Contents at a Glance

Introduction	1
Part I Welcome to Microsoft SQL Server	
1 SQL Server 2008 Overview.....	9
2 What's New in SQL Server 2008.....	35
3 Examples of SQL Server Implementations	51
Part II SQL Server Tools and Utilities	
4 SQL Server Management Studio	63
5 SQL Server Command-Line Utilities	103
6 SQL Server Profiler	121
Part III SQL Server Administration	
7 SQL Server System and Database Administration.....	165
8 Installing SQL Server 2008.....	185
9 Upgrading to SQL Server 2008	227
10 Client Installation and Configuration	263
11 Security and User Administration	291
12 Data Encryption.....	335
13 Security and Compliance.....	359
14 Database Backup and Restore	377
15 Database Mail.....	427
16 SQL Server Scheduling and Notification	449
17 Administering SQL Server 2008 with PowerShell	481
18 SQL Server High Availability	523
19 Replication	545
20 Database Mirroring	617
21 SQL Server Clustering	655
22 Administering Policy-Based Management.....	687
Part IV Database Administration	
23 Creating and Managing Databases	709
24 Creating and Managing Tables	741
25 Creating and Managing Indexes	791
26 Implementing Data Integrity.....	811
27 Creating and Managing Views in SQL Server	837
28 Creating and Managing Stored Procedures	869

29	Creating and Managing User-Defined Functions	917
30	Creating and Managing Triggers	949
31	Transaction Management and the Transaction Log	995
32	Database Snapshots.	1043
33	Database Maintenance.	1069

Part V SQL Server Performance and Optimization

34	Data Structures, Indexes, and Performance	1091
35	Understanding Query Optimization	1209
36	Query Analysis	1301
37	Locking and Performance	1341
38	Database Design and Performance	1403
39	Monitoring SQL Server Performance.	1427
40	Managing Workloads with the Resource Governor	1493
41	A Performance and Tuning Methodology.	1519

Chapters on the CD

Part VI SQL Server Application Development

42	What's New for Transact-SQL in SQL Server 2008.	1551
43	Transact-SQL Programming Guidelines, Tips, and Tricks	1637
44	Advanced Stored Procedure Programming and Optimization.	1733
45	SQL Server and the .NET Framework	1787
46	SQLCLR: Developing SQL Server Objects in .NET	1825
47	Using XML in SQL Server 2008	1865
48	SQL Server Web Services.	1927
49	SQL Server Service Broker	1959
50	SQL Server Full-Text Search	1997

Part VII SQL Server Business Intelligence Features

51	SQL Server 2008 Analysis Services.	2029
52	SQL Server Integration Services	2099
53	SQL Server 2008 Reporting Services	2169

Part VIII Bonus Chapters

54	Managing Linked and Remote Servers	2243
55	Configuring, Tuning, and Optimizing SQL Server Options	2273
56	SQL Server Disaster Recovery Planning.	2329 2353

Table of Contents

Introduction	1
Part I Welcome to Microsoft SQL Server	
1 SQL Server 2008 Overview	9
SQL Server Components and Features	9
The SQL Server Database Engine.....	10
SQL Server 2008 Administration and Management Tools	12
Replication	15
Database Mirroring.	17
Full-Text Search.	17
SQL Server Integration Services (SSIS).....	18
SQL Server Analysis Services (SSAS)	19
SQL Server Reporting Services (SSRS).....	20
SQL Server Service Broker.	22
SQL Server 2008 R2 Editions	23
SQL Server 2008 Standard Edition	23
SQL Server 2008 Enterprise Edition	24
Differences Between the Enterprise and Standard Editions of SQL Server	25
Other SQL Server 2008 Editions.....	26
SQL Server Licensing Models.	30
Web Edition	32
Developer Edition Licensing	32
Express Edition Licensing.....	32
Compact Edition 3.5 Licensing.....	32
Choosing a Licensing Model	32
Mixing Licensing Models	33
Passive Server/Failover Licensing	33
Virtual Server Licensing.....	33
Multiple Instances of SQL Server	34
Summary	34
2 What's New in SQL Server 2008	35
New SQL Server 2008 Features	35
New Storage Features.....	36
New Data Types	37
New Transact-SQL Constructs	37
New Performance Features	38
New Security Features.....	39

New Database Administration Features	40
New SQL Server Management Studio Features	41
PowerShell Integration	42
New Premium SQL Server Editions	42
SQL Server Utility for Multiserver Management	43
PowerPivot for Excel and SharePoint	43
New Reporting Services Features	44
SQL Server 2008 Enhancements	45
SQL Server Management Studio	45
Dynamic Management Views	45
Database Mirroring	46
SQLCLR Enhancements	46
Replication Enhancements	46
SQL Server Integration Services Enhancements	47
Service Broker Enhancements	47
Analysis Services Enhancements	48
Installation Enhancements	49
Deprecated Features	49
Summary	50
3 Examples of SQL Server Implementations	51
Application Terms	52
OLTP Application Examples	53
OLTP ERP Example	53
OLTP Shopping Cart Example	56
DSS Application Examples	57
DSS Example One	57
DSS Example Two	58
DSS Example Three	59
Summary	61
Part II SQL Server Tools and Utilities	
4 SQL Server Management Studio	63
What's New in SSMS	63
The Integrated Environment	64
Window Management	65
Integrated Help	68
Administration Tools	71
Registered Servers	71
Object Explorer	73
Activity Monitor	75

Log File Viewer	77
SQL Server Utility	79
Development Tools	85
The Query Editor	85
Managing Projects in SSMS	93
Integrating SSMS with Source Control.....	95
Using SSMS Templates	97
T-SQL Debugging	100
Multiserver Queries.....	101
Summary	102
5 SQL Server Command-Line Utilities	103
What's New in SQL Server Command-Line Utilities	104
The sqlcmd Command-Line Utility	105
Executing the sqlcmd Utility.....	106
Using Scripting Variables with sqlcmd	108
The dta Command-Line Utility.	109
The tablediff Command-Line Utility.....	112
The bcp Command-Line Utility	115
The sqldiag Command-Line Utility.....	116
The sqlservr Command-Line Utility.....	118
Summary	119
6 SQL Server Profiler	121
What's New with SQL Server Profiler.....	121
SQL Server Profiler Architecture	122
Creating Traces.	123
Events.....	125
Data Columns.....	127
Filters.	130
Executing Traces and Working with Trace Output	132
Saving and Exporting Traces.	132
Saving Trace Output to a File	133
Saving Trace Output to a Table	134
Saving the Profiler GUI Output.....	134
Importing Trace Files	135
Importing a Trace File into a Trace Table.....	135
Analyzing Trace Output with the Database Engine Tuning Advisor.....	138
Replaying Trace Data	138
Defining Server-Side Traces.....	140
Monitoring Running Traces	153
Stopping Server-Side Traces	155

Profiler Usage Scenarios	157
Analyzing Slow Stored Procedures or Queries	157
Deadlocks	158
Identifying Ad Hoc Queries	159
Identifying Performance Bottlenecks	160
Monitoring Auto-Update Statistics	162
Monitoring Application Progress	162
Summary	164

Part III SQL Server Administration

7 SQL Server System and Database Administration 165

What's New in SQL Server System and Database Administration.	165
System Administrator Responsibilities	166
System Databases	166
The master Database.....	167
The resource Database	168
The model Database	168
The msdb Database.....	168
The distribution Database	168
The tempdb Database	169
Maintaining System Databases.....	169
System Tables	170
System Views.....	171
Compatibility Views	172
Catalog Views	175
Information Schema Views	177
Dynamic Management Views.....	179
System Stored Procedures	181
Useful System Stored Procedures.....	182
Summary	183

8 Installing SQL Server 2008 185

What's New in Installing SQL Server 2008	185
Installation Requirements.	186
Hardware Requirements	186
Software Requirements	188
Installation Walkthrough	192
Install Screens, Step by Step	192
Other Options Available in the SQL Server Installation Center	211
Installing SQL Server Using a Configuration File	212
Running an Automated or Manual Install.....	217

Installing Service Packs and Cumulative Updates	218
Installing SP1 from the Command Line	220
Slipstream Installations.	222
Summary	225
9 Upgrading to SQL Server 2008	227
What's New in Upgrading SQL Server.	227
Using the SQL Server Upgrade Advisor (UA)	228
Getting Started with the UA.	229
The Analysis Wizard	230
The Report Viewer	235
Destination: SQL Server 2008 or SQL Server 2008 R2	236
Side-by-Side Migration.	236
Upgrading In-Place	242
Upgrading Using a Configuration File	250
Slipstreaming Upgrades	251
Upgrading from SQL Server 7 or SQL Server 6.5	252
Upgrading Other SQL Server Components	253
Upgrading Analysis Services	253
Upgrading Reporting Services	255
Summary	261
10 Client Installation and Configuration	263
What's New in Client Installation and Configuration	263
Client/Server Networking Considerations.	264
Server Network Protocols	264
The Server Endpoint Layer	267
The Role of SQL Browser	270
Client Installation	271
Installation Requirements	271
Installing the Client Tools.	271
Installing SNAC	272
Client Configuration	274
Client Configuration Using SSCM	275
Connection Encryption.	278
Client Data Access Technologies	279
Provider Choices	280
Driver Choices	281
Connecting Using the Various Providers and Drivers	281
General Networking Considerations and Troubleshooting.	287
Summary	289

11	Security and User Administration	291
	What's New in Security and User Administration	291
	An Overview of SQL Server Security	292
	Authentication Methods.	294
	Windows Authentication Mode	294
	Mixed Authentication Mode	294
	Setting the Authentication Mode.	295
	Managing Principals	295
	Logins.	296
	SQL Server Security: Users	298
	User/Schema Separation	301
	Roles	302
	Managing Securables.	309
	Managing Permissions	311
	Managing SQL Server Logins	313
	Using SSMS to Manage Logins	313
	Using T-SQL to Manage Logins	317
	Managing SQL Server Users	318
	Using SSMS to Manage Users	318
	Using T-SQL to Manage Users	320
	Managing Database Roles	321
	Using SSMS to Manage Database Roles.	321
	Using T-SQL to Manage Database Roles.	322
	Managing SQL Server Permissions	322
	Using SSMS to Manage Permissions.	323
	Using T-SQL to Manage Permissions.	330
	The Execution Context.	331
	Explicit Context Switching	332
	Implicit Context Switching.	333
	Summary	334
12	Data Encryption	335
	What's New in Data Encryption.	336
	An Overview of Data Security	336
	An Overview of Data Encryption	338
	SQL Server Key Management.	339
	Extensible Key Management	341
	Column-Level Encryption	343
	Encrypting Columns Using a Passphrase.	344
	Encrypting Columns Using a Certificate	346

Transparent Data Encryption	350
Implementing Transparent Data Encryption	351
Managing TDE in SSMS	352
Backing Up TDE Certificates and Keys.	353
Limitations of TDE	355
Column-Level Encryption Versus Transparent Data Encryption.	356
Summary	357
13 Security and Compliance	359
Exposure and Risk	360
Across the Life Cycle	361
The Security Big Picture	362
Identity Access Management Components	364
Compliance and SQL Server	366
SQL Server Auditing	368
Setting Up Auditing via T-SQL	372
SQL Injection Is Easy to Do	374
Summary	376
14 Database Backup and Restore	377
What's New in Database Backup and Restore	377
Developing a Backup and Restore Plan	378
Types of Backups.	379
Full Database Backups	380
Differential Database Backups	380
Partial Backups.	381
Differential Partial Backups	381
File and Filegroup Backups	381
Copy-Only Backups	382
Transaction Log Backups	382
Recovery Models	382
Full Recovery	383
Bulk-Logged Recovery.	384
Simple Recovery.	385
Backup Devices	385
Disk Devices	386
Tape Devices	386
Network Shares	386
Media Sets and Families	387
Creating Backup Devices	387

Backing Up a Database	388
Creating Database Backups with SSMS	388
Creating Database Backups with T-SQL	390
Backing Up the Transaction Log	393
Creating Transaction Log Backups with SSMS	394
Creating Transaction Log Backups with T-SQL	394
Backup Scenarios.	396
Full Database Backups Only	396
Full Database Backups with Transaction Log Backups	396
Differential Backups.	397
Partial Backups.	398
File/Filegroup Backups.	400
Mirrored Backups.	401
Copy-Only Backups.	402
Compressed Backups	402
System Database Backups	403
Restoring Databases and Transaction Logs.	403
Restores with T-SQL	404
Restoring by Using SSMS	409
Restore Information.	411
Restore Scenarios.	414
Restoring to a Different Database	414
Restoring a Snapshot	416
Restoring a Transaction Log	416
Restoring to the Point of Failure	417
Restoring to a Point in Time	419
Online Restores.	421
Restoring the System Databases	421
Additional Backup Considerations.	423
Frequency of Backups	423
Using a Standby Server	424
Snapshot Backups	425
Considerations for Very Large Databases	425
Maintenance Plans	426
Summary	426
15 Database Mail	427
What's New in Database Mail	427
Setting Up Database Mail	428
Creating Mail Profiles and Accounts	429
Using T-SQL to Update and Delete Mail Objects	432

