful when you allocate fixed memory to SQL Server. If you allocate more memory to SQL Server than the machine has, SQL Server fails to start. You use the `-f` option during startup to bring up SQL Server with the default configuration. You can then change the value to the correct value and restart SQL Server.

The following is an example of this option:

```
exec sp_configure 'max server memory', 200
go
RECONFIGURE
Go
exec sp_configure 'min server memory', 8
go
RECONFIGURE
go
```

Because memory is managed dynamically, these settings basically create the lower and upper bounds within which SQL Server must operate. When SQL Server is started, it uses the minimum server memory amount to pre-allocate space to SQL Server. If the load on the server never requires allocating the amount of memory specified in the `minimum server memory` option, SQL Server runs with less memory.

Figure 55.5 shows both the `minimum server memory` and `maximum server memory` settings on the Server Properties page.

The following is a general recommendation of what to specify based on the different application types you are running:

- ▶ **OLTP**—For those with heavy loads, this is a good candidate for high minimum memory settings.
- ▶ **Data warehouse**—Use the default values.
- ▶ **OLAP**—Use the default values.
- ▶ **Mixed**—For those with heavy loads, this is a good candidate for high minimum memory settings.

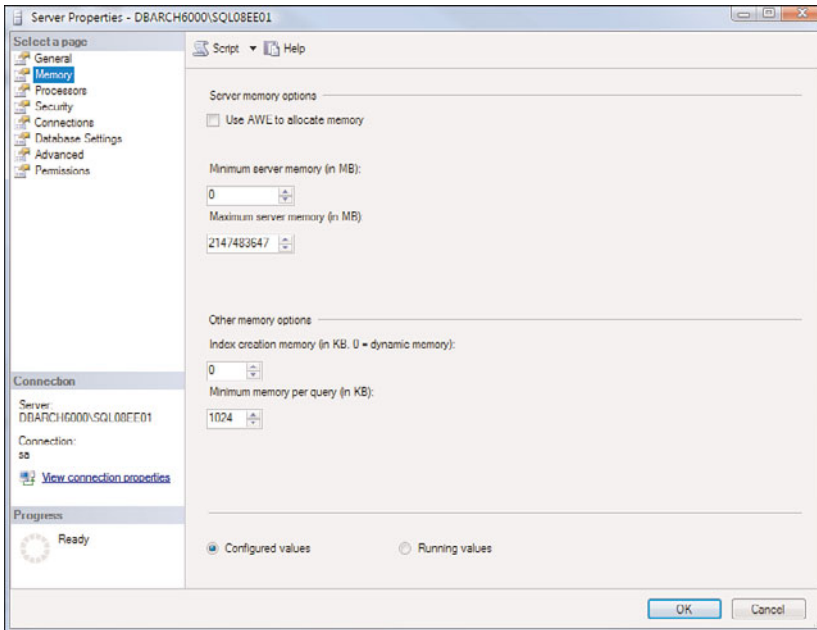

FIGURE 55.5 The minimum server memory and maximum server memory configuration settings in SSMS.

max text repl size

Type: Basic

Default value: 65536

The `max text repl size` parameter specifies the maximum size of the text, `ntext`, `varchar(max)`, `nvarchar(max)`, and `image` data types for columns participating in replication during single insert, update, `writetext`, and `updatetext` statements. You might need to raise this value if the image sizes your application deals with are consistently large and the data is part of a replication configuration.

The following is an example of this option:

```
exec sp_configure 'max text repl size', 131072
go
RECONFIGURE
go
```

max worker threads

Type: Basic

Default value: 0

SQL Server uses native operating system threads. The `max worker threads` parameter specifies the maximum number of threads available for SQL Server processes. One or more threads are used for supporting each network protocol (for example, TCP/IP, named pipes). SQL Server is configured to listen. The checkpoint and lazywriter processes also consume threads. A pool of threads is used to handle user connections. When the number of connections is lower than the `max worker threads` parameter value, a thread is created for each connection. When more connections are on the server than the value defined by the `max worker threads` parameter, SQL Server provides thread pooling for efficient resource utilization. The default value of 0 autoconfigures the number of `max worker threads` to be $(256 + ((\text{number of processors} - 4) \times 8))$ for a 32-bit processor and twice that for a 64-bit processor. So, for an 8 processor 32-bit machine, the `max worker threads` value would be autoconfigured to be $(256 + ((8 - 4) \times 8)) = 288$.

More threads can create overhead on the system processors. Therefore, lowering this value might sometimes improve the performance of a system. For a system with a few hundred user connections, a reasonable value for this parameter is 288. You might want to experiment with various values to determine the appropriate setting for this parameter. A multiprocessor environment can easily handle more threads, and you can increase the number of threads accordingly.

The following is an example of this option:

```
exec sp_configure 'max worker threads', 288
go
RECONFIGURE
go
```

The following is a general recommendation of what to specify based on the different application types you are running:

- ▶ **OLTP**—For multiprocessor environments, set the value upward because those environments can handle servicing more threads. This yields performance gains.
- ▶ **Data warehouse**—Use the default value, 0.
- ▶ **OLAP**—Use the default value, 0.
- ▶ **Mixed**—For multiprocessor environments, set the value upward because those environments can handle servicing more threads. This yields performance gains.

min memory per query

Type: Advanced

Default value: 1024

The `min memory per query` option specifies the minimum amount of memory that will be allocated for the execution of a query. Normally, the SQL Server query processor attempts to determine the optimal amount of memory for a query. This option allows the `sysadmin` role to specify this value instead. Increasing this value usually improves queries that handle hash and sort operations on a large volume of data.

The following is an example of this option:

```
exec sp_configure 'min memory per query', 2048
go
RECONFIGURE
go
```

Looking back at Figure 55.5 showing the Memory page of the Server Properties dialog, you can see the `min query memory per query` option set at 1024 (the default).

The following is a general recommendation of what to specify based on the different application types you are running:

- ▶ **OLTP**—Use the default value, 1024.
- ▶ **Data warehouse**—This is a good opportunity to better service numerous canned queries in this environment. Set the value higher than the default.
- ▶ **OLAP**—Use the default value, 1024.
- ▶ **Mixed**—Use the default value, 1024.

nested triggers

Type: Basic

Default value: 1

As the name suggests, `nested triggers` specifies whether a trigger event on a table will fire another trigger (that is, cascade). The nesting level of triggers is 32. If you reach this limit of 32, SQL Server gives an error and rolls back the transaction. The default value of 1 means that a trigger on a table can cause another trigger to fire.

network packet size

Type: Basic

Default value: 4096

The `network packet size` parameter specifies the default network packet size for SQL Server. Setting this value to a higher number (which should be divisible by 512) can improve the performance of applications that involve a large amount of data transfer from

the server. Check your network configuration and set an appropriate value for this parameter. You can also improve performance by lowering the size value for applications that are small in data transfer size. However, the usual scenario is to increase this size to accommodate large amounts of data transfer, as with bulk loads.

The following is an example of this option:

```
exec sp_configure 'network packet size', 8192
go
RECONFIGURE
go
```

TIP

You can also specify the network packet size from the client when you connect to SQL Server (using the `-a` option for `isql`, `osql`, and `bcp`). Setting the network packet size from a client can be useful when the default network packet size is adequate for general application needs. However, a larger packet size might be needed for some specific operations, such as bulk copy. You can also call OLE DB, ODBC, and DB-Library functions to change the packet size.

The following is a general recommendation of what to specify based on the different application types you are running:

- ▶ **OLTP**—Possibly decrease this size to 512 if all queries deal with small amounts of data transfer, which is often the case in OLTP or ATM applications.
- ▶ **Data warehouse**—Perhaps increase this to 8192 or larger to handle the consistently large data transfers in this environment.
- ▶ **OLAP**—Use the default value, 4096.
- ▶ **Mixed**—Use the default value, 4096.

optimize for ad hoc workloads

Type: Advanced

Default value: 0

The `optimize for ad hoc workloads` option is used to improve the efficiency of the plan/procedure cache for workloads that contain many single-use ad hoc batches. When this option is set to 1, the Database Engine stores a small compiled plan stub in the plan/procedure cache when a batch is compiled for the first time, instead of the full compiled plan. This helps to relieve memory pressure by not allowing the plan/procedure cache to become filled with compiled plans that are not reused. The compiled plan stub allows SQL Server to recognize that this ad hoc batch has been compiled before but has stored only a compiled plan stub, so when this batch is invoked (compiled or executed)

again, SQL Server compiles the batch, removes the compiled plan stub from the plan/procedure cache, and adds the full compiled plan to the plan/procedure cache. Setting `optimize for ad hoc workloads` to 1 affects only new plans; plans that are already in the plan/procedure cache are unaffected. The compiled plan stub is one of the cache object types displayed by the `sys.dm_exec_cached_plans` catalog view.

The following is an example of this option:

```
exec sp_configure 'optimize for ad hoc workloads',1
go
RECONFIGURE
go
```

PH_timeout

Type: Advanced

Default value: **60**

You use the full-text protocol handler timeout option (`PH_timeout`) to specify the time, in seconds, that the handler should wait to connect to a database before timing out. The default value is 60 seconds. Increase the value when connection attempts are timing out due to temporary network issues or increased workloads. The full-text protocol handler is hosted in the filter daemon host and is used to fetch the data to be full-text indexed.

The following is an example of this option:

```
exec sp_configure 'PH_timeout', 120
go
RECONFIGURE
go
```

priority boost

Type: Advanced

Default value: **0**

The `priority boost` option is used to specify the process priority of SQL Server processes on the Windows operating system. The default value of `0` means that SQL Server should run on the same priority level—a priority base of 7—as other applications on the machine. This option can be turned on if you have plenty of horsepower to deal with all other services on the box, as in a multiprocessor environment. When you turn on `priority boost`, the priority base of SQL Server is elevated to 13.

The following is an example of this option:

```
exec sp_configure 'priority boost', 1
go
```

```
RECONFIGURE
go
```

NOTE

You shouldn't set the value of the `priority boost` parameter to 1 except in the case of a dedicated SQL Server machine with multiprocessors.

Looking back at Figure 55.3, you can see the Boost SQL Server Priority on Windows option in the Processors page of the Server Properties dialog. Use care when applying this option.

query governor cost limit

Type: Advanced

Default value: 0

Queries are often the cause of major performance problems. SQL Server can handle queries, but many are poorly written and don't restrict the search criteria enough. This can result in runaway queries that return large result sets, and they can adversely affect the entire server's performance. One way to control this situation is to cut off the query at the pass by specifying a maximum cost limit to queries, in seconds. If any query's cost, in seconds, is greater than this maximum value, the query is not allowed to execute. The `query governor cost limit` value is server-wide and cannot be applied to just one query. Remember, though, that 0 (the default) for this option turns off the query governor, and all queries are allowed to run without any time limitation.

The following is an example of this option:

```
exec sp_configure 'query governor cost limit', 300
go
RECONFIGURE
Go
```

To change the value on a per-connection basis, you use the `SET QUERY_GOVERNOR_COST_LIMIT` statement.

The following is a general recommendation of what to specify based on the different application types you are running:

- ▶ **OLTP**—Use the default value, 0.
- ▶ **Data warehouse**—This is a must-have option for this environment. Try setting this value to 300 seconds and then get ready for the users to scream at you. On the positive side, the server won't get bogged down or freeze again.
- ▶ **OLAP**—For OLAP systems that use SQL Server storage, set this value to 600 seconds to get started and then reduce it over time.

- **Mixed**—You have the same protection opportunity here as for OLAP. This won't affect the OLTP queries, so it is safe to apply.

query wait

Type: **Advanced**

Default value: **-1**

Queries that are memory intensive and involve huge sorts might take a long time to execute, based on the available memory during execution. SQL Server internally calculates the timeout interval for such queries. Usually, this is quite a large number. You can override this value by specifying a value (in seconds) for the `query wait` parameter in SQL Server. If you set this value too low, you risk more frequent query timeouts when your system is under a heavy load and a highly concurrent environment. If `-1` is specified (the default), the timeout is calculated as 25 times of the estimated query cost.

The following is an example of this option:

```
exec sp_configure 'query wait', 20
go
RECONFIGURE
go
```

recovery interval

Type: **Advanced, self-configuring**

Default value: **0**

The `recovery interval` parameter is used to specify the maximum time (in minutes) that SQL Server requires to recover a database during startup. During startup, SQL Server rolls forward all the changes committed during a SQL Server crash and rolls back the changes that were not committed. Based on the value specified for this parameter, SQL Server determines when to issue a checkpoint in every database of SQL Server so that in the event of a crash, SQL Server can recover the databases in the time specified by `recovery interval`. If the value of the `recovery interval` parameter is low, SQL Server issues checkpoints more frequently to allow a recovery to be faster; however, frequent checkpoints can slow down performance. Setting `recovery interval` too high creates a longer recovery time for databases in the event of a crash. The default value of `0` leaves this option open to SQL Server to determine the best value.