Setting System-wide Mail Settings.....	433
Testing Your Setup	433
Sending and Receiving with Database Mail	434
The Service Broker Architecture	434
Sending Email	435
Receiving Email	441
Using SQL Server Agent Mail.	441
Job Mail Notifications	442
Alert Mail Notifications.	443
Related Views and Procedures	445
Viewing the Mail Configuration Objects	445
Viewing Mail Message Data.	446
Summary	448
16 SQL Server Scheduling and Notification	449
What's New in Scheduling and Notification	450
Configuring the SQL Server Agent	450
Configuring SQL Server Agent Properties	450
Configuring the SQL Server Agent Startup Account	452
Configuring Email Notification	454
SQL Server Agent Proxy Account	455
Viewing the SQL Server Agent Error Log	456
SQL Server Agent Security	458
Managing Operators	458
Managing Jobs.	461
Defining Job Properties	461
Defining Job Steps	462
Defining Multiple Jobs Steps	464
Defining Job Schedules.....	465
Defining Job Notifications	467
Viewing Job History.	468
Managing Alerts.....	469
Defining Alert Properties.....	469
Defining Alert Responses.....	472
Scripting Jobs and Alerts.....	474
Multiserver Job Management	476
Creating a Master Server.....	476
Enlisting Target Servers.	477
Creating Multiserver Jobs	477
Event Forwarding.....	477
Summary	479

17	Administering SQL Server 2008 with PowerShell	481
	What's New with PowerShell.....	481
	Overview of PowerShell	482
	Start Using PowerShell Now.....	483
	Common Terminology	483
	Object-Based Functionality	484
	SQL Server Management Objects	484
	WMI	484
	Installing PowerShell	485
	PowerShell Console	485
	Scriptable and Interactive.	486
	Default Security	486
	Execution Policy	487
	Profiles	487
	Built-in Help Features	487
	PowerShell Scripting Basics.	490
	A Few Basic Cmdlets.....	490
	Creating a PowerShell Script	491
	Adding Comments	491
	Variables.	491
	Escaping Characters.	492
	Special Variable \$_.	493
	Joining Variables and Strings	493
	Passing Arguments.	494
	Using Param.	494
	Arrays	495
	Operators	496
	Conditional Statements.....	496
	Functions	497
	Looping Statements.	498
	Filtering Cmdlets	499
	Formatting Cmdlets.	500
	Dealing with CSV Files.....	501
	Dealing with Dates and Times	502
	-WhatIf/-Confirm Parameters.....	503
	PowerShell in SQL Server 2008.	503
	Adding PowerShell Support.....	503
	Accessing PowerShell.	505
	SQL Server PowerShell.	506
	SQL Provider	507
	SQL Cmdlets	508
	SQL Server Agent Support	509

Step-By-Step Examples	509
General Tasks	509
Scheduling Scripts	510
Common OS-Related Tasks	512
SQL Server–Specific Tasks	514
Using the Provider	515
Creating a Database Table	515
Performing a Database Backup	516
Checking Server Settings	518
Checking the Database Usage	519
Getting Table Properties	520
Cmdlet Example: Invoke-SqlCmd	520
Cmdlet Example: Invoke-PolicyEvaluation	521
Joining Columns	521
Retrieving an Entry	522
Summary	522
18 SQL Server High Availability	523
What’s New in High Availability	524
What Is High Availability?.	525
The Fundamentals of HA.	526
Hardware Factors	527
Backup Considerations	527
Operating System Upgrades	527
Vendor Agreements Followed	528
Training Kept Up to Date	528
Quality Assurance Done Well	528
Standards/Procedures Followed	528
Server Instance Isolation	528
Building Solutions with One or More HA Options.	530
Microsoft Cluster Services (MSCS)	530
SQL Clustering.	531
Data Replication	534
Log Shipping.	535
Database Mirroring.	537
Combining Failover with Scale-Out Options	538
Other HA Techniques That Yield Great Results	538
High Availability from the Windows Server Family Side	540
Microsoft Virtual Server 2005	541
Virtual Server 2005 and Disaster Recovery	542
Summary	542

19	Replication	545
	What's New in Data Replication	546
	What Is Replication?	547
	The Publisher, Distributor, and Subscriber Magazine Metaphor	549
	Publications and Articles	550
	Filtering Articles.	550
	Replication Scenarios.	555
	The Central Publisher Replication Model	555
	The Central Publisher with Remote Distributor Replication Model.	557
	The Publishing Subscriber Replication Model	558
	The Central Subscriber Replication Model	559
	The Multiple Publishers with Multiple Subscribers Replication Model	559
	The Updating Subscribers Replication Model	560
	The Peer-to-Peer Replication Model	561
	Subscriptions.	562
	Anonymous Subscriptions (Pull Subscriptions)	563
	The Distribution Database.	564
	Replication Agents.	565
	The Snapshot Agent	566
	The Log Reader Agent.	569
	The Distribution Agent.	569
	The Merge Agent.	570
	Other Specialized Agents.	571
	Planning for SQL Server Data Replication.	572
	Autonomy, Timing, and Latency of Data	572
	Methods of Data Distribution.	573
	SQL Server Replication Types.	574
	Snapshot Replication	574
	Transactional Replication	574
	Merge Replication.	575
	Basing the Replication Design on User Requirements.	577
	Data Characteristics	578
	Setting Up Replication.	579
	Creating a Distributor and Enabling Publishing	580
	Creating a Publication.	584
	Horizontal and Vertical Filtering.	592
	Creating Subscriptions.	594
	Scripting Replication.....	600
	Monitoring Replication	603
	Replication Monitoring SQL Statements.....	603
	Monitoring Replication within SQL Server Management Studio.....	606

	Troubleshooting Replication Failures.....	608
	New and Improved Peer-to-Peer Replication	609
	The Performance Monitor	610
	Replication in Heterogeneous Environments	611
	Backup and Recovery in a Replication Configuration.....	612
	Some Thoughts on Performance	613
	Log Shipping.	614
	Data Replication and Database Mirroring for Fault Tolerance and High Availability	614
	Summary	615
20	Database Mirroring	617
	What's New in Database Mirroring	617
	What Is Database Mirroring?.	618
	Copy-on-Write Technology	620
	When to Use Database Mirroring	621
	Roles of the Database Mirroring Configuration.	621
	Playing Roles and Switching Roles.....	622
	Database Mirroring Operating Modes.	622
	Setting Up and Configuring Database Mirroring.	623
	Getting Ready to Mirror a Database.....	624
	Creating the Endpoints	627
	Granting Permissions	629
	Creating the Database on the Mirror Server	630
	Identifying the Other Endpoints for Database Mirroring	632
	Configuring Database Mirroring by Using the Wizard	633
	Monitoring a Mirrored Database Environment	639
	Removing Mirroring	643
	Testing Failover from the Principal to the Mirror.	645
	Client Setup and Configuration for Database Mirroring.....	647
	Migrate to Database Mirroring 2008 as Fast as You Can	649
	Using Replication and Database Mirroring Together.....	651
	Using Database Snapshots from a Mirror for Reporting.....	652
	Summary	654
21	SQL Server Clustering	655
	What's New in SQL Server Clustering.	656
	How Microsoft SQL Server Clustering Works.....	656
	Understanding MSCS.....	658
	Extending MSCS with NLB.....	662
	How MSCS Sets the Stage for SQL Server Clustering.....	663

Installing SQL Server Clustering.	665
Configuring SQL Server Database Disks.....	666
Installing Network Interfaces	668
Installing MSCS	668
Installing SQL Server	668
Failure of a Node	679
The Connection Test Program for a SQL Server Cluster.....	681
Potential Problems to Watch Out for with SQL Server Clustering.....	684
Summary	685
22 Administering Policy-Based Management	687
Introduction to Policy-Based Management.....	687
Policy-Based Management Concepts.....	689
Facets.....	689
Conditions	693
Policies	693
Categories.....	693
Targets	693
Execution Modes	694
Central Management Servers	695
Implementing Policy-Based Management.	697
Creating a Condition Based on a Facet.....	697
Creating a Policy.	699
Creating a Category.	701
Evaluating Policies.	702
Importing and Exporting Policies	703
Sample Templates and Real-World Examples.	704
Sample Policy Templates	704
Evaluating Recovery Models.....	705
Implementing Surface Area Configuration Checks	705
SQL Server Health Checks	705
Ensuring Object Naming Conventions.....	706
Checking Best Practices Compliance	706
Policy-Based Management Best Practices	706
Summary.	707

Part IV Database Administration

23 Creating and Managing Databases	709
What's New in Creating and Managing Databases.....	710
Data Storage in SQL Server	710

Database Files711

- Primary Files712
- Secondary Files712
- Using Filegroups713
- Using Partitions716
- Transaction Log Files716

Creating Databases.717

- Using SSMS to Create a Database.....718
- Using T-SQL to Create Databases721

Setting Database Options.722

- The Database Options723
- Using T-SQL to Set Database Options725
- Retrieving Option Information726

Managing Databases729

- Managing File Growth.....729
- Expanding Databases.....730
- Shrinking Databases731
- Moving Databases.736
- Restoring a Database Backup to a New Location.....736
- Using ALTER DATABASE.....736
- Detaching and Attaching Databases737

Summary740

24 Creating and Managing Tables 741

What’s New in SQL Server 2008.....741

Creating Tables.742

- Using Object Explorer to Create Tables742
- Using Database Diagrams to Create Tables.743
- Using T-SQL to Create Tables744

Defining Columns747

- Data Types.....747
- Column Properties.755

Defining Table Location761

Defining Table Constraints.....763

Modifying Tables.765

- Using T-SQL to Modify Tables.....766
- Using Object Explorer and the Table Designer to Modify Tables.....769
- Using Database Diagrams to Modify Tables.....772

Dropping Tables773

Using Partitioned Tables774

- Creating a Partition Function776
- Creating a Partition Scheme.....778
- Creating a Partitioned Table.779

Adding and Dropping Table Partitions	782
Switching Table Partitions	785
Creating Temporary Tables	789
Summary	790
25 Creating and Managing Indexes	791
What's New in Creating and Managing Indexes	791
Types of Indexes.	792
Clustered Indexes	792
Nonclustered Indexes	793
Creating Indexes	795
Creating Indexes with T-SQL.....	795
Creating Indexes with SSMS.....	800
Managing Indexes.	803
Managing Indexes with T-SQL	803
Managing Indexes with SSMS	806
Dropping Indexes	807
Online Indexing Operations.....	807
Indexes on Views	809
Summary	810
26 Implementing Data Integrity	811
What's New in Data Integrity.....	811
Types of Data Integrity	812
Domain Integrity	812
Entity Integrity	812
Referential Integrity.....	812
Enforcing Data Integrity	812
Implementing Declarative Data Integrity	812
Implementing Procedural Data Integrity	813
Using Constraints	813
The PRIMARY KEY Constraint	813
The UNIQUE Constraint	815
The FOREIGN KEY Referential Integrity Constraint.....	816
The CHECK Constraint	820
Creating Constraints	821
Managing Constraints	827
Rules	830
Defaults	831
Declarative Defaults.....	831
Bound Defaults	833
When a Default Is Applied	833
Restrictions on Defaults.....	835
Summary	836

27	Creating and Managing Views in SQL Server	837
	What's New in Creating and Managing Views	837
	Definition of Views.	837
	Using Views.	839
	Simplifying Data Manipulation	839
	Focusing on Specific Data	840
	Abstracting Data	841
	Controlling Access to Data.	842
	Creating Views	844
	Creating Views Using T-SQL.....	845
	Creating Views Using the View Designer.....	849
	Managing Views.	852
	Altering Views	852
	Dropping Views with T-SQL.....	853
	Managing Views with SSMS	853
	Data Modifications and Views.	853
	Partitioned Views	854
	Modifying Data Through a Partitioned View	858
	Distributed Partitioned Views	859
	Indexed Views	860
	Creating Indexed Views.....	861
	Indexed Views and Performance.....	863
	To Expand or Not to Expand	866
	Summary	867
28	Creating and Managing Stored Procedures	869
	What's New in Creating and Managing Stored Procedures.....	869
	Advantages of Stored Procedures.	870
	Creating Stored Procedures.	871
	Creating Procedures in SSMS.....	872
	Temporary Stored Procedures.	879
	Executing Stored Procedures.....	880
	Executing Procedures in SSMS	881
	Execution Context and the EXECUTE AS Clause.....	882
	Deferred Name Resolution.....	885
	Identifying Objects Referenced in Stored Procedures.....	887
	Viewing Stored Procedures	888
	Modifying Stored Procedures.	891
	Viewing and Modifying Stored Procedures with SSMS.....	892
	Using Input Parameters	893
	Setting Default Values for Parameters.....	895
	Passing Object Names as Parameters.....	898