The following is an example of this option:

```
exec sp_configure 'recovery interval', 10
go
RECONFIGURE
go
```

The following is a general recommendation of what to specify based on the different application types you are running:

- ▶ **OLTP**—Use the default value, 0.
- ▶ **Data warehouse**—This is an opportunity to save on checkpoints and not degrade performance in this mostly read-only environment. Set this value high.
- ▶ **OLAP**—In this read-only environment, you have the same performance opportunity here as in a data warehouse.
- ▶ **Mixed**—Use the default value, 0.

remote admin connections

Type: Basic

Default value: 0

Microsoft SQL Server 2008 provides a dedicated administrator connection (DAC). The DAC lets an administrator access a running server to be able to execute diagnostic functions or T-SQL statements, or troubleshoot problems on the server, even when the server is locked or running in an abnormal state and not responding to any other type of user connection. By default, the DAC is available only from a client on the server. But if you set the `Remote Admin connections` option to 1, the DAC is available from a remote connection as well. By default, the DAC listens only on the loopback IP address (127.0.0.1), port 1434.

The following is an example of this option:

```
exec sp_configure 'remote admin connections', 1
go
RECONFIGURE
Go
```

remote login timeout

Type: Basic

Default value: 20

You use the `remote login timeout` option to specify the number of seconds to wait before returning from a failed attempt to log in to a remote server. If you are attempting to log in to a remote server and that server is down, `remote login timeout` ensures that you do not have to wait indefinitely before your computer ceases its attempts to log in.

This option affects connections to OLE DB providers made for heterogeneous queries. The default setting for `remote login timeout` is 20 (seconds). A value of 0 allows for an infinite wait.

The following is an example of this option:

```
exec sp_configure 'remote login timeout', 30
go
RECONFIGURE
Go
```

remote proc trans

Type: Basic

Default value: 0

The `remote proc trans` parameter allows remote procedures that are taking part in multi-server transactions to use MS DTC so that transaction integrity is maintained across servers. The default value of 0 means the remote procedure calls will not use MS DTC. Data modification at the remote server will not be a part of transactions at the local server. If you set this parameter to 1, SQL Server uses MS DTC to preserve transaction integrity across servers. This feature is still scheduled to be removed in the next version of Microsoft SQL Server. You should therefore avoid using this feature in new development work and plan to modify applications that currently use this feature.

The following is an example of this option:

```
exec sp_configure 'remote proc trans', 1
go
RECONFIGURE
Go
```

remote query timeout

Type: Basic

Default value: 600

You use the `remote query timeout` option to specify how long (in seconds) a remote operation can take before Microsoft SQL Server times out. The default is 600, which allows a 10-minute wait. This value applies to an outgoing connection initiated by the Database Engine as a remote query. This value has no effect on queries received by the Database Engine.

For heterogeneous queries, `remote query timeout` specifies the number of seconds (initialized in the command object using the `DBPROP_COMMANDTIMEOUT` rowset property) that a remote provider should wait for result sets before it times out. This value is also used to set `DBPROP_GENERALTIMEOUT`, if supported by the remote provider. This setting causes any other operations to time out after the specified number of seconds.

For remote stored procedures, `remote query timeout` specifies the number of seconds that must elapse after sending a remote EXEC statement before the remote stored procedure times out.

The following is an example of this option:

```
exec sp_configure 'remote query timeout', 300
go
RECONFIGURE
Go
```

scan for startup procs

Type: Advanced

Default value: 0

When the `scan for startup procs` option is set to 1, SQL Server scans for and executes all automatically executed stored procedures on the server on startup. To set a stored procedure to become automatically executed, you use the `sp_procoption` system stored procedure. Typically, a stored procedure is executed at startup time when you want to have certain processing occur that creates the proper working environment for all subsequent database processing on the server. You also can execute at startup when you want to make sure that certain stored procedures' execution plans (with proper optimizer decisions) are already in the procedure cache before anyone else requests their execution.

The following is an example of this option:

```
exec sp_configure 'scan for startup procs', 1
go
RECONFIGURE
go
```

show advanced options

Type: Basic

Default value: 0

By default, you do not see the advanced configuration parameters of SQL Server. If you set `show advanced options` to 1, you can see all the SQL Server parameters that can be set by the `sp_configure` command.

user connections

Type: Advanced, self-configuring

Default value: 0

The `user connections` option specifies the number of concurrent users allowed on SQL Server. When the value is 0 (which is the default), SQL Server can configure the needed user connections dynamically as they are needed (unlimited). If you specify a value, you

are limited to that maximum number of user connections until you specify a larger value. If you specify a value other than 0, the memory allocation for user connections is allocated at SQL Server startup time, and it burns up portions of the memory pool. Each connection takes up 40KB of memory space. For instance, if you configure SQL Server for 100 connections, SQL Server pre-allocates 4MB (40KB × 100) for user connections. You can see that setting this value too high might eventually impact performance because the extra memory could instead be used to cache data. In general, user connections are best left to be self-configuring.

The following is an example of this option:

```
exec sp_configure 'user connections', 300
go
RECONFIGURE
go
```

In Figure 55.6, you can see the current setting of 0 (unlimited) for the user connections value within SSMS. If you plan to set this option, the value must be between 5 and 32,767.

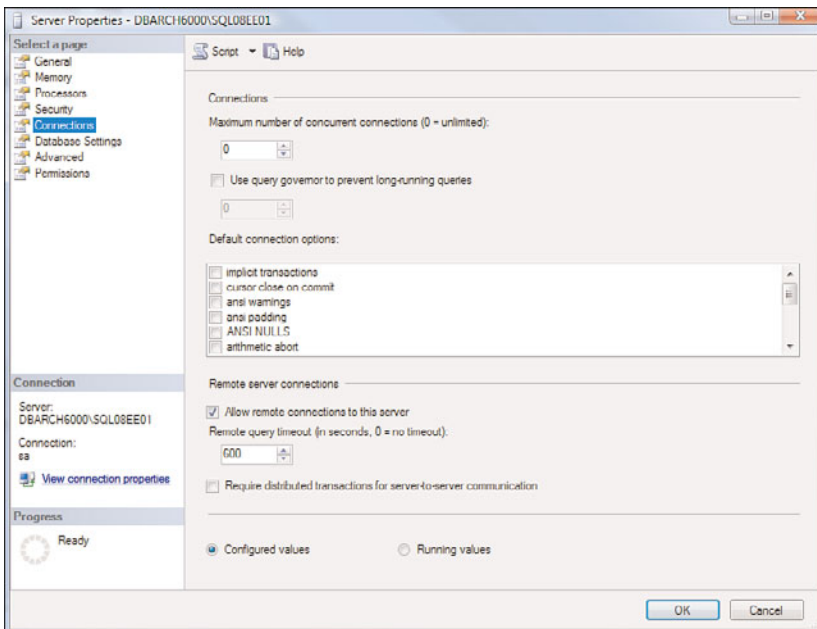

FIGURE 55.6 The Connections page of the Server Properties dialog in SSMS.

user options

Type: Basic

Default value: 0

The `user options` parameter allows you to specify certain defaults for all the options allowed with the `SET T-SQL` command. Individual users can override these values by using the `SET` command. You are essentially able to establish these options for all users unless the users override them for their own needs. `User options` is a bitmask field, and each bit represents a user option. Table 55.1 outlines the values you can set with this parameter.

TABLE 55.1 Specifying **User Options** Values

Bitmask Value	Description
1	<code>DISABLE_DEF_CNST_CHK</code> controls interim/deferred constraint checking.
2	<code>IMPLICIT_TRANSACTIONS</code> controls whether a transaction is started implicitly when a statement is executed.
4	<code>CURSOR_CLOSE_ON_COMMIT</code> controls the behavior of cursors after a commit has been performed.
8	<code>ANSI_WARNINGS</code> controls truncation and nulls in aggregate warnings.
16	<code>ANSI_PADDING</code> controls padding of fixed-length variables.
32	<code>ANSI_NULLS</code> controls null handling when using equality operators.
64	<code>ARITHABORT</code> terminates a query when an overflow or divide-by-zero error occurs during query execution.
128	<code>ARITHIGNORE</code> returns NULL when an overflow or divide-by-zero error occurs during a query.
256	<code>QUOTED_IDENTIFIER</code> differentiates between single and double quotation marks when evaluating an expression.
512	<code>NOCOUNT</code> turns off the message returned at the end of each statement that states how many rows were affected by the statement.
1024	<code>ANSI_NULL_DFLT_ON</code> alters the session's behavior to use ANSI compatibility for nullability. New columns that are defined without explicit nullability are defined to allow NULL values.
2048	<code>ANSI_NULL_DFLT_OFF</code> alters the session's behavior to not use ANSI compatibility for nullability. New columns defined without explicit nullability are defined not to allow NULL values.

TABLE 55.1 Specifying **User Options** Values

Bitmask Value	Description
4096	CONCAT_NULL_YIELDS_NULL has SQL Server return a NULL when concatenating a NULL value with a string.
8192	NUMERIC_ROUNDABORT has SQL Server generate an error if loss of precision ever occurs in an expression.
16344	XACT_ABORT has SQL Server roll back a transaction if a T-SQL statement raises a runtime error.

For a given user connection, you can use the @@options global variable to see the values that have been set.

The following is an example of this option:

```
exec sp_configure 'user options', 256
go
RECONFIGURE
Go
```

Again, a user can override these values with the SET command during a session.

XP-Related Configuration Options

Type: Advanced

Default: 0

A handful of advanced options are available with SQL Server 2008 to more granularly address the execution of extended stored procedures within different SQL server components:

- Agent XPs
- Database Mail XPs
- Replication XPs Option
- SMO and DMO XPs
- SQL Mail XPs
- xp_cmdshell

Each of these options defaults to 0, which means external stored procedures for these areas are not available in the instance. If you enable these options, you should fully understand that doing so opens these extended stored procedures to all on the instance.

As SQL Server 2008 expands in use, some of these options will probably be highlighted in more detail as more real-world examples support their use and attention.

Database Engine Tuning Advisor

Database Engine Tuning Advisor is a decent supplement for the SQL Server performance options. It is not the hottest offering from Microsoft, but it can be valuable in enforcing some basic design options in regard to partitioning, indexing, and basic table structures. You can use either the GUI version of the DTA or the batch command-line version to achieve the same results. With DTA, you can run an analysis against an entire database or just focus on as little as one table within a database. Say that you have one problem child table that is at the heart of all your misery. In this case, you would probably just want to tune that one table for optimal database access.

To tune and analyze anything, DTA must base its analysis on something. That something is usually a set of SQL queries that represent the “workload” of data accesses you want the database to support well. These data accesses (that is, the workload) can be attained in many ways. One way is to create a SQL script that contains any or all of the data accesses you want considered in the tuning effort; another is to simply capture real SQL transactions by using SQL Profiler traces. You can easily retain these traces in .trc file form or keep the captured SQL traces in a SQL table. In the example you are about to run, a SQL trace was done against the AdventureWorks database and stored in table form (in SQL Server). You will see how to use this captured workload representation in the next section. Let’s first look at the GUI version.

The Database Engine Tuning Advisor GUI

From the Tools menu in SSMS, you can select the Database Engine Tuning Advisor option to invoke the GUI for DTA. (You can also invoke this GUI by selecting Start, All Programs, Microsoft SQL Server 2008, Performance Tools, Database Engine Tuning Adviser Program from your desktop.) You are asked to initiate a new session for doing database tuning analysis.

NOTE

It’s best not to run the DTA against a live production database. You should make a copy of the database in a safe place for this type of detailed analysis. You should use a copy of the production database, though, because you want all decisions to be based on reality, and your workload should also reflect true production data accesses.

When you are connected to the target SQL Server platform, a default for a session name appears; it is the user’s name and the date on which the analysis is being done. Figure 55.7 shows this new session start and the specification of what workload to use for the analysis.

As you can also see in Figure 55.7, you specify a workload location where you have stored the SQL traces that are to be used for the analysis. This can be to a file or table location; DTA Example trace ASDB.trc in this example. You then specify AdventureWorks as the database for workload analysis to start in. Any USE database commands in the trace (or script) would be executed, but you want this analysis to start in a certain place. Then you select the database to tune from the bottom list of databases (again, the AdventureWorks

database in this example). If you click the Selected Tables drop-down for the AdventureWorks database, as shown in Figure 55.8, you could further limit what you want to tune down to an individual table level. In this example, you tune the entire database.