Using Wildcards in Parameters	899
Using Table-Valued Parameters	901
Using Output Parameters.....	902
Returning Procedure Status	904
Debugging Stored Procedures Using SQL Server Management Studio	905
Using System Stored Procedures.....	908
Startup Procedures	911
Summary	915
29 Creating and Managing User-Defined Functions	917
What's New in SQL Server 2008.....	917
Why Use User-Defined Functions?	918
Types of User-Defined Functions.	921
Scalar Functions.....	921
Table-Valued Functions	923
Creating and Managing User-Defined Functions.	925
Creating User-Defined Functions.....	925
Viewing and Modifying User-Defined Functions	936
Managing User-Defined Function Permissions.....	941
Rewriting Stored Procedures as Functions.	942
Creating and Using CLR Functions.....	944
Adding CLR Functions to a Database.....	944
Deciding Between Using T-SQL or CLR Functions	946
Summary	947
30 Creating and Managing Triggers	949
What's New in Creating and Managing Triggers	950
Using DML Triggers	950
Creating DML Triggers.....	951
Using AFTER Triggers.	953
Using inserted and deleted Tables.....	957
Enforcing Referential Integrity by Using DML Triggers	961
Cascading Deletes	963
Cascading Updates.	965
INSTEAD OF Triggers.....	967
Using DDL Triggers	976
Creating DDL Triggers.....	983
Managing DDL Triggers.....	986
Using CLR Triggers.....	988
Using Nested Triggers	991
Using Recursive Triggers	992
Summary	993

31	Transaction Management and the Transaction Log	995
	What's New in Transaction Management	995
	What Is a Transaction?	995
	How SQL Server Manages Transactions	996
	Defining Transactions	997
	AutoCommit Transactions	997
	Explicit User-Defined Transactions	998
	Implicit Transactions	1003
	Implicit Transactions Versus Explicit Transactions	1006
	Transactions and Batches	1007
	Transactions and Stored Procedures	1009
	Transactions and Triggers	1014
	Triggers and Transaction Nesting	1015
	Triggers and Multistatement Transactions	1017
	Using Savepoints in Triggers	1019
	Transactions and Locking	1021
	READ_COMMITTED_SNAPSHOT Isolation	1022
	Coding Effective Transactions	1022
	Transaction Logging and the Recovery Process	1023
	The Checkpoint Process	1024
	The Recovery Process	1028
	Managing the Transaction Log	1032
	Long-Running Transactions	1037
	Bound Connections	1039
	Distributed Transactions	1040
	Summary	1041
32	Database Snapshots	1043
	What's New with Database Snapshots	1044
	What Are Database Snapshots?	1044
	Limitations and Restrictions of Database Snapshots	1048
	Copy-on-Write Technology	1050
	When to Use Database Snapshots	1051
	Reverting to a Snapshot for Recovery Purposes	1052
	Safeguarding a Database Prior to Making Mass Changes	1053
	Providing a Testing (or Quality Assurance)	
	Starting Point (Baseline)	1054
	Providing a Point-in-Time Reporting Database	1054
	Providing a Highly Available and Offloaded	
	Reporting Database from a Database Mirror	1055
	Setup and Breakdown of a Database Snapshot	1056
	Creating a Database Snapshot	1057
	Breaking Down a Database Snapshot	1062

Reverting to a Database Snapshot for Recovery.	1062
Reverting a Source Database from a Database Snapshot	1063
Using Database Snapshots with Testing and QA	1064
Setting Up Snapshots Against a Database Mirror.	1064
Reciprocal Principal/Mirror Reporting Configuration	1065
Database Snapshots Maintenance and Security Considerations	1067
Security for Database Snapshots.....	1067
Snapshot Sparse File Size Management.....	1067
Number of Database Snapshots per Source Database	1067
Summary	1068
33 Database Maintenance	1069
What's New in Database Maintenance.	1070
The Maintenance Plan Wizard	1070
Backing Up Databases.....	1072
Checking Database Integrity	1075
Shrinking Databases	1076
Maintaining Indexes and Statistics	1077
Scheduling a Maintenance Plan.....	1080
Managing Maintenance Plans Without the Wizard	1084
Executing a Maintenance Plan	1088
Maintenance Without a Maintenance Plan	1089
Database Maintenance Policies	1090
Summary.	1090

Part V SQL Server Performance and Optimization

34 Data Structures, Indexes, and Performance	1091
What's New for Data Structures, Indexes, and Performance	1092
Understanding Data Structures	1093
Database Files and Filegroups	1093
Primary Data File	1095
Secondary Data Files.....	1095
The Log File	1096
File Management	1096
Using Filegroups	1097
FILESTREAM Filegroups.....	1100
Database Pages	1101
Page Types.....	1102
Data Pages.	1103
Row-Overflow Pages	1109
LOB Data Pages.....	1110
Index Pages	1112

Space Allocation Structures.....1113

- Extents1113
- Global and Shared Global Allocation Map Pages1114
- Page Free Space Pages1115
- Index Allocation Map Pages.....1115
- Differential Changed Map Pages.....1116
- Bulk Changed Map Pages1116

Data Compression.....1117

- Row-Level Compression1117
- Page-Level Compression1119
- The CI Record1122
- Implementing Page Compression1122
- Evaluating Page Compression1123
- Managing Data Compression with SSMS.....1126

Understanding Table Structures.1127

- Heap Tables1129
- Clustered Tables1130

Understanding Index Structures.1132

- Clustered Indexes1133
- Nonclustered Indexes1136

Data Modification and Performance1141

- Inserting Data1141
- Deleting Rows1144
- Updating Rows.....1145

Index Utilization.....1146

Index Selection.....1149

Evaluating Index Usefulness.....1150

Index Statistics1153

- The Statistics Histogram1155
- How the Statistics Histogram Is Used1157
- Index Densities1158
- Estimating Rows Using Index Statistics1159
- Generating and Maintaining Index and Column Statistics1161

SQL Server Index Maintenance1169

- Setting the Fill Factor1179
- Reapplying the Fill Factor.....1181
- Disabling Indexes1182
- Managing Indexes with SSMS1183

Index Design Guidelines.....1184

- Clustered Index Indications1185
- Nonclustered Index Indications.....1186
- Index Covering.1188

Included Columns	1190
Wide Indexes Versus Multiple Indexes	1191
Indexed Views	1192
Indexes on Computed Columns	1193
Filtered Indexes and Statistics	1195
Creating and Using Filtered Indexes	1196
Creating and Using Filtered Statistics	1198
Choosing Indexes: Query Versus Update Performance	1199
Identifying Missing Indexes	1201
The Database Engine Tuning Advisor	1201
Missing Index Dynamic Management Objects	1202
Missing Index Feature Versus Database Engine Tuning Advisor	1203
Identifying Unused Indexes	1205
Summary	1208
35 Understanding Query Optimization	1209
What's New in Query Optimization	1210
What Is the Query Optimizer?	1211
Query Compilation and Optimization	1212
Compiling DML Statements	1212
Optimization Steps	1213
Query Analysis	1213
Identifying Search Arguments	1214
Identifying OR Clauses	1214
Identifying Join Clauses	1215
Row Estimation and Index Selection	1216
Evaluating SARG and Join Selectivity	1216
Estimating Access Path Cost	1221
Using Multiple Indexes	1228
Optimizing with Indexed Views	1236
Optimizing with Filtered Indexes	1239
Join Selection	1241
Join Processing Strategies	1241
Determining the Optimal Join Order	1246
Subquery Processing	1248
Execution Plan Selection	1251
Query Plan Caching	1254
Query Plan Reuse	1254
Query Plan Aging	1256
Recompiling Query Plans	1257
Monitoring the Plan Cache	1258
Other Query Processing Strategies	1266
Predicate Transitivity	1266

Group by Optimization1267

Queries with DISTINCT1268

Queries with UNION1268

Parallel Query Processing.1268

 Parallel Query Configuration Options1271

 Identifying Parallel Queries1272

 Parallel Queries on Partitioned Objects1273

Common Query Optimization Problems1274

 Out-of-Date or Insufficient Statistics.....1274

 Poor Index Design1275

 Search Argument Problems1276

 Large Complex Queries1277

 Triggers.1278

Managing the Optimizer1278

 Optimizer Hints1280

 Forced Parameterization1285

 Using the USE PLAN Query Hint1287

 Using Plan Guides1290

 Limiting Query Plan Execution with the Query Governor1298

Summary1300

36 Query Analysis 1301

What’s New in Query Analysis1302

Query Analysis in SSMS.1302

 Execution Plan ToolTips1304

 Logical and Physical Operator Icons1308

 Analyzing Stored Procedures1315

 Saving and Viewing Graphical Execution Plans1316

 Displaying Execution Plan XML1317

 Missing Index Hints1317

SSMS Client Statistics1322

Using the SET SHOWPLAN Options1324

 SHOWPLAN_TEXT1324

 SHOWPLAN_ALL1326

 SHOWPLAN_XML1327

Using sys.dm_exec_query_plan1328

Query Statistics1330

 STATISTICS IO.....1330

 STATISTICS TIME.....1333

 Using datediff() to Measure Runtime.....1336

 STATISTICS PROFILE.....1337

 STATISTICS XML.....1337

Query Analysis with SQL Server Profiler	1338
Summary	1340

37 Locking and Performance 1341

What's New in Locking and Performance	1341
The Need for Locking	1342
Transaction Isolation Levels in SQL Server	1342
Read Uncommitted Isolation	1344
Read Committed Isolation	1344
Read Committed Snapshot Isolation	1345
Repeatable Read Isolation	1346
Serializable Read Isolation	1346
Snapshot Isolation	1347
The Lock Manager	1349
Monitoring Lock Activity in SQL Server	1350
Querying the sys.dm_tran_locks View	1350
Viewing Locking Activity with SQL Server Profiler	1355
Monitoring Locks with Performance Monitor	1357
SQL Server Lock Types	1359
Shared Locks	1360
Update Locks	1360
Exclusive Locks	1361
Intent Locks	1362
Schema Locks	1363
Bulk Update Locks	1363
SQL Server Lock Granularity	1364
Serialization and Key-Range Locking	1365
Using Application Locks	1369
Index Locking	1372
Row-Level Versus Page-Level Locking	1373
Lock Escalation	1374
Lock Compatibility	1376
Locking Contention and Deadlocks	1377
Identifying Locking Contention	1378
Setting the Lock Timeout Interval	1380
Minimizing Locking Contention	1381
Deadlocks	1382
Table Hints for Locking	1393
Transaction Isolation–Level Hints	1393
Lock Granularity Hints	1395
Lock Type Hints	1395

Optimistic Locking	1396
Optimistic Locking Using the rowversion Data Type.....	1396
Optimistic Locking with Snapshot Isolation	1399
Summary	1401
38 Database Design and Performance	1403
What's New in Database Design and Performance.	1403
Basic Tenets of Designing for Performance	1404
Logical Database Design Issues.	1405
Normalization Conditions	1405
Normalization Forms.	1406
Benefits of Normalization	1407
Drawbacks of Normalization	1407
Denormalizing a Database.	1408
Denormalization Guidelines	1408
Essential Denormalization Techniques	1409
Database Filegroups and Performance.	1415
RAID Technology	1417
RAID Level 0	1418
RAID Level 1	1419
RAID Level 10	1420
RAID Level 5	1421
SQL Server and SAN Technology.	1422
What Is a SAN?	1423
SAN Considerations for SQL Server	1423
Summary	1425
39 Monitoring SQL Server Performance	1427
What's New in Monitoring SQL Server Performance.....	1428
Performance Monitoring Tools.	1429
The Data Collector and the MDW	1429
SQL Server Utility	1451
SQL Server Extended Events.	1455
Windows Performance Monitor	1465
A Performance Monitoring Approach	1477
Monitoring the Network Interface.....	1478
Monitoring the Processors.	1480
Monitoring Memory.	1485
Monitoring the Disk System	1488
Monitoring SQL Server's Disk Activity.....	1490
Monitoring Other SQL Server Performance Items.....	1492
Summary	1492

40	Managing Workloads with the Resource Governor	1493
	Overview of Resource Governor	1494
	Resource Governor Components.....	1495
	Classification.....	1495
	Workload Groups.....	1496
	Resource Pools	1496
	Configuring Resource Governor.	1498
	Enabling Resource Governor	1499
	Defining Resource Pools.	1500
	Defining Workload Groups.	1502
	Creating a Classification Function.....	1506
	Monitoring Resource Usage	1509
	Modifying Your Resource Governor Configuration	1513
	Deleting Workload Groups.....	1514
	Deleting Resource Pools.....	1515
	Modifying a Classification Function.....	1516
	Summary	1517
41	A Performance and Tuning Methodology	1519
	The Full Architectural Landscape	1520
	Primary Performance and Tuning Handles	1521
	A Performance and Tuning Methodology.....	1522
	Designing In Performance and Tuning from the Start.....	1523
	Performance and Tuning for an Existing Implementation	1528
	Performance and Tuning Design Guidelines.	1534
	Hardware and Operating System Guidelines	1534
	SQL Server Instance Guidelines.....	1536
	Database-Level Guidelines.	1537
	Table Design Guidelines.	1537
	Indexing Guidelines.	1539
	View Design Guidelines.	1541
	Transact-SQL Guidelines.	1541
	Application Design Guidelines.	1545

	Microsoft Out-of-the-Box	1547
	Third-Party Performance and Tuning Tools.....	1548
	Summary	1550

Chapters on the CD

Part VI SQL Server Application Development

42	What's New for Transact-SQL in SQL Server 2008	1551
	MERGE Statement.....	1552
	MERGE Statement Best Practices and Guidelines.....	1558
	Insert over DML.....	1559
	GROUP BY Clause Enhancements.....	1561
	ROLLUP and CUBE Operator Syntax Changes.....	1561
	GROUPING SETS.....	1562
	The grouping_id() Function.....	1565
	Variable Assignment in DECLARE Statement.....	1568
	Compound Assignment Operators.....	1568
	Row Constructors.....	1569
	New date and time Data Types and Functions.....	1572
	Date and Time Conversions.....	1575
	Table-Valued Parameters.....	1576
	Table-Valued Parameters Versus Temporary Tables.....	1580
	Hierarchyid Data Type.....	1580
	Creating a Hierarchy.....	1580
	Populating the Hierarchy.....	1581
	Querying the Hierarchy.....	1583
	Modifying the Hierarchy.....	1587
	Using FILESTREAM Storage.....	1592
	Enabling FILESTREAM Storage.....	1593
	Setting Up a Database for FILESTREAM Storage.....	1596
	Using FILESTREAM Storage for Data Columns.....	1597
	Sparse Columns.....	1600
	Column Sets.....	1600
	Working with Sparse Columns.....	1601
	Sparse Columns: Good or Bad?.....	1604
	Spatial Data Types.....	1605
	Representing Spatial Data.....	1606
	Working with Geometry Data.....	1607
	Working with Geography Data.....	1609
	Spatial Data Support in SSMS.....	1611
	Spatial Data Types: Where to Go from Here?.....	1614
	Change Data Capture.....	1614
	The Change Data Capture Tables.....	1615
	Enabling CDC for a Database.....	1617
	Enabling CDC for a Table.....	1617

Querying the CDC Tables.....	1619
CDC and DDL Changes to Source Tables	1626
Change Tracking	1627
Implementing Change Tracking	1628
Identifying Tracked Changes.	1630
Identifying Changed Columns.....	1633
Change Tracking Overhead.	1634
Summary	1635
43 Transact-SQL Programming Guidelines, Tips, and Tricks	1637
General T-SQL Coding Recommendations.	1638
Provide Explicit Column Lists.....	1638
Qualify Object Names with a Schema Name.....	1640
Avoid SQL Injection Attacks When Using Dynamic SQL	1643
Comment Your T-SQL Code.....	1652
General T-SQL Performance Recommendations	1653
UNION Versus UNION ALL Performance	1654
Use IF EXISTS Instead of SELECT COUNT(*).....	1654
Avoid Unnecessary ORDER BY or DISTINCT Clauses	1654
Temp Tables Versus Table Variables Versus	
Common Table Expressions.....	1654
Avoid Unnecessary Function Executions.....	1656
Cursors and Performance	1656
Variable Assignment in UPDATE Statements.....	1659
T-SQL Tips and Tricks.	1663
Date Calculations	1663
Sorting Results with the GROUPING Function	1669
Using CONTEXT_INFO	1671
Working with Outer Joins	1673
Generating T-SQL Statements with T-SQL	1682
Working with @@ERROR and @@ROWCOUNT.....	1683
De-Duping Data with Ranking Functions.....	1684
In Case You Missed It: New Transact-SQL Features in SQL Server 2005	1687
The xml Data Type	1687
The max Specifier.	1688
TOP Enhancements	1689
The OUTPUT Clause.	1693
Common Table Expressions	1698
Recursive Queries with CTEs.....	1700
Ranking Functions	1708
The ROW_NUMBER Function.....	1708
The RANK and DENSE_RANK Functions	1711

The NTILE Function	1712
Using Row Numbers for Paging Results	1714
PIVOT and UNPIVOT	1718
The APPLY Operator	1722
CROSS APPLY	1722
OUTER APPLY	1723
TRY...CATCH Logic for Error Handling	1724
The TABLESAMPLE Clause.	1727
Summary	1731
44 Advanced Stored Procedure Programming and Optimization	1733
T-SQL Stored Procedure Coding Guidelines.	1733
Calling Stored Procedures from Transactions	1735
Handling Errors in Stored Procedures	1738
Using Source Code Control with Stored Procedures	1741
Using Cursors in Stored Procedures	1743
Using CURSOR Variables in Stored Procedures	1748
Nested Stored Procedures.	1753
Recursive Stored Procedures	1755
Using Temporary Tables in Stored Procedures	1759
Temporary Table Performance Tips	1760
Using the table Data Type	1762
Using Remote Stored Procedures	1764
Stored Procedure Performance.	1764
Query Plan Caching	1765
The SQL Server Plan Cache	1766
Shared Query Plans.	1766
Automatic Query Plan Recompilation	1767
Forcing Recompilation of Query Plans	1770
Using Dynamic SQL in Stored Procedures	1774
Using sp_executesql.....	1776
Installing and Using .NET CLR Stored Procedures.....	1779
Adding CLR Stored Procedures to a Database.....	1780
T-SQL or CLR Stored Procedures?.	1781
Using Extended Stored Procedures	1782
Adding Extended Stored Procedures to SQL Server	1782
Obtaining Information on Extended Stored Procedures	1783
Extended Stored Procedures Provided with SQL Server	1783
Using xp_cmdshell	1784
Summary	1786

45	SQL Server and the .NET Framework	1787
	What's New in SQL Server 2008 and the .NET Framework	1787
	Getting Comfortable with ADO.NET 3.5 and SQL Server 2008	1788
	ADO.NET: Advanced Basics	1788
	Developing with LINQ to SQL	1793
	Getting Started	1793
	Going Deeper	1796
	Uncovering LINQ to SQL with Linqpad	1798
	Using ADO.NET Data Services	1803
	Getting Set Up	1803
	Essentials	1803
	Building Your Data Service	1806
	CRUD Operations	1811
	Leveraging the Microsoft Sync Framework	1816
	Getting Started with MSF and Sync Services for ADO.NET	1817
	Building Our Example OCA	1818
	Summary	1823
46	SQLCLR: Developing SQL Server Objects in .NET	1825
	What's New for SQLCLR in SQL Server 2008	1825
	Developing Custom Managed Database Objects	1825
	An Introduction to Custom Managed Database Objects	1826
	Managed Object Permissions	1827
	Developing Managed Objects with Visual Studio 2008	1829
	Developing Managed Stored Procedures	1830
	Developing Managed User-Defined Functions (UDFs)	1835
	Developing Managed User-Defined Types (UDTs)	1844
	Developing Managed User-Defined Aggregates (UDAs)	1853
	Developing Managed Triggers	1856
	Using Transactions	1861
	Using the Related System Catalogs	1863
	Summary	1864
47	Using XML in SQL Server 2008	1865
	What's New in Using XML in SQL Server 2008	1865
	Understanding XML	1866
	Relational Data As XML: The FOR XML Modes	1866
	RAW Mode	1867
	AUTO Mode	1873
	EXPLICIT Mode	1877
	PATH Mode	1881

	FOR XML and the xml Data Type.....	1884
	XML As Relational Data: Using OPENXML	1887
	Using the xml Data Type.	1890
	Defining and Using xml Columns.....	1892
	Using XML Schema Collections.	1894
	The Built-in xml Data Type Methods	1899
	Indexing and Full-Text Indexing of xml Columns	1918
	Indexing xml Columns	1918
	Full-Text Indexing.	1924
	Summary	1925
48	SQL Server Web Services	1927
	What's New in SQL Server Web Services.	1927
	Web Services Migration Path	1928
	Web Services History and Overview.	1928
	The Web Services Pattern	1929
	Building Web Services.	1930
	The AS HTTP Keyword Group.....	1934
	The FOR SOAP Keyword Group	1938
	Examples: A C# Client Application.	1942
	Example 1: Running a Web Method Bound to a Stored Procedure from C#.....	1942
	Example 2: Running Ad Hoc T-SQL Batches from a SQL Server Web Service.....	1947
	Example 3: Calling a Web Method–Bound Stored Procedure That Returns XML.	1951
	Using Catalog Views and System Stored Procedures	1954
	Controlling Access Permissions.	1955
	Summary	1957
49	SQL Server Service Broker	1959
	What's New in Service Broker.....	1959
	Understanding Distributed Messaging	1960
	The Basics of Service Broker	1960
	Designing a Sample System	1964
	Understanding Service Broker Constructs.	1965
	Defining Messages and Choosing a Message Type	1965

About the Authors

Ray Rankins is owner and president of Gotham Consulting Services, Inc. (www.gothamconsulting.com), near Saratoga Springs, New York. Ray has been working with Sybase and Microsoft SQL Server for more than 23 years and has experience in database administration, database design, project management, application development, consulting, courseware development, and training. He has worked in a variety of industries, including financial, manufacturing, health care, retail, insurance, communications, public utilities, and state and federal government. His expertise is in database performance and tuning, query analysis, advanced SQL programming and stored procedure development, database design, data architecture, and database application design and development. Ray's presentations on these topics at user group conferences have been very well received. Ray is coauthor of *Microsoft SQL Server 2005 Unleashed*, *Microsoft SQL Server 2000 Unleashed* (first and second editions), *Microsoft SQL Server 6.5 Unleashed* (all editions), *Sybase SQL Server 11 Unleashed*, and *Sybase SQL Server 11 DBA Survival Guide*, Second Edition, all published by Sams Publishing. As an instructor, Ray brings his real-world experience into the classroom, teaching classes on SQL, advanced SQL programming and optimization, database design, database administration, and database performance and tuning. Ray can be reached at rrankins@gothamconsulting.com.

Paul Bertucci is the founder of Database Architects (www.dbarchitects.com), a global database consulting firm with offices in the United States and Paris, France. He has more than 30 years of experience with database design, data architecture, data replication, performance and tuning, master data management (MDM), data provenance/digital DNA, distributed data systems, data integration, high availability, and systems integration for numerous Fortune 500 companies, including Intel, 3COM, Coca-Cola, Apple, Toshiba, Lockheed, Wells Fargo, Safeway, Sony, Charles Schwab, Cisco, Sybase, Symantec, Veritas, and Honda, to name a few. He has authored numerous database articles, data standards, and high-profile database courses, such as Sybase's "Performance and Tuning" and "Physical Database Design" courses. Other Sams Publishing books that he has authored or coauthored include the highly popular *Microsoft SQL Server 2000 Unleashed*, *ADO.NET in 24 Hours*, *Microsoft SQL Server High Availability*, and *Microsoft SQL Server 2005 Unleashed*. Paul is a frequent speaker at industry conferences such as Informatica World, Oracle World, MDM Summits, and Microsoft-oriented conferences such as SQL Saturday's, PASS conferences, Tech Ed's, and SQL Server User Groups. He has deployed numerous systems with Microsoft SQL Server, Sybase, DB2, Postgres, MySQL, and Oracle database engines, and he has designed/architected several commercially available tools in the database, data modeling, performance and tuning, data integration, digital DNA, and multidimensional planning spaces. Formerly the Chief Data Architect at Symantec, Paul's current working arrangement is as Autodesk's Chief Enterprise Architect. Paul received his formal education in computer science and electrical engineering from the University of California, Berkeley (Go Bears!). He lives in the great Pacific northwest (Oregon) with his five children, Donny, Juliana, Nina, Marissa, and Paul Jr. Paul can be reached at pbertucci@dbarchitects.com or bertucci@alum.calberkeley.org.

Chris Gallelli is the president of CGAL Consulting Services, Inc. His company focuses on consulting services in the areas of database administration, database tuning, and database programming using Microsoft Visual Studio. Chris has more than 15 years of experience with SQL Server and more than 25 years in the field of information technology. He has a bachelor's degree in electrical engineering and a master's degree in business administration from Union College. Chris currently lives near Albany, New York, with his lovely wife, Laura, and two daughters, Rachael and Kayla. Other Sams Publishing books that he has coauthored include *Microsoft SQL Server 2000 Unleashed* and *Microsoft SQL Server 2005 Unleashed*. Chris can be reached at cgallelli@gmail.com.

Alex T. Silverstein is owner and chief information officer of Unified Digital Group, LLC, a consulting and custom software development firm headquartered near Saratoga Springs, New York. He specializes in designing SQL Server and Microsoft .NET–powered solutions using the principles of agile development and the Rational Unified Process. Alex has more than a decade of experience providing application development, database administration, and training services worldwide to a variety of industries. He was also a coauthor for *Microsoft SQL Server 2005 Unleashed* and a contributing author for *Microsoft SQL Server 2000 Unleashed*, both published by Sams Publishing. You can reach Alex anytime via email at alex@unifieddigital.com.

About the Contributing Author

Hilary Cotter is a SQL Server MVP with more than 20 years of IT experience working for Fortune 500 clients. He is the author of a book on SQL Server Replication and coauthor of *Microsoft SQL Server 2008 Management and Administration* from Sams Publishing. Hilary has also written numerous white papers and articles on SQL Server and databases.