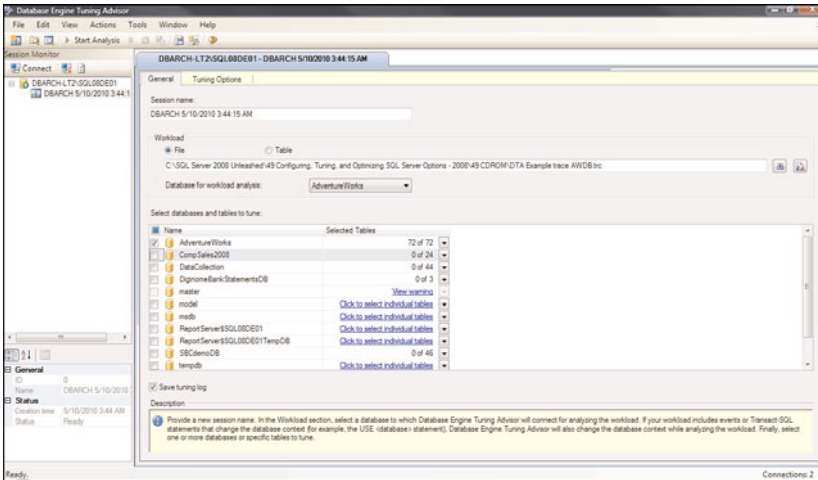

FIGURE 55.7 Database Engine Tuning Advisor new session setup.

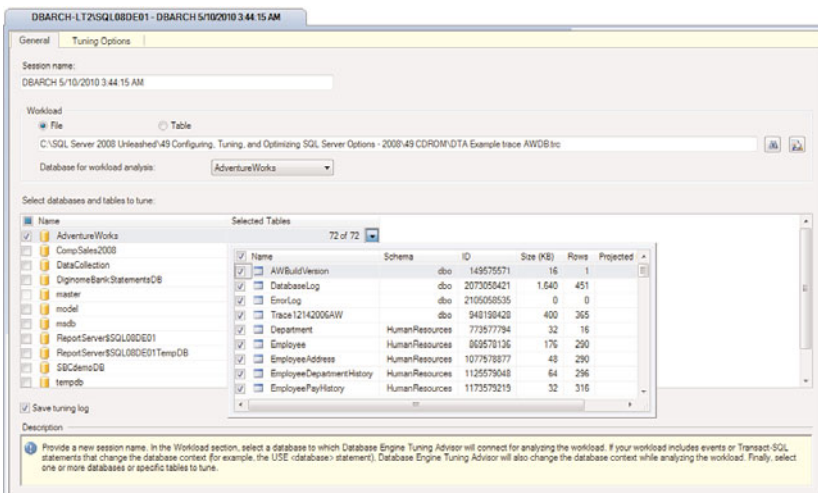

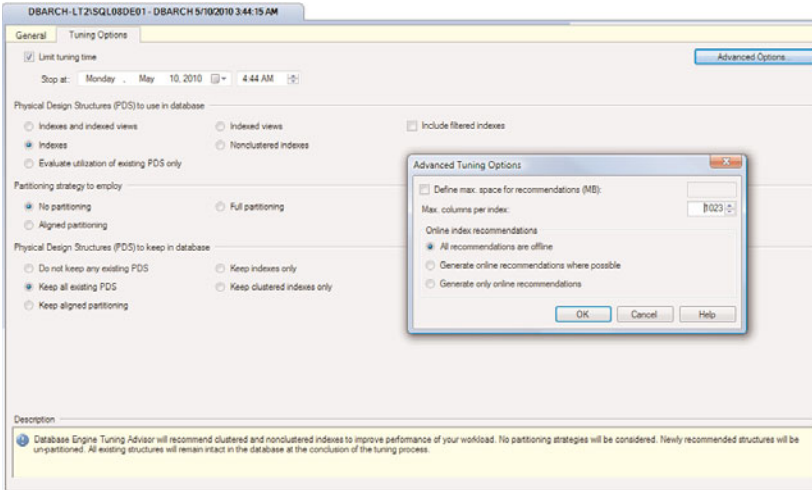

FIGURE 55.8 Database Engine Tuning Advisor selected tables for tuning.

You then click the Tuning Options tab to select exactly what you want to tune for. Figure 55.9 shows the various tuning options.

For this example, you tune all indexes, use no partitioning, and keep all existing physical data structures as the first tuning analysis you want the DTA to do. Someday, Microsoft

will triple the tuning types here, but for now, the offerings are limited. The Advanced Options button allows you to specify the maximum number of columns that could be contained in a new index recommendation (1,023 columns), whether DTA should generate only SQL DDL that can be executed online, and the maximum space that DTA can utilize for physical structure changes. The defaults for these settings are typically sufficient. Now, you simply click the Start Analysis menu item (the one with a little green right arrow next to it) or choose Actions, Start Analysis option. Figure 55.10 shows the execution progress of this analysis session.

55

FIGURE 55.9 Database Engine Tuning Advisor tuning options to use for this session.

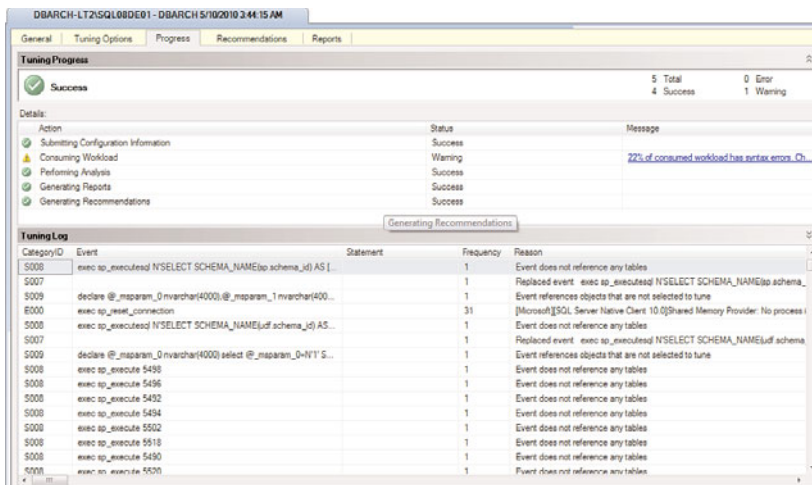

FIGURE 55.10 Database Engine Tuning Advisor tuning execution progress and tuning log.

The tuning log shows the SQL events, actual statements, and frequency of these statements (that is, the number of times the same SQL was processed). This information sheds some light on the mix of SQL hitting this database. When the progress is complete, a Recommendations tab and a Reports tab appear for this session (see Figure 55.11). Here, the DTA says that an estimated improvement of 24% can be gained if the recommendations it is advising are followed. Because you wanted only index recommendations, you don't see any partitioning recommendations. However, there are a few index recommendations for several tables based on the workload provided by the SQL Profiler trace file.

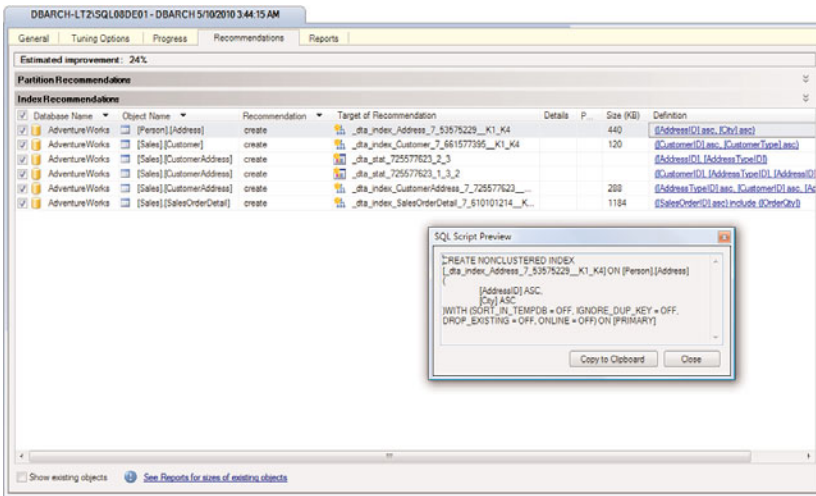

FIGURE 55.11 The Database Engine Tuning Advisor Recommendations tab following analysis.

The Reports tab shows the summary of the tuning session and all the tuning reports generated. In the Tuning Reports section at the bottom of Figure 55.12, you can see the index usage report (recommended). There are several reports, ranging from detailed index recommendations to workload analysis reports.

At any time, you can choose to preview the workload of the file or table you specified for the analysis. You simply choose View, Preview Workload Table or View, Preview Workload File, and SQL Profiler is invoked with your SQL trace.

If you are satisfied with the recommendations of any one of your tuning sessions, you can choose to have them saved to a .sql file and scheduled to be applied at some later time, or you can apply them immediately by selecting Actions, Apply Recommendations or Actions, Save Recommendations.

It's that simple.

TIP

If you regularly run the DTA with a good sampling of your typical transaction workload, you can proactively identify potential changes that will keep your application humming.

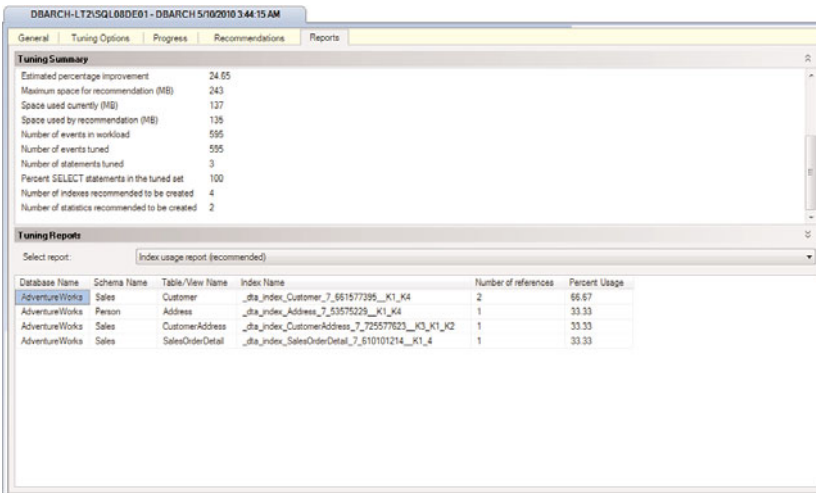

FIGURE 55.12 Index Usage report (recommended).

The Database Engine Tuning Advisor Command Line

DTA is also available in a batch mode so that you don't have to be around to run it online (because doing so can often take hours if you have a large workload to analyze). In addition, this mode allows you to run the same tests over and over, with varying options. You can easily view DTA command-line options by using the help option of the command itself (that is, the `-?` option). You simply run this option at the command line and have its output piped into a file for viewing in Notepad (or another editor):

```
C:> DTA -? > dta.out
Microsoft (R) SQL Server Microsoft SQL Server Database Engine
Tuning Advisor command line utility
Version 10.50.1352.12 ((KJ_PreRelease).091030-1758 )
Copyright(c) Microsoft Corporation. All rights reserved.
Usage:
DTA.EXE [-S ServerName[\Instance]]
        [-U LoginId]
        [-P Password]
        [-E]
        [-d DatabaseName]
        [-D DatabaseName[, DatabaseName]]
        [-Tl TableName[, TableName]]
        [-Tf TableListFileName]
        [-if WorkloadFileName]
        [-it WorkloadTableName]
        [-s SessionName]
        [-of [ScriptFileName]]
        [-or [ReportFileName]]
```

```

[-rl Report[, Report]]
[-ox [OutputXmlFileName]]
[-F]
[-ID SessionID]
[-ix InputXmlFileName]
[-A TuningTime]
[-n NumberOfEvents]
[-m MinimumImprovement]
[-fa PhysicalDesignStructure]
[-fp PartitionStrategy]
[-fk PhysicalDesignStructure]
[-fx]
[-B StorageSize]
[-c MaxKeyColumnsInIndex]
[-C MaxColumnsInIndex]
[-e TuningLogTable]
[-N OnlineOption]
[-q]
[-u]
[-x]
[-a]
[-?]

```

This output has the following components:

- ▶ **-S ServerName** [*\Instance*]**—**Indicates the name of the SQL Server instance with which to connect. This is the server against which all tuning analysis and supporting table updates will be made.
- ▶ **-U LoginId****—**Indicates the login ID to use in establishing a connection to SQL Server (specified via the -S option).
- ▶ **-P Password****—**Specifies the password for the specified login ID.
- ▶ **-E****—**Uses a trusted connection to connect to the server.
- ▶ **-d DatabaseName****—**Identifies the database to connect to when tuning.
- ▶ **-D DatabaseName****—**Provides a list of database names for tuning. Names are separated by commas.
- ▶ **-T1 TableName****—**Provides a list of table names that should be tuned. Names are separated by commas. If only one database is specified through the -D option, table names do not need to be qualified with the database name. Otherwise, the fully qualified name, in the form [*Database*]. [*Schema*]. [*Table*], is required for each table.
- ▶ **-Tf TableListFileName****—**Indicates the name of a file containing the list of tables to be tuned. Tables listed within the file must appear on separate lines, and the names must be qualified by database name and, optionally, by schema name. The

optional table-scaling feature may be invoked by following the name of a table with a number that indicates the projected number of rows in that table (for example, '[myDatabase].[dbo].[myTable] 500').

- ▶ **-if WorkloadFileName**—Specifies the path and filename of the workload file to use as input for tuning. These are the accepted formats:
 - ▶ ***.trc**—SQL Server Profiler trace file.
 - ▶ ***.xml**—SQL Server Profiler XML trace file.
 - ▶ ***.sql**—SQL Server script.
- ▶ **-it WorkloadTableName**—Indicates the name of the table containing the workload trace for tuning. The name is specified as [Database].[Schema].[Table].
- ▶ **-s SessionName**—Specifies the name of the new tuning session.
- ▶ **-of ScriptFileName**—Indicates that T-SQL script with recommendations should be written to a file. If a filename is supplied, the recommendations are written to that destination; otherwise, the filename is generated based on the session name.
- ▶ **-or ReportFileName**—Indicates that the report should be written to a file. If a filename is supplied, the report is written to that destination; otherwise, the filename is generated based on the session name.
- ▶ **-r1 Report**—Specifies the list of analysis reports to generate. You select one or more of the following:
 - ▶ **ALL**—Generate all reports.
 - ▶ **NONE**—Do not generate any reports.
 - ▶ **STMT_COST**—Statement cost report.
 - ▶ **EVT_FREQ**—Event frequency report.
 - ▶ **STMT_DET**—Statement detail report.
 - ▶ **CUR_STMT_IDX**—Statement-index relations report (current).
 - ▶ **REC_STMT_IDX**—Statement-index relations report (recommended).
 - ▶ **STMT_COSTRANGE**—Statement cost range report.
 - ▶ **CUR_IDX_USAGE**—Index usage report (current).
 - ▶ **REC_IDX_USAGE**—Index usage report (recommended).
 - ▶ **CUR_IDX_DET**—Index detail report (current).
 - ▶ **REC_IDX_DET**—Index detail report (recommended).
 - ▶ **VIW_TAB**—View-table relations report.
 - ▶ **WKLD_ANL**—Workload analysis report.
 - ▶ **DB_ACCESS**—Database access report.

- ▶ **TAB_ACCESS**—Table access report.
- ▶ **COL_ACCESS**—Column access report.

By default, all reports are generated.

- ▶ **-ox OutputXmlFileName**—Indicates the name of the XML file to which the application writes output.
- ▶ **-F**—Permits Database Engine Tuning Advisor to overwrite existing output files (specified using any of the *o?* options).
- ▶ **-ID SessionID**—Specifies the ID of a session for which Database Engine Tuning Advisor should generate results.
- ▶ **-ix InputXmlFileName**—Indicates the name of the XML file that specifies a user configuration (that is, a user-specified configuration). Note that command-line options take precedence in the event that duplicate parameters are found in the file.
- ▶ **-A TuningTime**—Indicates the maximum amount of time, in minutes, that Database Engine Tuning Advisor will spend tuning. In general, longer times produce higher-quality recommendations. When 0 is specified as a value, the tuning time is unlimited. When a value is not specified, the tuning time is limited to 8 hours.
- ▶ **-n NumberOfEvents**—Specifies the number of events to tune.
- ▶ **-m MinimumImprovement**—Specifies that Database Engine Tuning Advisor should offer only recommendations for which the estimated improvement meets or exceeds the supplied value (in percentages). If no value is specified, recommendations are provided regardless of the degree of improvement.
- ▶ **-fa PhysicalDesignStructure**—Specifies the physical design structures for which Database Engine Tuning Advisor should consider proposing new recommendations. You select one of the available options:
 - ▶ **IDX_IV**—Clustered and nonclustered indexes and indexed views.
 - ▶ **IDX**—Clustered and nonclustered indexes.
 - ▶ **IV**—Indexed views.
 - ▶ **NCL_IDX**—Nonclustered indexes.

When no option is specified, **IDX** is used.

- ▶ **-fp PartitionStrategy**—Specifies the partitioning support requested that Database Engine Tuning Advisor should consider adding. You select one of the available options:
 - ▶ **NONE**—No partitioning strategies.
 - ▶ **FULL**—Full partitioning (best performance).
 - ▶ **ALIGNED**—Aligned partitioning (best manageability).

When no option is specified, NONE is used.

- ▶ **-fk PhysicalDesignStructure**—Specifies the physical design structures that Database Engine Tuning Advisor cannot remove from the existing database scheme. You select one of the available options:
 - ▶ **ALL**—Keep all existing physical design structures.
 - ▶ **NONE**—Do not keep any existing physical design structures.
 - ▶ **CL_IDX**—Keep clustered indexes.
 - ▶ **IDX**—Keep clustered and nonclustered indexes.
 - ▶ **ALIGNED**—Keep aligned partitioning.

When no option is specified, ALL is used.

- ▶ **-fx**—Specifies that Database Engine Tuning Advisor will evaluate the usefulness of existing physical design structures and will follow up with recommendations to drop low-use structures. This option cannot be used with the **-fa** and **-fp** options.
- ▶ **-B StorageSize**—Specifies the maximum space, in megabytes, that can be consumed by the total size of all recommendations.
- ▶ **-c MaxKeyColumnsInIndex**—The maximum number of key columns in indexes proposed by the application.
- ▶ **-C MaxColumnsInIndex**—The maximum number of columns in indexes proposed by the application.
- ▶ **-e TuningLogTable**—The name of a table or file where Database Engine Tuning Advisor writes log messages that occurred during tuning. The table name should be supplied in the form `[Database].[Schema].[Table]`. That table is created on the server against which tuning is conducted. The filename must have the `.xml` extension. If no table or filename is passed, the default table is used.
- ▶ **-N OnlineOption**—Specifies whether objects should be created online, offline, or online where possible. If online indices are to be created, the tag "ONLINE=ON" is appended to the DDL script for all objects that can or should be created online. Select one of the available options:
 - ▶ **OFF**—Offline only.
 - ▶ **MIXED**—Online where possible.
 - ▶ **ON**—Online only.

OFF is the default.

- ▶ **-q**—Sets quiet mode. No information is written to the console, including progress and header information.

- ▶ **-u**—Launches the Database Engine Tuning Advisor GUI and passes all supplied command-line arguments as the initial configuration settings.
- ▶ **-x**—Starts the session and exits. All results are written to a database only. The output may be generated later by supplying the **-ID** parameter.
- ▶ **-a**—Tunes and applies recommendations without prompting.
- ▶ **-?**—Displays usage information.

Typical DTA command-line execution would look like this:

```
C:> DTA -S DBARCHLT\SQL08DEV01 -E -D AdventureWorks2008R2 -if MyScript.sql
-s MySession2 -of MySession2OutputScript.sql -ox MySession2Output.xml
-fa IDX_IV -fp NONE -fk NONE
```

Data Collection Sets

Utilizing other tools as you fine-tune your SQL Server instance configuration options is much easier now. The Data Collection services within SSMS provide a great way to get that high-level picture of your SQL Server's execution quickly. This capability is new to SQL Server. Chapter 39 covers this feature in much more depth. However, if you look at Figure 55.13, you can see a server-wide view of disk usage for database on a SQL Server instance. You can also easily drill down into any one of the databases for a more in-depth picture of how the database is being used.

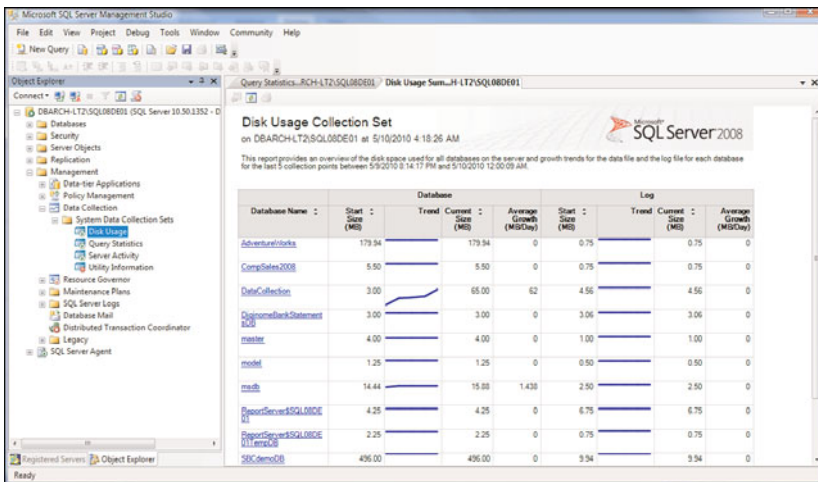

FIGURE 55.13 Data Collection: Disk Usage.

Figure 55.14 shows the Data Collection set of Query Details for a particular database. In this case, it shows a query that is at the heart of a very heavy workload and readily shows all the primary execution statistics around that query's execution.

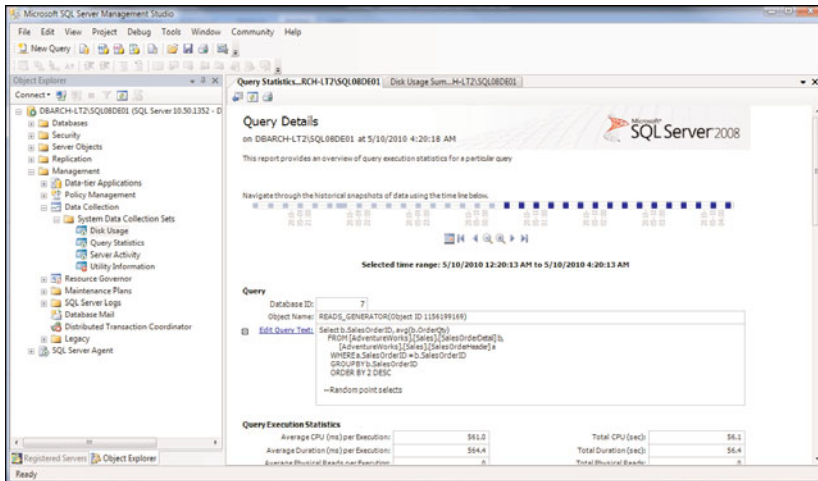

FIGURE 55.14 Data Collection: Query Details.

We also really like to see the overall server activity perspective, as shown in Figure 55.15, as we adjust our server-wide configuration options. The Data Collection report shows most of the major areas at the instance level: memory usage, CPU utilization, disk I/O usage, network usage, and so on. Data Collection services provides you with an integrated tool that also can show you time-based improvements (or degradations).

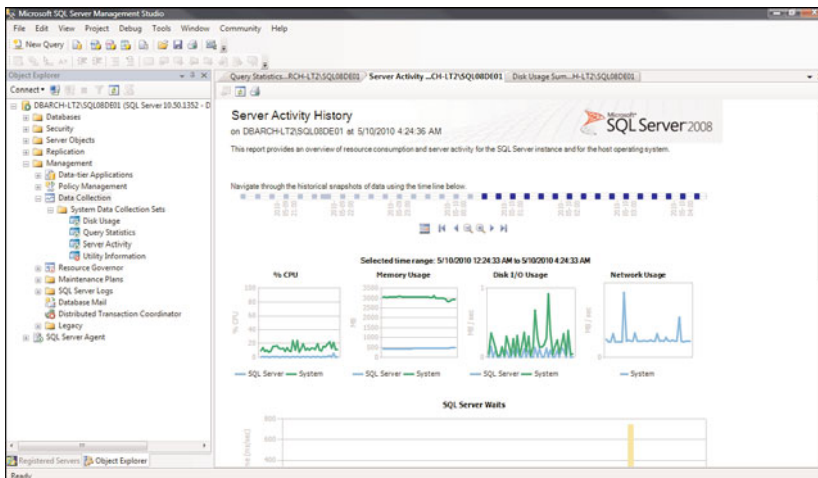

FIGURE 55.15 Data Collection: Server Activity History.