Dedication

I would like to dedicate this book in loving memory of my grandmother, Gertrude Holdridge, who recently passed away at the “young” age of 87. You will be dearly missed, “Gramma Gert.”

—Ray Rankins

Dedicated to my children, for the countless times they heard me say “No, not now, I’m writing chapters!” Thanks, Paul Jr., Marissa, Nina, Juliana, and Donny; I love you all very much!

—Paul Bertucci

This book is dedicated to my Mom and Dad. My mother, Arlene Gallelli, is the perfect mom. Her love, kindness, and relentless support have helped me in all aspects of my life, including the creation of this book. My Dad, Joe Gallelli, is a great father and a great friend. He is an encyclopedia of knowledge, and I can always count on his wisdom and guidance. Thank you both.

—Chris Gallelli

My work on this book is dedicated to my father, Harry Silverstein, a fellow man of letters. For, while his stay with us on this planet was not nearly long enough, he left us with a feeling of kindness and a call to humanity and fellowship with all that has remained for a lifetime. Thank you, Harry, for having been you.

—Alex T. Silverstein

Acknowledgments

I would first like to thank my coauthors for their tireless efforts in helping to turn out a quality publication and their willingness to take on more work when needed to help keep things on track. I would also like to thank Neil Rowe at Sams Publishing for providing us the opportunity to write this book and for his seemingly infinite patience as we repeatedly missed our deadlines.

I would also like to acknowledge my colleague and friend David Solomon for developing the Word macro used to extract the code listings and examples presented in the chapters so we could make them available on the included CD. His efforts made that task significantly easier. I would also like to thank David for his help reviewing some of my chapters.

I would also like to acknowledge and thank Ross Mistry for providing content for the “Administering Policy Based Management” and “Automating SQL Server Tasks Using PowerShell” chapters.

Most of all, I wish to thank my loving wife, Elizabeth, for her patience and understanding during the long days, late nights, and lost weekends spent working on yet another book. I’ll be getting to that “honey-do” list now, my dear.

—Ray Rankins

With any writing effort, there is always a huge sacrifice of time that must be made to properly research, demonstrate, and describe leading-edge subject matter. The brunt of the burden usually falls on those many people who are near and very dear to me. With this in mind, I desperately need to thank my family for allowing me to encroach on many months of what should have been my family’s “quality time.”

However, with sacrifice also comes reward in the form of technical excellence and high-quality business relationships. Many individuals were involved in this effort, both directly and indirectly, starting with the other authors (thanks RR, CG, and AS!), Steve Luk, Raymond Hardman, Jason Riedberger, John Martin, Gene Vilain, Yves Moison, Thierry Gerardin, Mark Ginnebaugh (of DesignMind), and Nathan Gustafson. Their expertise in and knowledge of database engines, SQL, performance and tuning, data replication, database mirroring, database snapshots, business intelligence, data integration, and high availability are unmatched.

—Paul Bertucci

Writing a book of this size and scope requires a tremendous amount of time and dedication. The time and dedication apply not only to the authors who are writing the book but also to their family members. My wife and daughters were very understanding while I was holed up working on this book, and that understanding helped make the book happen. My love and thanks to them.

I would also like to thank many of my clients who embraced SQL Server 2008 and gave me the opportunity to use it in the real world. In particular, I would like to thank Ray McQuade and his company, Spruce Computer Systems. Spruce has had tremendous success with SQL Server 2005 and SQL Server 2008.

—Chris Gallelli

I would like to acknowledge the following people for helping make my contribution to this book possible: Ray Rankins, Paul Bertucci, Chris Gallelli, Neil Rowe, Gregory Abbruzzese, Frank Esposito, Jonathan Rubenstein, Linda Motzkin, Lane McCarthy, Bob

Barter, Amatzia Segal, all the wonderful customers who keep Unified Digital in business, and, most importantly, El Shaddai. You all are the *sine qua non* of my world, and I thank you most heartily.

—Alex T. Silverstein

We Want to Hear from You!

As the reader of this book, *you* are our most important critic and commentator. We value your opinion and want to know what we're doing right, what we could do better, what areas you'd like to see us publish in, and any other words of wisdom you're willing to pass our way.

You can email or write me directly to let me know what you did or didn't like about this book—as well as what we can do to make our books stronger.

Please note that I cannot help you with technical problems related to the topic of this book, and that due to the high volume of mail I receive, I might not be able to reply to every message.

When you write, please be sure to include this book's title and author as well as your name and phone or email address. I will carefully review your comments and share them with the author and editors who worked on the book.

Introduction

Over the past decade, SQL Server has established itself as a robust and reliable database platform whose performance, scalability, and reliability meet the implementation needs of businesses and corporations from small desktop applications on up to multiterabyte enterprise-wide systems. The updates and enhancements in SQL Server 2008 and SQL Server 2008 R2 further solidify its position in the marketplace as a robust enterprise-wide database system that can compete on the same level as the other major enterprise-wide database products, providing a database engine foundation that can be highly available 7 days a week, 365 days a year.

NOTE

The position of SQL Server 2008 as a leader in the market of enterprise-wide database management systems (DBMS) was confirmed in a report released by Forrester Research on June 30, 2009 (The Forrester Wave: Enterprise Database Management Systems, Q2 2009). In this report, Forrester analyst Noel Yuhanna indicated that Microsoft along with Oracle and IBM DB2 were the leaders in the DBMS market. The report from Forrester Research indicated that Microsoft's strong commitment to its data platform starting with SQL Server 2005 and continuing with the latest iteration of the product, SQL Server 2008, had boosted Microsoft to the top of the DBMS market. Key findings in the report concluded that Microsoft received high scores in database programmability, security, availability, and application/data integration, and for delivering the best price performance for most business applications. The report also acknowledged that Microsoft "has shown increasing focus and commitment to going after the enterprise market," and that SQL Server 2008 has "enabled Microsoft to take market share in moderately sized to large enterprises, delivering good performance, scalability, security, and availability functionality." The report also indicated that "five years ago, hardly any enterprises ran multi-terabyte databases with SQL Server to support critical applications. Today, hundreds of enterprises are running 10-terabyte and larger transactional SQL Server databases."

One of the biggest challenges we face writing the *SQL Server Unleashed* series of books is how to provide comprehensive, in-depth, all-inclusive coverage of all the features of SQL Server within a single book. Over the past few releases, the number of SQL Server features and components has increased, and many of these features and components (for example, SQL Server Integration Services, Reporting Services, and .NET Framework integration) provide material enough to warrant their own separate titles. To cover each topic sufficiently would require more information than could reasonably fit in print in a single volume. Thus, we had to make some hard decisions as to what to include in print.

We decided that the printed portion of the book would provide detailed coverage of the core database server features and the day-to-day administrative and management aspects

and tools of SQL Server 2008 and 2008 R2. We want to ensure that we provide enough of the necessary information, tips, and guidelines to get you started making effective use of these features. At the same time, there is a wealth of useful information we want to provide on additional SQL Server 2008 features and major components of SQL Server, such as SQL Server Integration Services, Reporting Services, Analysis Services, T-SQL programming, and SQL Server integration with the .NET Framework. Rather than leave this valuable information out entirely, we decided to include the chapters with this material on the CD provided with this book. Also, as in the past, the CD contains all our sample scripts, databases, and other code samples and material that support the book content.

Our other main goal when writing this book was for it to be more than just a syntax reference. SQL Server Books Online is a fine resource as a syntax reference. This book attempts to pick up where Books Online leaves off, by providing, in addition to syntax where necessary, valuable insight, tips, guidelines, and useful examples derived from our many years of experience working with SQL Server. Although we do provide the core, and sometimes advanced, syntax elements for the SQL commands discussed, SQL Server Books Online provides a much more extensive syntax reference than would make sense to try to duplicate here. As a matter of fact, at times, we may even direct you to Books Online for more detail on some of the more esoteric syntax options available for certain commands.

We hope that we have succeeded in meeting the goals we set out for this book and that it becomes an essential reference and source of expert information for you as you work with the either version of SQL Server 2008.

NOTE

Although this book includes coverage of SQL Server 2008 R2, most of the material presented applies to SQL Server 2008 as well. Actually, there are few significant differences in the core product between SQL Server 2008 and SQL Server 2008 R2. Most of the new features are related to enhancements to Reporting Services. You can be comfortable using this book as a reference for either version of SQL Server 2008.

When the book discusses features available only in the R2 release, this fact is specifically spelled out in the chapter.

Who This Book Is For

This *Unleashed* book is intended for intermediate- to advanced-level users: for SQL Server administrators who want to understand SQL Server more completely to be able to effectively manage and administer their SQL Server environments, and for developers who want a more thorough understanding of SQL Server to help them write better Transact-SQL (T-SQL) code and develop more robust SQL Server applications. If you are responsible for analysis, design, implementation, support, administration, or troubleshooting of SQL Server 2008, this book provides an excellent source of experiential information for you. You can think of this as a book of applied technology. The emphasis is on the more

complex aspects of the product, including using the new tools and features, administering SQL Server, analyzing and optimizing queries, implementing data warehouses, ensuring high availability, and tuning SQL Server performance.

This book is for both developers and SQL Server administrators who are new to SQL Server 2008 or SQL Server 2008 R2 as well as those who are already familiar with prior versions of SQL Server. At the beginning of each chapter is a brief summary of the major changes or new features or capabilities of SQL Server related to that topic. If you are already familiar with SQL Server, you can use this information to focus on the information in the chapters that covers the new features and capabilities in more detail.

This book is intended to provide a behind-the-scenes look into SQL Server, showing you what goes on behind the various wizards and GUI-based tools so you can learn what the underlying SQL commands are. Although the GUI tools can make your average day-to-day operations much simpler, every database administrator should learn the underlying commands to the tools and wizards to fully unlock the power and capabilities of SQL Server.

What This Book Covers

The book is divided into the following sections:

- ▶ **Part I, “Welcome to Microsoft SQL Server”**—This part introduces you to the Microsoft SQL Server 2008 environment, the various editions of SQL Server that are available, and the capabilities of each edition in the various Windows environments. In addition, it provides an overview of and introduction to the new features found in SQL Server 2008 and SQL Server 2008 R2, which are covered in more detail throughout the rest of the book.
- ▶ **Part II, “SQL Server Tools and Utilities”**—This part covers the tools and utility programs that SQL Server 2008 provides for you to administer and manage your SQL Server environments. You’ll find information on the various management tools you use on a daily basis, such as SQL Server Management Studio and the new SQLCMD command-line query tool, along with information on SQL Server Profiler. If you are not familiar with these tools, you should read this part of the book early on because these tools are often used and referenced throughout many of the other chapters in the book.
- ▶ **Part III, “SQL Server Administration”**—This part discusses topics related to the administration of SQL Server at the database server level. It begins with an overview of what is involved in administering a SQL Server environment and then goes on to cover the tasks related to setting up and managing the overall SQL Server environment, including installing and upgrading to SQL Server 2008 and SQL Server 2008 R2 as well as installing SQL Server clients. This part also includes coverage of security and user administration, database backup and restore, replication, and using the Database Mail facility. Chapters on SQL Server clustering, database mirroring, and

SQL Server high availability provide some expert advice in these areas. Task scheduling and notification using SQL Server Agent and using the new Policy Based Management feature are also discussed in this part.

- ▶ **Part IV, “SQL Server Database Administration”**—This part delves into the administrative tasks associated with creating and managing a SQL Server 2008 database, including the creation and management of database objects, such as tables, indexes, views, stored procedures, functions, and triggers. It also provides coverage of the Database Snapshots and an overview of database maintenance tasks and responsibilities.
- ▶ **Part V, “SQL Server Performance and Optimization”**—This part provides information to help you get the best performance out of SQL Server. It begins with a discussion of data structures, indexes, and performance, key items to understand to help ensure good database performance. It then builds on that information with chapters on query optimization and analysis, locking, database design and performance, and ways to manage workloads using the new Resource Governor; then it finishes with a methodology for monitoring and optimizing SQL Server performance.
- ▶ **Part VI, “SQL Server Application Development”**—This part includes a comprehensive overview of what’s new in T-SQL in SQL Server 2008 and SQL Server 2008 R, T-SQL programming guidelines, tips, and tricks, and advanced stored procedure programming and optimization. In addition, chapters in this Part provide an overview of .NET integration with SQL Server and creating .NET CLR objects information, working with XML in SQL Server, and working with additional SQL Server components that are not part of the core database engine such as Web Services, Service Broker, and Full-Text Search.
- ▶ **Part VII, “SQL Server Business Intelligence Features”**—This Part includes a comprehensive overview of SQL Server 2008 R2’s built-in business intelligence features: Analysis Services, Integration Services, and Reporting Services, with a specific focus on the enhancements to Reporting Services introduced with the R2 release.
- ▶ **Bonus Chapters on the CD**—This Part provides a few chapters for which there just wasn’t room enough to include elsewhere in the book. These chapters provide expert advice and information on managing remote and linked servers, configuring, tuning and optimizing SQL Server, and planning for SQL Server Disaster Recoverys.
- ▶ **Book Materials on the CD**—Also included on the CD are many of the code samples, scripts, databases, and other materials that supplement various chapters. This has always been one of the most valuable reasons to buy books in the *Unleashed* series. It is our goal not just to discuss a SQL technique or solution, but to also provide working samples and examples that actually do it. Learning by seeing is essential for understanding.