Summary

Dealing with the large number of configurable options in SQL Server is a big undertaking. You not only need to know about the internal address space of SQL Server, but also need to understand what types of applications will be running on the server so that the configuration decisions you make are not counterproductive.

Many of the configurable options have a direct effect on the most dynamic part of SQL Server: the memory pool. This is truly where all the action is. Whether you have chosen to let SQL Server help you manage this space dynamically via self-configuring options or you have decided to manage this yourself, you must constantly monitor the current settings and be prepared to modify them at any time. In general, you can start with the default values given to the server at installation time and then slowly enhance those options over time. In addition, to proactively identify needed enhancements to the indexing, partitioning, or physical table design, you should be running the DTA with a good representation of the production workload you are trying to optimize. In addition, you now have tools such as Data Collection services to easily report on the performance of your SQL Server instance all the way down to a particular SQL query execution.

Chapter 56, “SQL Server Disaster Recovery Planning,” describes a solid approach to planning for, testing, and ensuring business continuity for SQL Server-based implementations.

CHAPTER 56

SQL Server Disaster Recovery Planning

What? You think disasters never happen? Your SQL Servers and applications have been running fine for months on end? What could possibly happen to your data center in Kansas? If you think it can't happen to you, you are dreaming. Disasters happen in all sorts of sizes, shapes, and forms. Whether a disaster is human-made (terrorism, hacking, viruses, fires, human errors, and so on), an act of God (weather, earthquakes, fires, and so on), or just a plain failure of some kind (server failure), it can be catastrophic to your company's very existence. It is believed that some companies spend up to 25% of their budget on disaster recovery (DR) plans; however, this expenditure is to avoid bigger losses. Of companies that have a major loss of computerized records, 43% never reopen, 51% close within two years, and only 6% will survive long term. Which way would you go on this subject?

Likely, you are really thinking about getting serious about devising some type of disaster recovery plan that supports your company's business continuity requirements. This plan must be something that protects the primary (typically revenue generating) applications that your business relies on. Many applications are secondary when it comes to disaster recovery and business continuity. After you identify what systems need to be protected, you can go about planning and testing a true disaster plan using all the best disaster recovery capabilities you have at your disposal. Microsoft doesn't have something it calls "disaster recovery for SQL Server," but it does have pieces of the puzzle that can be leveraged in your specialized plans for your own disaster recovery effort.

IN THIS CHAPTER

- ▶ What's New in SQL Server Disaster Recovery Planning
- ▶ How to Approach Disaster Recovery
- ▶ Microsoft SQL Server Options for Disaster Recovery
- ▶ The Overall Disaster Recovery Process
- ▶ Have You Detached a Database Recently?
- ▶ Third-Party Disaster Recovery Alternatives

What's New in SQL Server Disaster Recovery Planning

Microsoft still hasn't really introduced a specific new feature that says "disaster recovery" on it. But the company continues to release enhancements to existing features that can be leveraged on various approaches to disaster recovery in a SQL Server environment. In particular, a peer-to-peer replication model to the data replication offering is of high interest in regards to creating active/active disaster recovery solutions. Database mirroring (along with database snapshots) is also another feature that can be used to support both active/active and active/passive disaster recovery needs. These, and other more traditional offerings, round out the arsenal from Microsoft for giving you the comfortable feeling of attaining business continuity.

How to Approach Disaster Recovery

Often, disaster recovery specialists refer to a seven-tier disaster recovery paradigm. These tiers start at the bottom of the disaster recovery food chain—Tier 0 (no offsite data—possibly no recovery) and progress up to the highest level of disaster recovery possible—Tier 7 (zero to near-zero data loss with highly automated recovery). We developed a much more simplified and more generalized five-level representation that should aid you in understanding DR and how you can approach it more readily. Let's start with where we think most small to midsize companies find themselves: they have little to no disaster recovery plan and are operating at a fairly high risk exposure level. When we look at Figure 56.1, this places those folks in the very bottom of the upside-down pyramid at Level 1 and perhaps not even in the DR pyramid at all (below the line—no data backup offsite at all—Level 0).

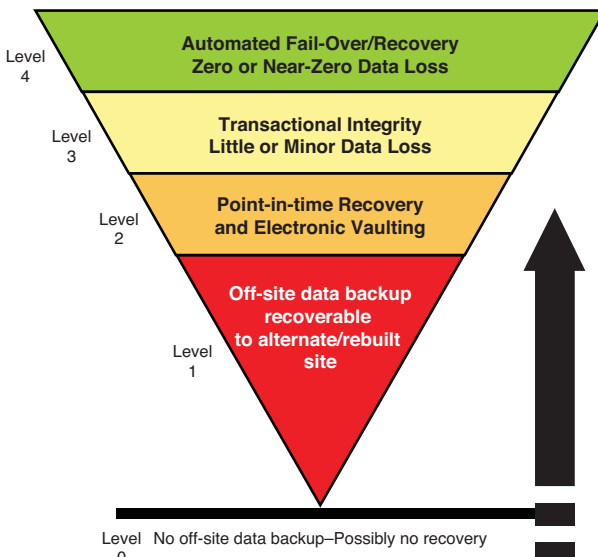

FIGURE 56.1 Disaster recovery levels pyramid.

Very likely, many of these companies are running a huge risk that they may not really want to have. The good news is that getting to a more protected level with your SQL Server–based applications isn’t really that hard to do. But nothing is free. After you establish some type of DR plan and create the technical process and mechanisms for your DR, you still have to implement and test it. Now, let’s examine more closely the disaster recovery levels and what level your company is currently or needs to go to.

Level 0 is very understandable because it relates to undergoing a disaster and being able to recover from it. You basically have to pick up the pieces (after a fire or something) and see what is salvageable from your site. Even the best onsite backup plans are rendered meaningless in regard to disaster recovery if the backups were not stored somewhere safe (offsite).

You must get to *Level 1* as soon as possible if you are even remotely serious about disaster recovery. We are talking about some very basic capability of creating a recoverable image (database backups, system configuration backups, user ID, permissions, role backups, and so on) that can effectively allow you to rebuild your critical applications and databases that are running on SQL Server at an alternate location. Data loss is probably involved, but it may not be enough to cause your company to completely go out of business. If you are not doing this right now, do it *today!*

Level 2 adds a much more real-time recovery time frame into the mix and gets to more of a point-in-time recovery capability. Using capabilities such as electronic vaulting aids greatly in your being able to restore systems (databases) rapidly and get back online to the world within a short amount of time. There is still a certain level of data loss here. That cannot be avoided.

Level 3 moves you to the complexities of recovering transactional integrity in your applications and minimizing your data losses. This level requires much more effort, resources, and sophistication, but is very doable.

Finally, many larger companies have *Level 4* in place to completely protect themselves from single-site failures or disasters without missing a single order transaction. This chapter identifies the different SQL Server–based options that allow you to achieve from Level 1 through Level 4 DR. In some cases, achieving this recovery involves using a Microsoft product combined with a third-party product.

The mandate we put on you is to devise a highly efficient disaster recovery plan in support of your business continuity needs and then *test it* completely! You need to make sure it considers all aspects of completely being able to come up onto an alternate location as smoothly, quickly, and with as little data loss as possible. Defining a disaster recovery plan can be a tedious job owing to the potential complexities of your configuration. But, keep in mind, a disaster recovery plan is essential to your company’s sheer existence and should be treated as such. Your objective is to move up the pyramid (to Level 4 or near it) to match your company’s needs for business continuity. We don’t want to read in the trades how your company took weeks to recover from a failed data center disaster and eventually went out of business; industry statistics are against you if you haven’t prepared.

Disaster Recovery Patterns

In general, you should consider three main DR patterns when trying to achieve Level 1 through Level 4 DR.

Active/Passive DR Sites Pattern

Figure 56.2 illustrates the active/passive DR sites pattern. This typical disaster recovery configuration is probably the most common in the world (for those who are doing DR). It involves a primary site (the normal environments in which you do business day in and day out) and a passive DR site. This passive DR (alternative) site can be anything and anywhere. It could be a “hot” alternate site that is ready for you to apply a current database backup to (and application image, too), or it could be a “cold” alternate site that you have to either go out and lease, co-locate with, or build completely from scratch. The available resources, money, and business need determines which method you choose. Obviously, the colder your DR site, the longer it will take for you to recover using it. A typical estimate of the time needed for a small to midsized company to completely rebuild the essential systems on an alternate site (DR site) is between 23 and 31 days.

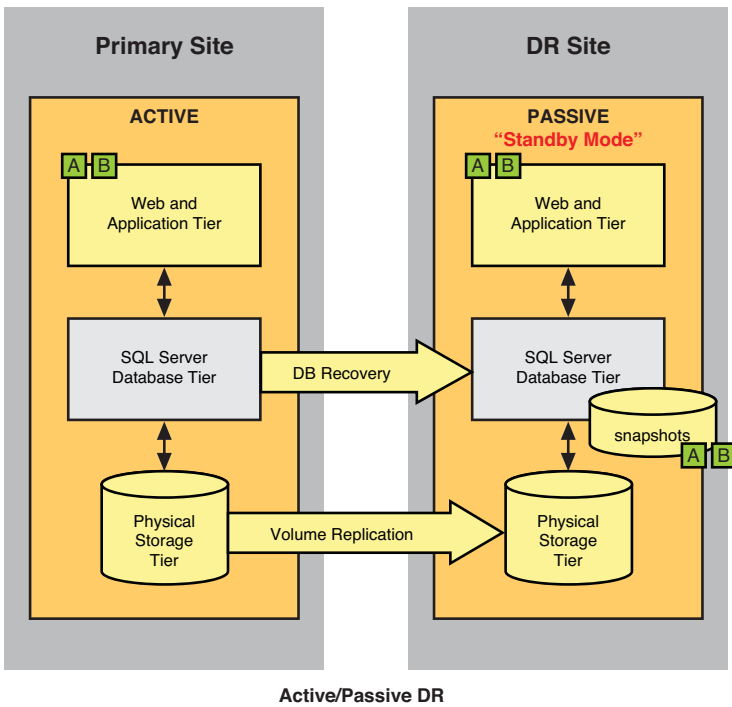

FIGURE 56.2 Active/passive DR sites pattern.

The Microsoft products to help you achieve this DR pattern are database backups taken offsite and readily recallable to recover (restore) your database tier and, if you have a “hot”

DR site available, you can utilize data replication to the DR site or log shipping or even asynchronous database mirroring. Some third-party products, such as Symantec's Veritas Volume Replicator, push physical byte-level changes to the passive (hot) DR site physical tier level. In most of these options, the DR site is passive, literally sitting there idle until it is needed. The only exception to that rule is when you are using Microsoft data replication or database snapshots with database mirroring. Even in those cases, the DR site does not support transactional change (updates, deletes, inserts); it supports read access only. Also, you need to remember that log shipping is on the way out in future Microsoft releases, so don't plan too much new usage of that feature.

Active/Active DR Sites Pattern

An active/active DR configuration essentially provides two primary sites that can process transactions equally. Any particular external or internal usage of the applications doesn't really know which site is processing the requests (and, in fact, doesn't need to know). This configuration has the entire application stack completely deployed on both sites. The data is kept in sync in real-time, and either site could be lost and not affect the operation of the company. Some data loss is possible, but this is usually kept at a minimum, depending on which Microsoft options you are using. Figure 56.3 shows an active/active DR configuration that bidirectionally keeps the databases in sync.

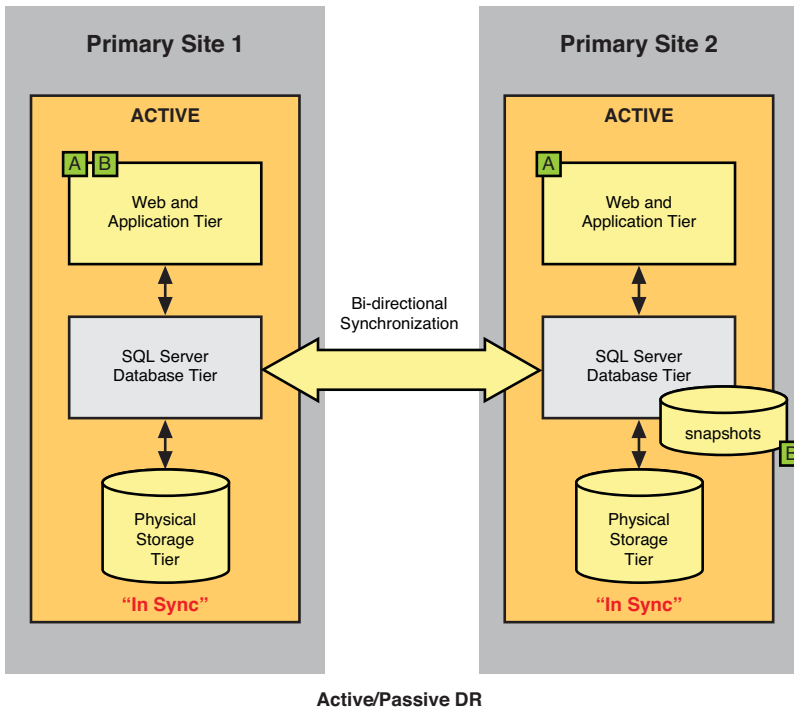

FIGURE 56.3 Active/active DR sites pattern.

A few things may cause issues for this pattern, such as the need to make sure that no application keeps “state” from one transaction to the other. Additionally, the application and/or the web tier needs to be able to route user connections (the load) to either site in some type of balanced or round-robin method. This is often done with big IP routers that use round-robin routing algorithms, for example, to determine which site to direct connections to. Active/active configurations can be created using peer-to-peer continuous data replication as well as other multi-updating subscriber replication topologies. A slight twist to having two primary sites is to have one primary site and a secondary site that doesn’t process transactions but is actively used for reporting, testing, and other tasks (just no processing that changes anything). In the event of a primary failure, the secondary site can take over full primary site responsibilities quickly. This is sort of active/passive, with active “secondary usage” on the passive site (following the first active/passive DR pattern described previously). This type of configuration can take advantage of database mirroring and database snapshots (for the reporting). There are plenty of advantages to this variation, which greatly distributes the workload and moves up the DR pyramid.

Active Multisite DR Pattern

An active multisite DR configuration contains three or more active sites, with the intention of using any one of them as the DR site for the other (as shown in Figure 56.4). This pattern allows you to distribute your applications redundantly between any pair of sites, but not to all three (or more). For instance, you could have half of Primary Site 1’s applications on Primary Site 2 and the other half on Primary Site 3. This way, you spread out the risk further and increase your odds of uninterrupted processing.

Again, having “stateless” applications is critical here, as is some smart routing of all connections to the right sites. Using continuous data replication and the database mirroring options allows you to easily create such a DR topology. And, again, you also have the secondary usage variation available to you if one or more alternative sites were passive (with secondary usage supporting reporting, for example).

Choosing a Disaster Recovery Pattern

We reduce these to patterns because, at the foundational level, they represent what you need to do to support the level of business continuity your company demands. Some companies can tolerate different levels of loss because of the nature of their business; others cannot. At the highest levels, it is fairly easy to match these patterns to what your business requires. In this chapter, we look at what SQL Server capabilities are available to help you implement these patterns.

Often, global companies devise a DR configuration that reserves each major data center site in their regions as the active or passive DR site for another region. Figure 56.5 shows one large high-tech company’s global data center locations. Its Alexandria, Virginia, site is also the passive DR site for its Phoenix, Arizona, site. Its Paris, France, regional site is also the DR site for its Alexandria, Virginia, site, and so on.

For companies that have multiple data center sites but only need to support the active/passive DR pattern, a very popular variation can be used. This variation is called *reciprocal DR*. As you can see in Figure 56.6, there are two sites (Site 1 and Site 2). Each is active for some applications (Applications 1, 3, and 5 on Site 1 and Applications 2, 4, and

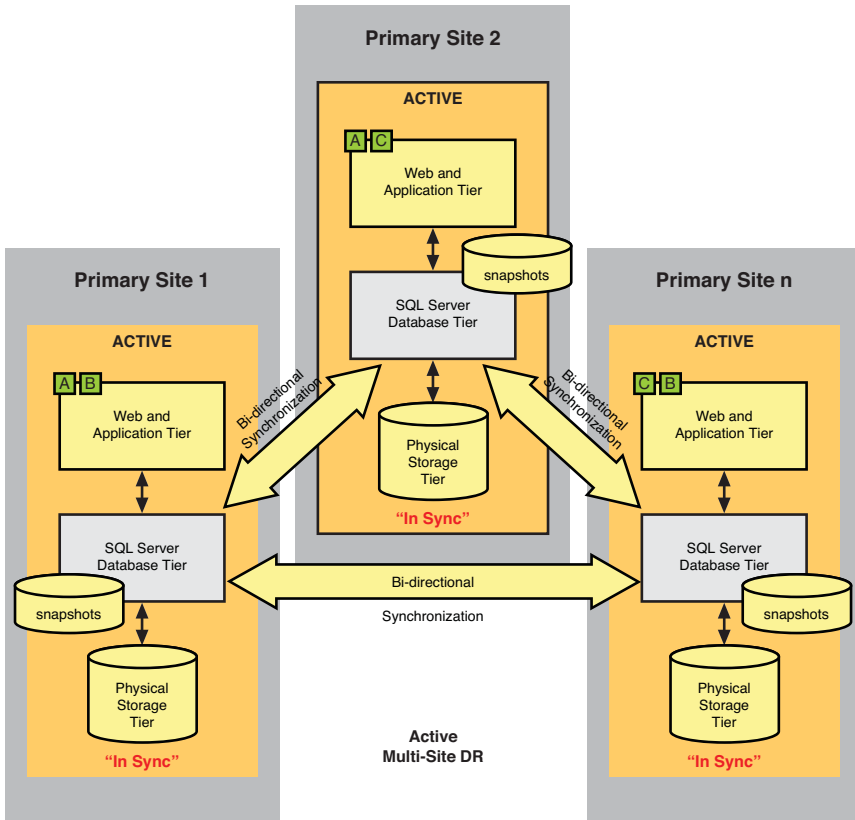

FIGURE 56.4 Active multisite DR pattern.

6 on Site 2). Site 1’s applications are passively supported on Site 2, and Site 2’s applications are passively supported on Site 1. Rolling out the configuration this way eliminates the “stateless” application issue completely and is fairly easy to implement. It is also possible to provide the passive applications data available via database snapshots at the other reciprocal site (for free!), further leveraging distributing workload geographically.

This configuration also spreads out the risk of losing all applications if one site ever happens to be lost (as in a disaster). Again, the Microsoft products to help you achieve this DR pattern variation are data replication to the DR site, or log shipping, and even asynchronous database mirroring with database snapshots available to help with some distributed reporting. As we noted previously, third-party products such as Symantec’s Veritas Volume Replicator can be used to push physical byte-level changes to the passive (hot) DR site physical tier level.

FIGURE 56.5 Using active regional sites for passive DR.

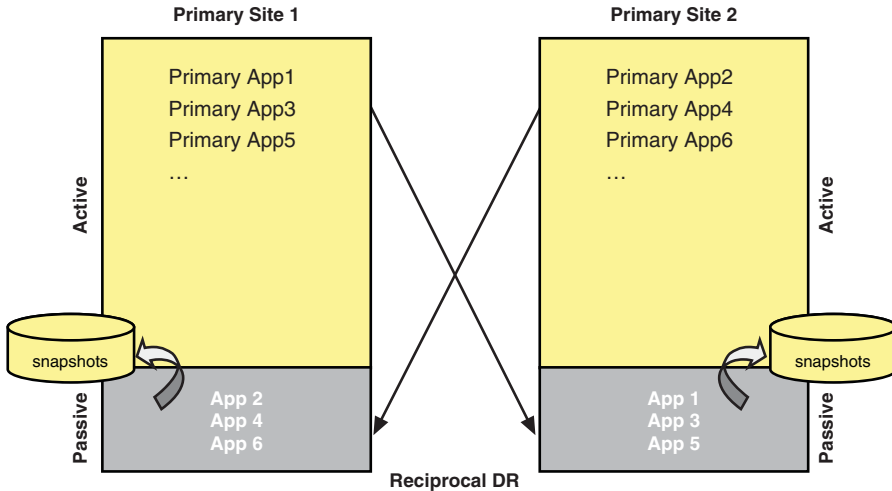

FIGURE 56.6 Reciprocal DR.

Recovery Objectives

You need to understand two main recovery objectives: the point in time to which data must be restored to be able to successfully resume processing (called the *recovery point objective*) and the acceptable amount of downtime that is tolerable (called the *recovery time objective*). The recovery point objective (RPO) is often thought of as the time between the

last backup and the point when the outage occurred. It indicates the amount of data that will be lost. The recovery time objective (RTO) is determined based on the acceptable downtime in case of a disruption of operations. It indicates the latest point in time at which the business operations must resume after disaster (that is, how much time can elapse).

The RPO and RTO form the basis on which a data protection strategy is developed. This helps to provide a picture of the total time that a business may lose due to a disaster. The two of them together are very important requirements when designing a solution. Let's put these terms in the form of algorithms:

RTO = Difference between the *time* of the disaster to the *time* the system is operational – *Time* operational (up) – *Time* disaster occurred (down)

RPO = *Time* since the last backup of complete transactions representing data that must be re-acquired or entered – *Time* disaster occurred – *Time* of last usable data backup

Therefore:

Total lost business time = *Time* operational (up) – *Time* disaster occurred (down) – *Time* of the last usable data backup

Knowing your RPO and RTO requirements is essential in determining what DR pattern to use and what Microsoft options to utilize.

A Data-Centric Approach to Disaster Recovery

Disaster recovery is a complex undertaking unto itself. However, it isn't really necessary to recover every system or application in the event of a disaster. Priorities must be set on determining exactly which systems or applications must be recovered. These are typically the revenue-generating applications (such as order entry, order fulfillment, and invoicing) that your business relies on to do basic business with its customers. Therefore, you set the highest priorities for DR with those revenue-generating systems. Then the next level of recovery is for the second-priority applications (such as HR systems).

After you prioritize which applications should be part of your DR plans, you need to fully understand what must be included in recovery to ensure that these priority applications are fully functional. The best way is to take a data-centric approach, which focuses on what data is needed to bring up the application. Data comes in many flavors, as Figure 56.7 shows:

- ▶ **Metadata**—The data that describes structures, files, XSDs, and so on that the applications, middleware, or back end needs.
- ▶ **Configuration data**—The data that the application needs to define what it must do, or the middleware needs to execute with, and so on.
- ▶ **Application data values**—The data itself within your database files that represents the transactional data in your systems.

As just mentioned, you first identify which applications you must include in your DR plans, and then you must make sure you back up and are able to recover that application's

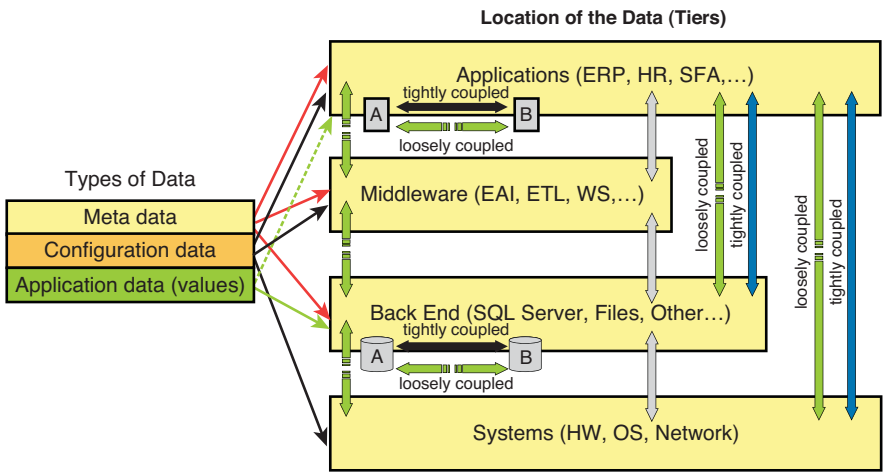

FIGURE 56.7 Types of data and where the data resides.

data (metadata, configuration data, and application data). As part of this exercise, you must determine how tightly or loosely coupled the data is to other applications. In other words (as you can also see in Figure 56.7), if on the back-end tier, Database A has the orders transactions and Database B has the invoicing data, both must be included in the DR plans (because they are tightly coupled). In addition, you must also know how tightly or loosely coupled the application stack components are with each layer. In other words (again looking at Figure 56.7), if the ERP application (in the application tier) requires some type of middleware to be present to handle all its messaging, that middleware tier component is tightly coupled with the ERP application and so on.