In addition to the included CD content, please visit the web page for this book at www.sampublishing.com periodically for any updated or additional bonus material as it becomes available.

Conventions Used in This Book

Names of commands and stored procedures are presented in a special monospaced computer typeface. We have tried to be consistent in our use of uppercase and lowercase for keywords and object names. However, because the default installation of SQL Server doesn't make a distinction between upper- and lowercase for SQL keywords or object names and data, you might find some of the examples presented in either upper- or lowercase.

Code and output examples are presented separately from regular paragraphs and are also in a monospaced computer typeface. The following is an example:

```
select object_id, name, type_desc
from sys.objects
where type = 'SQ'
```

```
object_id  name                                     type_desc
-----
1977058079 QueryNotificationErrorsQueue           SERVICE_QUEUE
2009058193 EventNotificationErrorsQueue           SERVICE_QUEUE
2041058307 ServiceBrokerQueue                   SERVICE_QUEUE
```

When syntax is provided for a command, we have followed these conventions:

Syntax Element	Definition
command	These are command names, options, and other keywords.
placeholder	Monospaced italic indicates values you provide.
{ }	You must choose at least one of the enclosed options.
[]	The enclosed value/keyword is optional.
()	Parentheses are part of the command.
	You can select only one of the options listed.
,	You can select any of the options listed.
[...]	The previous option can be repeated.

Consider the following syntax example:

```
grant {all | permission_list} on object [(column_list)]
    to {public | user_or_group_name [, [...]]}
```

In this case, *object* is required, but *column_list* is optional. Note also that items shown in plain computer type, such as *grant*, *public*, and *all*, should be entered literally, as shown. Placeholders are presented in *italic*, such as *permission_list* and *user_or_group_name*. A *placeholder* is a generic term for which you must supply a specific value or values. The ellipsis (*[...]*) in the square brackets following *user_or_group_name* indicates that multiple user or group names can be specified, separated by commas. You can specify either the keyword *public* or one or more user or group names, but not both.

Some of the examples presented in this book make use of the AdventureWorks2008 and AdventureWorks2008R2 databases, which are not automatically installed with SQL Server 2008 or SQL Server 2008 R2. To install the AdventureWorks sample databases, you must first download the installer from the Microsoft SQL Server Samples and Community Projects website at <http://www.codeplex.com/sqlserversamples>.

NOTE

Most of the examples presented in this book that use the AdventureWorks database can be run in either AdventureWorks2008 or AdventureWorks2008R2. Structurally, these databases are identical. However, the following tables in AdventureWorks2008R2 have different data values for some of the columns:

- ▶ Person
- ▶ SalesPerson
- ▶ SalesOrderHeader
- ▶ SalesTerritory
- ▶ Shift
- ▶ TransactionHistory

If any of the examples use any of these tables, you may see different results depending on whether you run them in AdventureWorks2008 or AdventureWorks2008R2. When necessary, it will be stated in the chapter which version of the AdventureWorks database was used to generate the results displayed.

Although it is not necessary to install both versions of the AdventureWorks database, it is possible to install both versions in the same SQL Server instance if you wish.

For many of the examples presented in Part V, larger tables than what are available in the AdventureWorks database were needed to demonstrate many of the concepts with more meaningful examples. For many of the chapters in this part, as well as some other chapters throughout the book, the examples come from the *bigpubs2008* database. A copy of the database, along with an Entity-Relationship (ER) diagram and table descriptions, is also on the CD.

To install the `bigpubs2008` database on your system so you can try the various examples, do the following:

1. Copy the `bigpubs2008.mdf` file into the SQL Server data folder where you want it to reside.
2. After copying the file to the destination folder, ensure that the Read-Only property of the `bigpubs2008.mdf` file is not enabled (this can happen when the file is copied from the CD). Right-click the file in Windows Explorer and select Properties to bring up the Properties dialog. Click the Read-Only check box to remove the check mark. Click OK to save the changes to the file attributes.
3. Attach the `bigpubs2008` database by using a command similar to the following:

```
sp_attach_single_file_db 'bigpubs2008',  
    N'D:\MSSQL\DATA\MSSQL.1\MSSQL\Data\bigpubs2008.mdf
```

Note that you might need to edit the path to match the location where you copied the `bigpubs2008.mdf` file.

Alternatively, you can attach the database by using SQL Server Management Studio. To do this, right-click the Databases node in the Object Explorer and select Attach. When the Attach Databases dialog appears, click the Add button, locate the `bigpubs2008.mdf` file, and click OK. In the bottom window pane, click the transaction log file entry (it should say Not Found in the message column) and click the Remove button. Next, click the OK button to attach the database. A new transaction log file is automatically created in the same folder as the `bigpubs2008.mdf` file. For more information on attaching database files, see Chapters 14, “Database Backup and Restore,” and 23, “Creating and Managing Databases.”

NOTE

In addition to the `bigpubs2008` database, the `.mdf` file for the database used for examples in Chapter 51, “SQL Server Analysis Services,” is also provided. To install the `CompSales` database, do the following:

1. Copy the `CompSales.mdf` file into the SQL Server data folder where you want it to reside.
2. Ensure that the Read-Only property of the `CompSales.mdf` file is not enabled.
3. Attach the `CompSales` database by using a command similar to the following (edit the path to match the location of the `CompSales.mdf` file on your system):

```
sp_attach_single_file_db 'CompSales',  
    N'D:\MSSQL\DATA\MSSQL.1\MSSQL\Data\CompSales.mdf
```

Good Luck!

If you have purchased this book, you are on your way to getting the most from SQL Server 2008 or SQL Server 2008 R2. You have already chosen a fine platform for building database applications, one that can provide outstanding performance and rock-solid reliability and availability at a reasonable cost. With this book, you now have the information you need to make the best of it.

Many of us who worked on this book have been using SQL Server since it was first released. Writing about each new version challenges us to reassess our understanding of SQL Server and the way it works. It's an interesting and enjoyable process, and we learn a lot writing each of these books. We hope you get as much enjoyment and knowledge from reading this book as we have from writing it.

CHAPTER 1

SQL Server 2008 Overview

Exactly what is SQL Server 2008? When you first install the product, what are all the pieces you get, what do they do, and which of them do you need?

At its core, SQL Server 2008 is an enterprise-class database management system (DBMS) that is capable of running anything from a personal database only a few megabytes in size on a handheld Windows Mobile device up to a multi-server database system managing terabytes of information. However, SQL Server 2008 is much more than just a database engine.

The SQL Server product is made up of a number of different components. This chapter describes each of the pieces that make up the SQL Server product and what role each plays. Each of these topics is dealt with in more detail later in the book. In addition, this chapter looks at the environments that support SQL Server 2008 and SQL Server 2008 R2 and the features available in each of the various SQL Server editions.

SQL Server Components and Features

The main component of SQL Server 2008 is the Database Engine. Before you can use the other components and features of SQL Server 2008, which are discussed in the following sections, you need to have an instance of the Database Engine installed.

IN THIS CHAPTER

- ▶ SQL Server Components and Features
- ▶ SQL Server 2008 R2 Editions
- ▶ SQL Server Licensing Models

The SQL Server Database Engine

The Database Engine is the core application service in the SQL Server package for storing, processing, and securing data with SQL Server 2008. The SQL Server 2008 Database Engine is a Windows service that can be used to store and process data in a relational format, as XML documents, and new for 2008, as spatial data. The following are the main responsibilities of the Database Engine:

- ▶ Provide reliable storage for data
- ▶ Provide a means to rapidly retrieve this data
- ▶ Provide consistent access to the data
- ▶ Control access to the data through security
- ▶ Enforce data integrity rules to ensure that the data is reliable and consistent.

Each of these responsibilities is examined in greater detail in later chapters in this book. For now, this chapter provides just a brief overview on each of these points to show how Microsoft SQL Server fulfills these core responsibilities.

Reliable Storage

Reliable storage starts at the hardware level. This isn't the responsibility of the Database Engine, but it's a necessary part of a well-built database. Although you can put an entire SQL database on a single IDE or SATA drive (or even burn a read-only copy on a CD), it is preferable to maintain the data on RAID arrays. The most common RAID arrays can survive hardware failures at the disk level without loss of data.

NOTE

For more information on the reliability characteristics and performance implications of the various RAID configurations and guidelines for implementing RAID configurations with SQL Server, see Chapter 38, "Database Design and Performance."

Using whatever hardware you have decided to make available, the Database Engine manages all the data structures necessary to ensure reliable storage of your data. Rows of data are stored in *pages*, and each page is 8KB in size. Eight pages make up an *extent*, and the Database Engine keeps track of which extents are allocated to which tables and indexes.

NOTE

A *page* is an 8KB chunk of a data file, the smallest unit of storage available in the database. An *extent* is a collection of eight 8KB pages.

Another key feature the Database Engine provides to ensure reliable storage is the transaction log. The transaction log makes a record of every change that is made to the database.

For more information on the transaction log and how it's managed, see Chapter 31, "Transaction Management and the Transaction Log."

NOTE

It is not strictly true that the transaction log records *all* changes to the database; some exceptions exist. Operations on binary large objects—data of type `image` and `text`—can be excepted from logging, and bulk copy loads into tables can be minimally logged to get the fastest possible performance.

Rapid Data Access

SQL Server allows the creation of indexes, enabling fast access to data. See Chapter 34, "Data Structures, Indexes, and Performance," for an in-depth discussion of indexes.

Another way to provide rapid access to data is to keep frequently accessed data in memory. Excess memory for a SQL Server instance is used as a data cache. When pages are requested from the database, the SQL Server Database Engine checks to see if the requested pages are already in the cache. If they are not, it reads them off the disk and stores them in the data cache. If there is no space available in the data cache, the least recently accessed pages (that is, those that haven't been accessed in a while since they were read into memory) are flushed out of the data cache to make room for the newly requested pages. If the pages being flushed contain changes that haven't been written out yet, they are written to disk before being flushed from memory. Otherwise, they are simply discarded.

NOTE

With sufficient memory, an entire database can fit completely into memory, providing the best possible I/O performance for the database.

Consistent Data Access

Getting to your data quickly doesn't mean much if the information you receive is inaccurate. SQL Server follows a set of rules to ensure that the data you receive from queries is consistent.

The general idea with consistent data access is to allow only one client at a time to change the data and to prevent others from reading data from the database while it is undergoing changes. Data and transactional consistency are maintained in SQL Server by using transactional locking.

Transactional consistency has several levels of conformance, each of which provides a trade-off between accuracy of the data and concurrency. These levels of concurrency are examined in more detail in Chapter 37, "Locking and Performance."

Access Control

SQL Server controls access by providing security at multiple levels. Security is enforced at the server, database, schema, and object levels. Server-level access is enforced either by

using a SQL Server username and password or through integrated network security, which uses the client's network login credentials to establish identity.

SQL Server security is examined in greater detail in Chapter 11, "Security and User Administration."

Data Integrity

Some databases have to serve the needs of more than a single application. A corporate database that contains valuable information might have a dozen different departments wanting to access portions of the database for different needs.

In this kind of environment, it is impractical to expect the developers of each application to agree on an identical set of standards for maintaining data integrity. For example, one department might allow phone numbers to have extensions, whereas another department may not need that capability. One department might find it critical to maintain a relationship between a customer record and a salesperson record, whereas another might care only about the customer information.

The best way to keep everybody sane in this environment—and to ensure that the data stays consistent and usable by everyone—is to enforce a set of data integrity rules within the database itself. This is accomplished through data integrity constraints and other data integrity mechanisms, such as triggers. See Chapter 26, "Implementing Data Integrity," for details.

SQL Server 2008 Administration and Management Tools

SQL Server 2008 and SQL Server 2008 R2 provide a suite of tools for managing and administering the SQL Server Database Engine and other components. The following sections provide an overview of the primary tools for day-to-day administration, management, and monitoring of your SQL Server environments.

SQL Server Management Studio (SSMS)

SSMS is the central console from which most database management tasks can be coordinated. SSMS provides a single interface from which all servers in a company can be managed. SSMS is examined in more detail in Chapter 4, "SQL Server Management Studio."

Figure 1.1 shows SSMS being used for some everyday administration tasks.

Figure 1.1 shows a list of registered servers in the upper-left pane. Below that is the Object Explorer, which lets you browse the contents of the databases within a SQL Server instance. The `bigpubs2008` database has been expanded, and the right pane shows the columns for the authors table.