Microsoft SQL Server Options for Disaster Recovery

You have seen the fundamental DR patterns you will be targeting and also recognize how to identify the highest priority applications and their tightly coupled components for DR. Now let's look again at the specific Microsoft options available to implement various DR solutions. These options include data replication, log shipping, database mirroring, and database snapshots.

Data Replication

One of the strongest and more stable Microsoft options that can be leveraged for disaster recovery is data replication. Not all variations of data replication fit this bill, though. In particular, the central publisher using either continuous or very frequently scheduled distribution is very good for creating a hot spare of a SQL Server database across almost any geographical distance, as shown in Figure 56.8. The primary site is the only one actively processing transactions (updates, inserts, deletes) in this configuration, with all transactions being replicated to the subscriber, usually in a continuous replication mode.

The subscriber at the DR site is as up-to-date as the last distributed (replicated) transaction from the publisher—usually near real-time. The subscriber *can* be used for a read-only type of processing if controlled properly and that read-only access does not hinder the replication processing and put your DR pattern at risk.

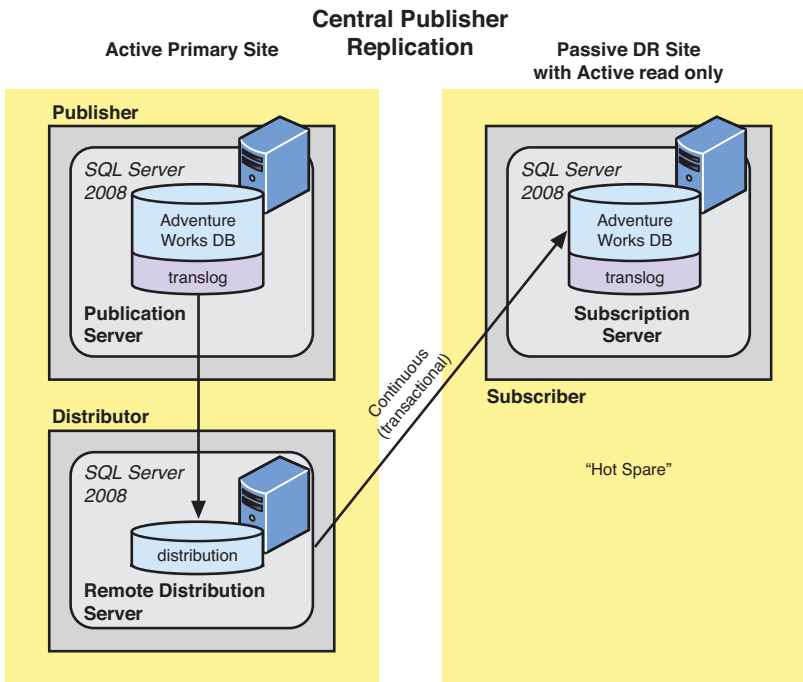

FIGURE 56.8 Central publisher data replication configuration for active/passive DR.

The newer peer-to-peer replication option provides a viable active/active capability that keeps both primaries in sync as transactions flow into each server's database, as shown in Figure 56.9. Both sites contain a full copy of the database, with transactions being consumed and then replicated simultaneously between them.

The complete setup of these data replication configurations is covered in Chapter 19, "Replication."

Log Shipping

As you can see in Figure 56.10, log shipping is readily usable for the active/passive DR pattern. You must understand that log shipping is only as good as the last successful transaction log shipment. Frequency of these log ships is critical in the RTO and RPO aspects of DR. This is really not a real-time solution. Even if you are using continuous log shipping mode, there is a lag of some duration due to the file movement and log application on the destination.

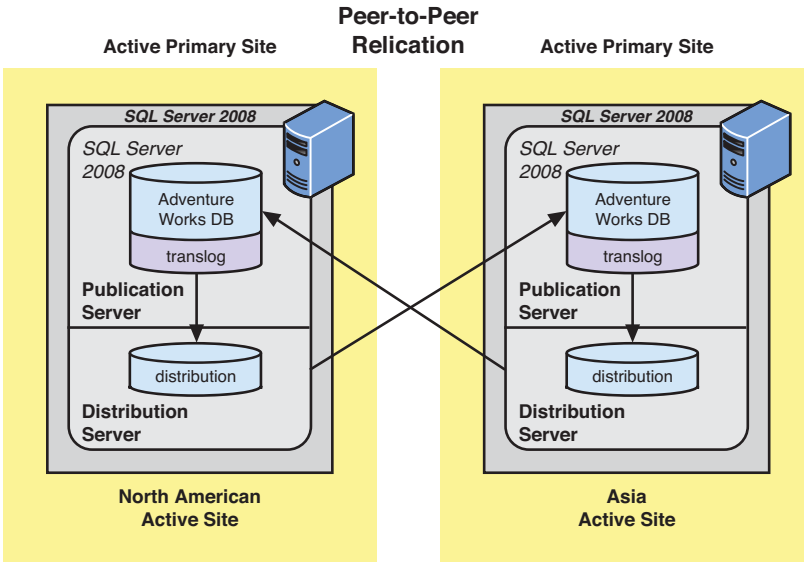

FIGURE 56.9 Peer-to-peer data replication configuration for active/active DR.

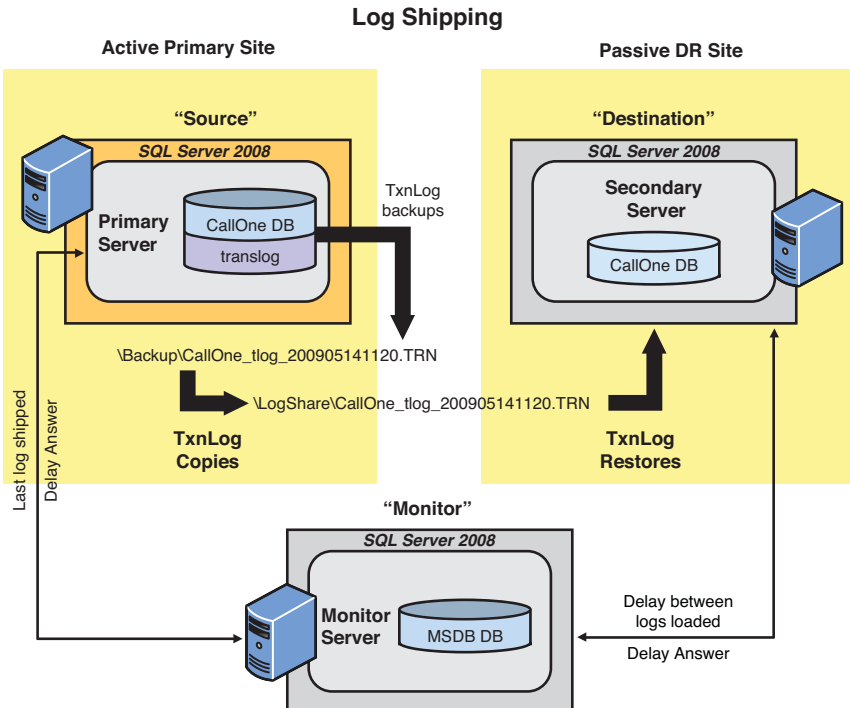

FIGURE 56.10 Log shipping configuration for active/passive DR.

Remember, log shipping is destined to be deprecated by Microsoft (unofficially announced). So it is perhaps not a good idea to start planning a future DR implementation that will go away.

Database Mirroring and Snapshots

Database mirroring is rapidly becoming the new, viable DR option from Microsoft. In either a high-availability mode (synchronous) or performance mode (asynchronous), this capability can help minimize data loss and time to recover (RPO and RTO). As you can see in Figure 56.11, database mirroring can be used across any reasonable network connection that may exist from one site to another. It effectively creates a mirror image that is completely intact for failover purposes if a site is lost. It is viable in both an active/passive pattern and in an active/active pattern (where a database snapshot is created from the unavailable mirror database and is used for active reporting).

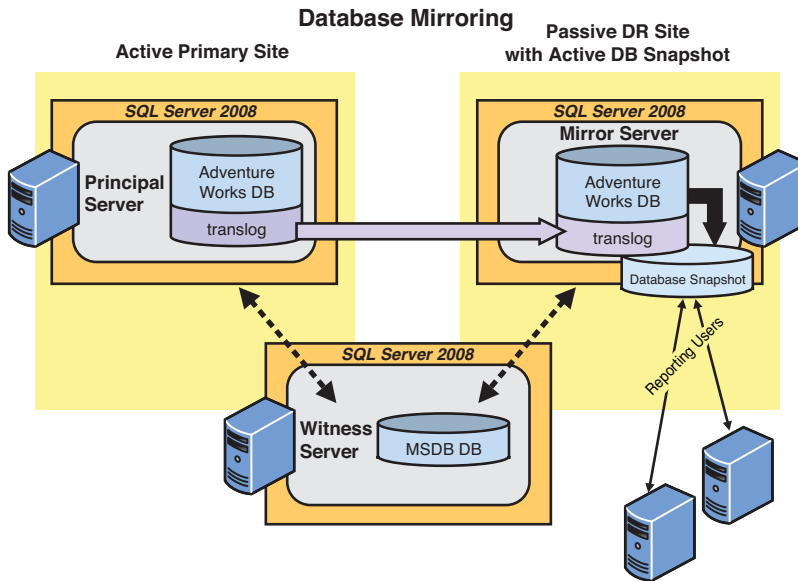

FIGURE 56.11 Database mirroring and database snapshots for active/passive DR.

NOTE

It is likely Microsoft will rapidly enhance database mirroring to support all DR patterns over time.

Setup and configuration of database mirroring are covered in Chapter 20, "Database Mirroring," along with full details of database snapshots in Chapter 32, "Database Snapshots."

Now, to complete the DR planning for your SQL Server platform, you must do much more homework and preparation. The next section explains a great overall disaster approach that includes pulling all the right information available and executing on a DR plan (and testing it thoroughly).

The Overall Disaster Recovery Process

In general, a handful of things need to be put together (that is, defined and executed upon) as the basis for an overall disaster recovery process or plan. The following list clearly identifies where you need to start:

1. Create a disaster recovery execution tasks/run book. This should include all steps to take to recover from a disaster and cover all system components that need to be recovered.
2. Arrange for or procure a server/site to recover to. This should be a configuration that can house what is needed to get you back online.
3. Guarantee that a complete database backup/recovery mechanism is in place (including offsite/alternate site archive and retrieval of databases).
4. Guarantee that an application backup/recovery mechanism is in place (for example, COM+ applications, .NET applications, web services, other application components, and so on).
5. Make sure you can completely re-create and resynchronize your security (Microsoft Active Directory, domain accounts, SQL Server logins/passwords, and so on). We call this “security resynchronization readiness.”
6. Make sure you can completely configure and open up network/communication lines. This also includes ensuring that routers are configured properly, IP addresses are made available, and so on.
7. Train your support personnel on all elements of recovery. You can never know enough ways to recover a system. And it seems that a system never recovers the same way twice.
8. Plan and execute an annual or bi-annual disaster recovery simulation. The one or two days that you do this will pay you back a hundred times over if a disaster actually occurs. And, remember, disasters come in many flavors.

Many organizations have gone to the concept of having hot alternate sites available via stretch clustering or log shipping techniques. Costs can be high for some of these advanced and highly redundant solutions.

The Focus of Disaster Recovery

If you create some very solid, time-tested mechanisms for re-creating your SQL Server environment, they will serve you well when you need them most. Following are the things to focus on for disaster recovery:

- ▶ Always generate scripts for as much of your work as possible (anything created using a wizard, SMSS, and so on). These scripts will save your hide. They should include the following:
 - ▶ Complete replication buildup/breakdown scripts
 - ▶ Complete database creation scripts (DB, tables, indexes, views, and so on).
 - ▶ Complete SQL login, database user IDs and password scripts (including roles and other grants)
 - ▶ Linked/remote server setup (linked servers, remote logins)
 - ▶ Log shipping setup (source, target, and monitor servers)
 - ▶ Any custom SQL Agent tasks
 - ▶ Backup/restore scripts
 - ▶ Potentially other scripts, depending on what you have built on SQL Server
- ▶ Make sure you document all aspects of SQL database maintenance plans being used. This includes frequencies, alerts, email addresses being notified when errors occur, backup file/device locations, and so on.
- ▶ Document all hardware/software configurations used:
 - ▶ Leverage `sqldiag.exe` for this (as described in the next section).
 - ▶ Record what accounts were used to start up the SQL Agent service for an instance and MS Distributed Transaction Coordinator (MS DTC) service. This step is especially important if you're using distributed transactions and data replication.
 - ▶ The favorite SQL Server implementation characteristics that we script and record for a SQL Server instance are
 - ▶ **select @@SERVERNAME**—Provides the full network name of the SQL Server and instance.
 - ▶ **select @@SERVICENAME**—Provides the Registry key under which Microsoft SQL Server is running.
 - ▶ **select @@VERSION**—Provides the date, version, and processor type for the current installation of Microsoft SQL Server.
 - ▶ **exec sp_helpserver**—Provides the server name; the server's network name; the server's replication status; and the server's identification number, collation name, and time-out values for connecting to, or queries against, linked servers.
 - ▶ **exec sp_helplogins**—Provides information about logins and the associated users in each database.