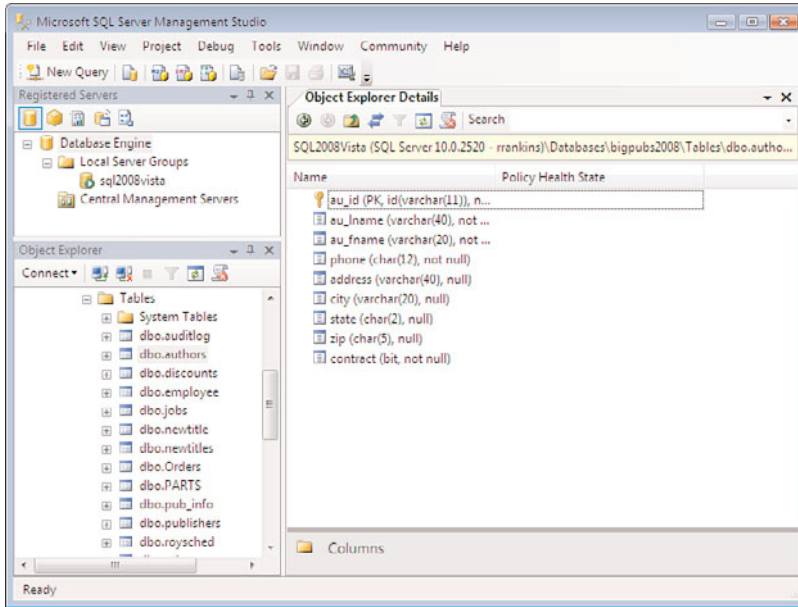

FIGURE 1.1 SSMS, showing a list of columns for the **authors** table in the **bigpubs2008** database.

Following are some of the tasks you can perform with SSMS. Most of these tasks are discussed in detail later in the book:

- ▶ Completely manage many servers in a convenient interface
- ▶ Set server options and configuration values, such as the amount of memory and number of processors to use, default language, and default location of the data and log files
- ▶ Manage logins, database users, and database roles
- ▶ Create, edit, and schedule automated jobs through the SQL Server Agent
- ▶ Back up and restore databases and define maintenance plans
- ▶ Create new databases
- ▶ Browse table contents
- ▶ Create and manage database objects, such as tables, indexes, and stored procedures
- ▶ Generate DDL scripts for databases and database objects
- ▶ Configure and manage replication
- ▶ Create, edit, execute, and debug Transact-SQL (T-SQL) scripts
- ▶ Define, implement, manage, and invoke SQL Server Policies

- ▶ Enable and disable features of SQL Server
- ▶ Manage and organize scripts into projects and save versions in source control systems such as Visual SourceSafe

NOTE

Much of SQL Server Managements Studio's interaction with SQL Server is done through standard T-SQL statements. For example, when you create a new database through the SSMS interface, behind the scenes, SSMS generates a `CREATE DATABASE` SQL statement to be executed in the target server. Essentially, whatever you can do through the SSMS GUI, you can do with T-SQL statements. As a matter of fact, nearly every dialog in SSMS provides the capability to generate the corresponding T-SQL script for the action(s) it performs. This capability can be very useful as a timesaver for tasks that you need to perform repeatedly, avoiding the need to step through the options presented in the GUI.

If you're curious about how SSMS is accomplishing something that doesn't provide the capability to generate a script, you can run SQL Profiler to capture the commands that SSMS is sending to the server. You can use this technique to discover some interesting internal information and insight into the SQL Server system catalogs.

SQL Server Configuration Manager

SQL Server Configuration Manager is a tool provided with SQL Server 2008 for managing the services associated with SQL Server and for configuring the network protocols used by SQL Server. Primarily, SQL Server Configuration Manager is used to start, pause, resume, and stop SQL Server services and to view or change service properties.

SQL Server Agent

SQL Server Agent is a scheduling tool integrated into SSMS that allows convenient definition and execution of scheduled scripts and maintenance jobs. SQL Server Agent also handles automated alerts—for example, if the database runs out of space.

SQL Server Agent is a Windows service that runs on the same machine as the SQL Server Database Engine. The SQL Server Agent service can be started and stopped through either SSMS, the SQL Server Configuration Manager, or the ordinary Windows Services Manager.

In enterprise situations in which many SQL Server machines need to be managed together, the SQL Server Agent can be configured to distribute common jobs to multiple servers through the use of Multiserver Administration. This capability is most helpful in a wide architecture scenario, in which many SQL Server instances are performing the same tasks with the databases. Jobs are managed from a single SQL Server machine, which is responsible for maintaining the jobs and distributing the job scripts to each target server. The results of each job are maintained on the target servers but can be observed through a single interface.

If you had 20 servers that all needed to run the same job, you could check the completion status of that job in moments instead of logging in to each machine and checking the status 20 times.

The SQL Server Agent also handles event forwarding. Any system events recorded in the Windows system event log can be forwarded to a single machine. This gives a busy administrator a single place to look for errors.

More information about how to accomplish these tasks, as well as other information on the SQL Server Agent, is available in Chapter 16, “SQL Server Scheduling and Notification.”

SQL Server Profiler

The SQL Server Profiler is a GUI interface to the SQL Trace feature of SQL Server that captures the queries and results flowing to and from the database engine. It is analogous to a network sniffer, although it does not operate on quite that low a level. The Profiler can capture and save a complete record of all the T-SQL statements passed to the server and the occurrence of SQL Server events such as deadlocks, logins, and errors. You can use a series of filters to pare down the results when you want to drill down to a single connection or even a single query.

You can use the SQL Profiler to perform these helpful tasks:

- ▶ You can capture the exact SQL statements sent to the server from an application for which source code is not available (for example, third-party applications).
- ▶ You can capture all the queries sent to SQL Server for later playback on a test server. This capability is extremely useful for performance testing with live query traffic.
- ▶ If your server is encountering recurring access violations (AVs), you can use the Profiler to reconstruct what happened leading up to an AV.
- ▶ The Profiler shows basic performance data about each query. When your users start hammering your server with queries that cause hundreds of table scans, the Profiler can easily identify the culprits.
- ▶ For complex stored procedures, the Profiler can identify which portion of the procedure is causing the performance problem.
- ▶ You can audit server activity in real-time.

More information on SQL Server Profiler is available in Chapter 6, “SQL Server Profiler.”

Replication

Replication is a server-based tool that you can use to synchronize data between two or more databases. Replication can send data from one SQL Server instance to another, or it can replicate data to Oracle, Access, or any other database that is accessible via ODBC or OLE DB.

SQL Server supports three kinds of replication:

- ▶ Snapshot replication
- ▶ Transactional replication
- ▶ Merge replication

The availability and functionality of replication might be restricted, depending on the edition of SQL Server 2008 you are running.

NOTE

Replication copies the changes to data from your tables and indexed views, but it does not normally re-create indexes or triggers at the target. It is common to have different indexes on replication targets than on the source to support different requirements.

Snapshot Replication

With snapshot replication, the server takes a picture, or snapshot, of the data in a table at a single point in time. Usually, if this operation is scheduled, the target data is simply replaced at each update. This form of replication is appropriate for small data sets, infrequent update periods (or for a one-time replication operation), or management simplicity.

Transactional Replication

Initially set up with a snapshot, the server maintains downstream replication targets by reading the transaction log at the source and applying each change at the targets. For every insert, update, and delete operation, the server sends a copy of the operation to every downstream database. This is appropriate if low-latency replicas are needed. Transactional replication can typically keep databases in sync within about five seconds of latency, depending on the underlying network infrastructure. Keep in mind that transactional replication does not guarantee identical databases at any given point in time. Rather, it guarantees that each change at the source will eventually be propagated to the targets. If you need to guarantee that two databases are transactionally identical, you should look into Distributed Transactions or database mirroring.

Transactional replication might be used for a website that supports a huge number of concurrent browsers but only a few updates, such as a large and popular messaging board. All updates would be done against the replication source database and would be replicated in near-real-time to all the downstream targets. Each downstream target could support several web servers, and each incoming web request would be balanced among the web farm. If the system needed to be scaled to support more read requests, you could simply add more web servers and databases and add the database to the replication scheme.

Merge Replication

With snapshot and transactional replication, a single source of data exists from which all the replication targets are replenished. In some situations, it might be necessary or desirable to allow the replication targets to accept changes to the replicated tables and merge these changes together at some later date.

Merge replication allows data to be modified by the subscribers and synchronized at a later time. This synchronization could be as soon as a few seconds, or it could be a day later.

Merge replication would be helpful for a sales database that is replicated from a central SQL Server database out to several dozen sales laptops. As the sales personnel make sales calls, they can add new data to the customer database or change errors in the existing

data. When the salespeople return to the office, they can synchronize their laptops with the central database. Their changes are submitted, and the laptops get refreshed with whatever new data was entered since the last synchronization.

Immediate Updating

Immediate updating allows a replication target to immediately modify data at the source. This task is accomplished by using a trigger to run a distributed transaction. Immediate updating is performance intensive, but it allows for updates to be initiated from anywhere in the replication architecture.

More details on replication are available in Chapter 19, “Replication.”

Database Mirroring

The database mirroring feature available in SQL Server 2008 provides a solution for increasing database availability. Essentially, database mirroring maintains two copies of a single database that reside on different instances of SQL Server, typically on server instances that reside on computers in different locations. In a typical database mirroring scenario, one server instance serves as the primary database to which the client applications connect, and the other server instance acts as a hot or warm standby server.

Database mirroring involves re-applying every modification operation that occurs on the primary database onto the mirror database as quickly as possible. This is accomplished by sending every active transaction log record generated on the primary server to the mirror server. The log records are applied to the mirror database, in sequence, as quickly as possible. Unlike replication, which works at the logical level, database mirroring works at the level of the physical log record. The mirror database is an exact copy of the primary database.

For more information on setting up and using database mirroring, see Chapter 20, “Database Mirroring.”

Full-Text Search

SQL Server 2008 provides the capability to issue full-text queries against plain character-based data in your SQL Server tables. This capability is useful for searching large text fields, such as movie reviews, book descriptions, or case notes. Full-text queries can include words and phrases, or multiple forms of a word or phrase.

Full-Text Search capabilities in Microsoft SQL Server 2008 are provided by the Microsoft Full-Text Engine for SQL Server (MSFTESQL). The MSFTESQL service works together with the SQL Server Database Engine. You specify tables or entire databases that you want to index. The full-text indexes are built and maintained outside the SQL Server database files in special full-text indexes stored in the Windows file system. You can specify how often the full-text indexes are updated to balance performance issues with timeliness of the data.

The SQL Server Database Engine supports basic text searches against specific columns. For example, to find all the rows where a text column contained the word *guru*, you might write the following SQL statement:

```
select *
  from resume
 where description like '%guru%'
```

This statement finds all the rows in the `resume` table where the description contains the word *guru*. This method has a couple problems, however. First, the search is slow. Because the Database Engine can't index text columns, a full table scan has to be done to satisfy the query. Even if the data were stored in a `varchar` column instead of a `text` column, an index may not help because you're looking for *guru* anywhere in the column, not just at the beginning, so the index cannot be used to locate the matching rows. (Chapter 34 contains more information on avoiding such situations.)

What if you wanted to search for the word *guru* anywhere in the table, not just in the description column? What if you were looking for a particular set of skills, such as "SQL" and "ability to work independently"? Full-text indexing addresses these problems. To perform the same search as before with full-text indexing, you might use a query like this:

```
select *
  from resume
 where contains(description, 'guru')
```

To perform a search that looks for a set of skills, you might use a query like this:

```
select *
  from resume
 where contains(*, 'SQL and "ability to work independently"')
```

For more information on setting up and searching Full-Text Search indexes, see Chapter 50, "SQL Server Full-Text Search" (on the CD).

SQL Server Integration Services (SSIS)

SSIS is a platform for building high-performance data integration solutions and workflow solutions. You can build extract, transform, and load (ETL) packages to update data warehouses, interact with external processes, clean and mine data, process analytical objects, and perform administrative tasks. Following are some of the features of SSIS:

- ▶ Graphical tools and wizards for building, debugging, and deploying SSIS packages
- ▶ Workflow functions, such as File Transfer Protocol (FTP), SQL statement execution, and more
- ▶ SSIS Application Programming Interfaces (APIs)
- ▶ Complex data transformation for data cleansing, aggregation, merging, and copying

- ▶ An email messaging interface
- ▶ A service-based implementation
- ▶ Support for both native and managed code (C++ or any common language runtime [CLR]-compliant language, such as C# or J#)
- ▶ An SSIS object model

SSIS is a tool that helps address the needs of getting data—which is often stored in many different formats, contexts, file systems, and locations—from one place to another. In addition, the data often requires significant transformation and conversion processing as it is being moved around. Common uses of SSIS might include the following:

- ▶ Exporting data out of SQL Server tables to other applications and environments (for example, ODBC or OLE DB data sources, flat files)
- ▶ Importing data into SQL Server tables from other applications and environments (for example, ODBC or OLE DB data sources, flat files)
- ▶ Initializing data in some data replication situations, such as initial snapshots
- ▶ Aggregating data (that is, data transformation) for distribution to/from data marts or data warehouses
- ▶ Changing the data's context or format before importing or exporting it (that is, data conversion)

For more information on creating and using SSIS packages, see Chapter 52, “SQL Server Integration Services.”

SQL Server Analysis Services (SSAS)

SSAS provides online analytical processing (OLAP) and data mining functionality for business intelligence (BI) solutions. SSAS provides a rich set of data mining algorithms to enable business users to mine data, looking for specific patterns and trends. These data mining algorithms can be used to analyze data through a Unified Dimensional Model (UDM) or directly from a physical data store.