- ▶ **exec sp_linkedservers**—Returns the list of linked servers defined in the local server.
- ▶ **exec sp_helplinkedserverlogin**—Provides information about login mappings defined against a specific linked server used for distributed queries and remote stored procedures.
- ▶ **exec sp_server_info**—Returns a list of attribute names and matching values for Microsoft SQL Server.
- ▶ **exec sp_helpdb dbnamexyz**—Provides information about a specified database or all databases. This includes the database allocation names, sizes, and locations.

```
use dbnamexyz
go
exec sp_spaceused
```

- ▶ **exec sp_spaceused**—Set of SQL statements that provide the actual database usage information of both data and indexes for the specified database name (dbnamexyz).

```
use dbnamexyz
go
exec sp_spaceused
go
```

- ▶ **exec sp_configure** - Get the current SQL Server configuration values by running **sp_configure** (with the “show advanced option”):

```
USE master
EXEC sp_configure 'show advanced option', '1'
RECONFIGURE
go
EXEC sp_configure
Go
```

- ▶ Disk configurations, sizes, and current size availability (use standard OS directory listing commands on all disk volumes being used).
- ▶ Capture the sa login password and OS administrator password so that anything can be accessed and anything can be installed (or re-installed).
- ▶ Document all contact information for your vendors:
 - ▶ Microsoft support services contacts (do you use “Premier Product Support Services”?)
 - ▶ Storage vendor contact info
 - ▶ Hardware vendor contact info
 - ▶ Offsite storage contact info (to get your archived copy fast)
 - ▶ Network/telecom contact info
 - ▶ Your CTO, CIO, and other senior management contact info

- ▶ CD-ROMs available for everything (SQL Server, service packs, operating system, utilities, and so on)

sqldiag.exe

One good way to get a complete environmental picture is to run the `sqldiag.exe` program provided with SQL Server 2008 on your production box (which you would have to re-create on an alternate site if a disaster occurred). It is located in the Binn directory where all SQL Server executables reside (C:\Program Files\Microsoft SQL Server\100\Tools\Binn). It shows how the server is configured, all hardware and software components (and their versions), memory sizes, CPU types, operating system version and build information, paging file information, environment variables, and so on. If you run this program on your production server periodically, it serves as good environment documentation to supplement your disaster recovery plan. This utility is also used to capture and diagnose SQL Server-wide issues and has a prompt that you must respond to when re-creating issues on which you want to collect diagnosis information. For the purposes of this chapter, when prompted for the SQLDIAG Collection, you can just terminate that portion by pressing Ctrl+C. Figure 56.12 shows the expected execution DOS windows and system information dialog window.

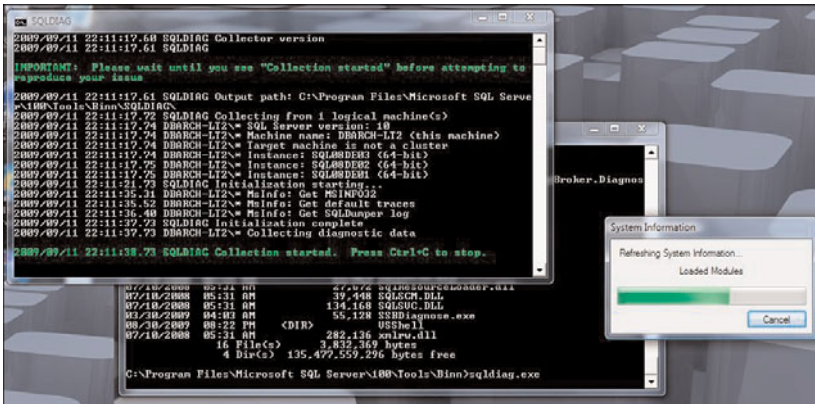

FIGURE 56.12 `sqldiag.exe` execution.

To run this utility, you open a DOS command prompt and change directory to the SQL Server Binn directory. Then, at the command prompt, you run `sqldiag.exe`:

```
C:\Program Files\Microsoft SQL Server\100\Tools\Binn> sqldiag.exe
```

The results are written into several text files within the SQLDIAG subdirectory. Each file contains different types of data about the physical machine (server) that SQL Server is

running on and information about each SQL Server instance. The machine (server) information is stored in a file named `XYZ_MSINF032.TXT`, where `XYZ` is the machine name. It really contains a verbose snapshot of everything that relates to SQL Server (in one way or another) and all the hardware configuration, drivers, and so on. It is the tightly coupled metadata and configuration information directly related to the SQL Server instance. The following is an example of what it contains:

System Information report written at: 09/11/09 22:13:16

System Name: DBARCH-LT2

[System Summary]

Item	Value
OS Name	Microsoft® Windows Vista™ Home Premium
Version	6.0.6001 Service Pack 1 Build 6001
Other OS Description	Not Available
OS Manufacturer	Microsoft Corporation
System Name	DBARCH-LT2
System Manufacturer	Hewlett-Packard
System Model	HP G60 Notebook PC
System Type	x64-based PC
Processor	Pentium(R) Dual-Core CPU T4300 @ 2.10GHz, 2100 Mhz, 2 Core(s), 2 Logical Processor(s)
BIOS Version/Date	Hewlett-Packard F.3C, 6/23/2009
SMBIOS Version	2.4
Windows Directory	C:\Windows
System Directory	C:\Windows\system32
Boot Device	\Device\HarddiskVolume1
Locale	United States
Hardware Abstraction Layer	Version = "6.0.6001.18000"
User Name	DBARCH-LT2\DBARCH
Time Zone	Pacific Daylight Time
Installed Physical Memory (RAM)	Not Available
Total Physical Memory	3.90 GB
Available Physical Memory	1.87 GB
Total Virtual Memory	8.04 GB
Available Virtual Memory	5.63 GB
Page File Space	4.20 GB
Page File	C:\pagefile.sys

and so on.

A separate file is generated for each SQL Server instance you have installed on a server. These files are named `XYZ_ABC_sp_sqldiag_Shutdown.OUT`, where `XYZ` is the machine name and `ABC` is the SQL Server instance name. This file contains most of the internal SQL Server information regarding how it is configured, including a snapshot of the SQL Server log as this server is operating on this machine. The following example shows this critical information from the `DBARCH-LT2_SQL08DE01_sp_sqldiag_Shutdown.OUT` file:

```

2009-09-07 23:50:21.540 Server      Microsoft SQL Server 2008 (SP1) - 10.0.2531.0
(X64)

2009-09-07 23:50:21.560 Server      Server process ID is 1884.
2009-09-07 23:50:21.560 Server      Logging SQL Server messages in file
'C:\Program Files\Microsoft SQL Server\MSSQL10.SQL08DE01\MSSQL\Log\ERRORLOG'.
2009-09-07 23:50:21.570 Server      Registry startup parameters:
    -d C:\Program Files\Microsoft SQL
Server\MSSQL10.SQL08DE01\MSSQL\DATA\master.mdf
    -e C:\Program Files\Microsoft SQL Server\MSSQL10.SQL08DE01\MSSQL\Log\ERRORLOG
    -l C:\Program Files\Microsoft SQL Server\MSSQL10.SQL08DE01\MSSQL\DATA\mast-
log.ldf
2009-09-07 23:50:21.610 Server      Detected 2 CPUs.
This is an informational message; no user action is required.
2009-09-07 23:50:21.910 Server      Using dynamic lock allocation.
Initial allocation of 2500 Lock blocks and 5000 Lock Owner blocks per node.
This is an informational message only. No user action is required.
2009-09-07 23:50:23.050 spid7s      FILESTREAM: effective level = 3,
configured level = 3, file system access share name = 'SQL08DE01'.
2009-09-07 23:50:23.820 spid7s      Server name is 'DBARCH-LT2\SQL08DE01'.
This is an informational message only. No user action is required.

```

From this output, you are able to ascertain the complete SQL Server instance information as it was running on the primary site. It is excellent documentation for your SQL Server implementation. We suggest that you run this utility regularly and compare the outcome with prior executions to guarantee that you know exactly what you have to have in place in case of disaster.

Planning and Executing a Disaster Recovery

The process of planning and executing a complete disaster recovery is serious business, and many companies around the globe set aside a few days a year to perform this exact task. Here's what it involves:

- ▶ Simulate a disaster.
- ▶ Record all actions taken.
- ▶ Time all events from start to finish. Sometimes this means someone is standing around with a stopwatch.
- ▶ Hold a postmortem following the DR simulation.

Many companies tie the results of a DR simulation to the IT group's salaries (their raise percentage). This is more than enough motivation for IT to get this drill right and to perform well.

Correcting any failures or issues that occur is critical. The next time might not be a simulation.

Have You Detached a Database Recently?

We suggest that you consider all methods of backup and recovery when dealing with DR. Another crude but extremely powerful method for creating a snapshot of a database (for any purpose, even for backup and recovery) is to simply detach the database and attach it in another location—pretty much anywhere. There will be some downtime during the detach time, the compressing of the database files (.mdf and .ldf), some time during the data transfer of these files (or single zipped file) from one location to another, some uncompress time, and the final attach time (seconds). All in all, it is a very reliable way to move an entire database from one place to another. This approach is crude, but fairly fast and extremely safe. To give you an example of what it takes, a database that is about 30GB can be detached, compressed, moved to another server across a network (with a 1GB backbone), uncompressed, and attached in about 10 minutes. You should make sure your administrators know they can do this in a pinch.

Third-Party Disaster Recovery Alternatives

Third-party alternatives to replication, mirroring, and synchronization approaches of support disaster recovery are fairly prevalent. Symantec and a handful of other companies lead the way with very viable, but often expensive, solutions. However, many are bundled with their disk subsystems (which makes them easy to use and manage out-of-the-box). Following are some very strong solutions:

- ▶ **Symantec**—The Symantec replication solutions, including Veritas Storage Replicator and Veritas Volume Replicator, can create duplicate copies of data across any distance for data protection. These are certified with SQL Server. See www.symantec.com.
- ▶ **SteelEye Technologies**—The SteelEye LifeKeeper family of data replication, high-availability clustering, and disaster recovery products are for Linux and Windows environments. They are all certified solutions (on a variety of other vendor products) across a wide range of applications and databases running on Windows and Linux, including mySAP, Exchange, Oracle, DB2, and SQL Server. See www.steeleye.com.

- ▶ **EMC**—EMC Corporation provides cost-effective, continuous remote replication and continuous data protection via tools such as AutoStart, MirrowView, Open Migrator/LM, Replication Manager, and RepliStor. The Legato AA family of products includes capabilities required to manage systems performance and to automate recovery from failures. Legato AA also automates data mirroring and replication, to enable data consolidation, migration, distribution, and preservation through failures and disasters. See www.emc.com.

Our recommendation is that if you are already a customer of one of these vendors, you should look closely at these solutions because they may be available with a product you already are using.

Summary

Perhaps thousands of considerations must be dealt with when you are building a viable production implementation, let alone one that needs to have disaster recovery built in. You would be well advised to make the extra effort of first properly determining which disaster recovery solution matches your company's needs and then to switch focus to what is the most effective way to implement that chosen solution. If, for example, you choose data replication to support your DR needs, you must determine the right type of replication model to use (like a central publisher or peer-to-peer), what the limitations might be, the failover process that needs to be devised, and so on. Understanding other characteristics of your DR needs, such as what applications or databases are tightly coupled to your most important revenue-generation applications, is paramount. Not only is disaster recovery planning important, but testing the DR solution to make sure it works is even more important. You don't want to test your DR solution for the first time when your primary site has actually failed. You need to set some short-term attainable goals of getting to DR Level 1. This gets you in a basic level of protection (mitigating some of the risk from a disaster). Then you can start pushing upward to Level 2 and beyond to create the highest DR capability possible within your budget and capabilities.