SSAS uses both server and client components to supply OLAP and data mining functionality for BI applications. SSAS consists of the analysis server, processing services, integration services, and a number of data providers. It has both server-based and client-/local-based analysis services capabilities. This essentially provides a complete platform for SSAS. The basic components within SSAS are all focused on building and managing data cubes.

SSAS allows you to build dimensions and cubes from heterogeneous data sources. It can access relational OLTP databases, multidimensional data databases, text data, and any other source that has an OLE DB provider available. You don't have to move all your data into a SQL Server database first; you just connect to its source. In addition, SSAS allows a

designer to implement OLAP cubes, using a variety of physical storage techniques directly tied to data aggregation requirements and other performance considerations.

You can easily access any OLAP cube built with SSAS via the Pivot Table Service, you can write custom client applications by using Multidimensional Expressions (MDX) with OLE DB for OLAP or ActiveX Data Objects Multidimensional (ADO MD), and you can use a number of third-party OLAP-compliant tools. MDX enables you to formulate complex multidimensional queries.

SSAS is commonly used to perform the following tasks:

- ▶ Perform trend analysis to predict the future. For example, based on how many widgets you sold last year, how many will you sell next year?
- ▶ Combine otherwise disconnected variables to gain insight into past performance. For example, was there any connection between widget sales and rainfall patterns? Searching for unusual connections between your data points is a typical data mining exercise.
- ▶ Perform offline summaries of commonly used data points for instant access via a web interface or custom interface. For example, a relational table might contain one row for every click on a website. OLAP can be used to summarize these clicks by hour, day, week, and month and then to further categorize them by business line.

Included for Analysis Services in SQL Server 2008 R2 is PowerPivot for Excel and PowerPivot for SharePoint. PowerPivot for Excel and SharePoint are client and server components that integrate Analysis Services with Excel and SharePoint. PowerPivot for Excel is an add-in that allows you to create PowerPivot workbooks that can assemble and relate large amounts of data from different sources. PowerPivot workbooks typically contain large, multidimensional datasets that you create in a separate client application and use with PivotTables and PivotCharts in a worksheet. The PowerPivot add-in removes the one million row limit for worksheets and provides rapid calculations for the large data that you assemble.

PowerPivot for SharePoint extends SharePoint 2010 and Excel Services to add server-side processing, collaboration, and document management support for the PowerPivot workbooks that you publish to SharePoint.

Together, the PowerPivot client add-in and server components provide an end-to-end solution that furthers business intelligence data analysis for Excel users on the workstation and on SharePoint sites.

SSAS is a complex topic. For more information on MDX, data cubes, and ways to use data warehousing analysis services, see Chapter 52, “SQL Server 2008 Analysis Services.”

SQL Server Reporting Services (SSRS)

SQL Server Reporting Services is a server-based reporting platform that delivers enterprise, web-enabled reporting functionality so you can create reports that draw content from a variety of data sources, publish reports in various formats, and centrally manage security and subscriptions.

Reporting Services includes the following core components:

- ▶ A complete set of tools you can use to create, manage, and view reports
- ▶ A report server component that hosts and processes reports in a variety of formats, including HTML, PDF, TIFF, Excel, CSV, and more
- ▶ An API that allows developers to integrate or extend data and report processing into custom applications or to create custom tools to build and manage reports

There are two design tools for building reports: Report Designer, a powerful development tool integrated with Visual Studio, and Report Builder 3.0, which is a simpler point-and-click tool that you use to design ad hoc reports. Both report design tools provide a WYSIWYG experience.

Reports are described using the Report Definition Language (RDL). RDL contains the description of the report layout, formatting information, and instructions on how to fetch the data. After a report is defined, it can be deployed on the report server, where it can be managed, secured, and delivered to a variety of formats, including HTML, Excel, PDF, TIFF, and XML. Various delivery, caching, and execution options are also available, as are scheduling and historical archiving.

One major set of enhancements in SQL Server 2008 R2 includes the new and enhanced features in Reporting Services, which includes

- ▶ **New features for SharePoint integration with Reporting Services**—These features include support for multiple SharePoint Zones, support for the SharePoint Universal Logging service, and a query designer for SharePoint Lists as a data source.
- ▶ **Report parts**—These are reusable report items that are stored on a report server or on a SharePoint site integrated with a report server.
- ▶ **Shared datasets**—These datasets can be shared, stored, processed and cached externally from the report, thus providing a consistent set of data that can be shared by multiple reports.
- ▶ **Cache refresh plans**—These plans allow you to cache reports or shared dataset query results on first use or from a schedule.
- ▶ **Sparklines and data bars**—These simple charts convey a lot of information in a little space, often inline with text. Sparklines and data bars are often used in tables and matrices.
- ▶ **Indicators**—These minimal gauges convey the state of a single data value at a glance. Indicators can be used by themselves in dashboards or free-form reports, but they are most commonly used in tables or matrices to visualize data in rows or columns.
- ▶ **Calculating aggregates of aggregates**—You can now create expressions that calculate an aggregate of an aggregate.

- ▶ **Better report pagination**—Page breaks on tablix data regions (table, matrix, and list), groups, and rectangles give you better control of report pagination.
- ▶ **Map reports**—Report Designer now provides a Map Wizard and Map Layer Wizard to add maps and map layers to your report to help visualize data against a geographic background. A map layer displays map elements based on spatial data from a map in the Map Gallery, from a SQL Server query that returns SQL Server spatial data, or from an Environmental Systems Research Institute, Inc. (ESRI) shapefile.
- ▶ **Business Intelligence Development Studio Support for SQL Server 2008 Reports and Report Server projects**—Business Intelligence Development Studio now supports working with both SQL Server 2008 and SQL Server 2008 R2 reports, and with Report Server projects in the SQL Server 2008 R2 version of Business Intelligence Development Studio.
- ▶ **Improved Previewing of Report**—Report Builder 3.0 provides a better preview experience with the introduction of edit sessions that enable the reuse of cached datasets when previewing reports. Reports render more quickly when using the cached datasets.

Report Manager has also been updated in the SQL Server 2008 R2 release to provide an improved user experience and look and feel. This includes an updated color scheme and layout in an effort to provide easier navigation to manage report properties and Report Server items. You can now use a new drop-down menu on each report or Report Server item in a folder to access the various configuration options for the report or item you choose. Following are some of the key enhancements to Report Manager in SQL Server 2008 R2:

- ▶ Workflow has been improved for viewing and managing reports and report server items. You can use a new drop-down menu to access various configuration options for each report or report server item in a folder.
- ▶ The need to render a report before accessing and configuring report properties when in default view has been eliminated.
- ▶ The visible display area is now larger in the Report Viewer when rendering reports.
- ▶ An updated Report Viewer toolbar includes some updates to the toolbar controls, as well as the capability to export report data to an Atom service document and data feeds.

For more information on designing and deploying reports using Reporting Services and more information on the extensive R2 enhancements, see Chapter 53, “SQL Server 2008 Reporting Services.”

SQL Server Service Broker

SQL Server Service Broker provides a native SQL Server infrastructure that supports asynchronous, distributed messaging between database-driven services. Service Broker handles all the hard work of managing coordination among the constructs required for distributed messaging, including transactional delivery and storage, message typing and validation, multithreaded activation and control, event notification, routing, and security.

Service Broker is designed around the basic functions of sending and receiving messages. An application sends messages to a *service*, which is a name for a set of related tasks. An application receives messages from a *queue*, which is a view of an internal table. Service Broker guarantees that an application receives each message exactly once, in the order in which the messages were sent.

Service Broker can be useful for any application that needs to perform processing asynchronously or that needs to distribute processing across a number of computers. An example would be a bicycle manufacturer and seller who must provide new and updated parts data to a company that implements a catalog management system. The manufacturer must keep the catalog information up-to-date with its product model data, or it could lose market share or end up receiving orders from distributors based on out-of-date catalog information. When the parts data is updated in the manufacturer's database, a trigger could be invoked to send a message to Service Broker with information about the updated data. Service Broker would then asynchronously deliver the message to the catalog service. The catalog service program would then perform the work in a separate transaction. When this work is performed in a separate transaction, the original transaction in the manufacturer's database can commit immediately. The application avoids system slowdowns that result from keeping the original transaction open while performing the update to the catalog database.

For more information on using Service Broker, see Chapter 49, "SQL Server Service Broker" (on the CD).

SQL Server 2008 R2 Editions

You can choose from several editions of SQL Server 2008 R2. The edition you choose depends on your database and data processing needs, as well as the Windows platform on which you want to install it.

For actual deployment of SQL Server in a production environment, you can choose from any edition of SQL Server 2008 except Developer Edition and Evaluation Edition. Which edition you choose to deploy depends on your system requirements and need for SQL Server components.

The following sections examine the different editions of SQL Server and discuss their features and capabilities. Using this information, you can better choose which edition provides the appropriate solution for you.

SQL Server 2008 Standard Edition

The Standard Edition of SQL Server 2008 is the version intended for the masses—those running small- to medium-sized systems who don't require the performance, scalability, and availability provided by Enterprise Edition. Standard Edition scalability is limited to up to four processors. There is no built-in memory limitation in SQL Server 2008 Standard Edition; it can utilize as much memory as provided by the operating system.

SQL Server 2008 Standard Edition includes the following features:

- ▶ CLR procedures, functions, and data types
- ▶ SQL Server Analysis Services
- ▶ Service Broker
- ▶ Reporting Services
- ▶ SQL Server Integration Services
- ▶ Full-Text Search
- ▶ Built-in XML support
- ▶ Spatial Indexes
- ▶ SQL Server Profiler and performance analysis tools
- ▶ SQL Server Management Studio
- ▶ Policy Based Management
- ▶ Replication
- ▶ Two-node failover clustering
- ▶ Database mirroring (safety full mode only)
- ▶ Log shipping
- ▶ Backup Compression (available in R2 only)

The Standard Edition can be installed on any of the Windows 2003 SP2 and Windows 2008 Server platforms, as well as Windows XP Professional, Windows Vista Ultimate, Enterprise, or Business Editions, and Windows 7 Ultimate, Enterprise, or Professional Editions.

The Standard Edition should meet the needs of most departmental and small- to mid-sized applications. However, if you need more scalability, availability, advanced security or performance features, or comprehensive analysis features, you should implement the Enterprise Edition of SQL Server 2008.

SQL Server 2008 Enterprise Edition

The Enterprise Edition of SQL Server 2008 is the most comprehensive and complete edition available. It provides the most scalability and availability of all editions and is intended for systems that require high performance and availability, such as large-volume websites, data warehouses, and high-throughput online transaction processing (OLTP) systems.

SQL Server 2008 Enterprise Edition supports as much memory and as many CPUs as supported by the operating system on which it is installed. It can be installed on any of the Windows 2003 SP2 and Windows 2008 Server platforms.

In addition, SQL Server 2008 Enterprise Edition provides performance enhancements, such as parallel queries, indexed views, and enhanced read-ahead scanning.

Which version is right for you? The next section explores the feature sets of Enterprise and Standard Editions so you can decide which one provides the features you need.

Differences Between the Enterprise and Standard Editions of SQL Server

For deploying SQL Server 2008 in a server environment, either the Standard Edition or Enterprise Edition of SQL Server is a logical choice. To help you decide between the two editions, Table 1.1 compares the major features that each edition supports.

TABLE 1.1 SQL Server 2008 Feature Comparison: Enterprise and Standard Editions

Feature	Enterprise Edition	Standard Edition
Max number of CPUs	8	4
64-bit support	Yes	Yes
CLR runtime integration	Yes	Yes
Full-Text Search	Yes	Yes
Native XML Support	Yes	Yes
FILESTREAM Support	Yes	Yes
Spatial Data Support	Yes	Yes
SQL Server Integration Services	Yes	Yes
Database Mail	Yes	Yes
Policy Based Management	Yes	Yes
SQL Profile	Yes	Yes
Integration Services with Basic Transforms	Yes	Yes
Integration Services with Advanced Data Mining and Cleansing Transforms	Yes	No
Star Join Query Optimization	Yes	No
Change Data Capture	Yes	No
Service Broker	Yes	Yes
Reporting Services	Yes	Yes
Replication	Yes	Yes
Log Shipping	Yes	Yes
Database mirroring	Yes	Yes (Single REDO thread with Safety FULL only)

TABLE 1.1 SQL Server 2008 Feature Comparison: Enterprise and Standard Editions

Feature	Enterprise Edition	Standard Edition
Database snapshots	Yes	No
Indexed views	Yes	Yes (Can be created, but automatic matching by Query Optimizer not supported)
Updatable distributed partitioned views	Yes	No
Table and index partitioning	Yes	No
Online index operations	Yes	No
Parallel index operations	Yes	No
Parallel DBCC	Yes	No
Online page and file restoration	Yes	No
Fast Recovery	Yes	No
Data Compression	Yes	No
Compressed Backups	Yes	Yes
Resource Governor	Yes	No
Fine Grained Encryption	Yes	No
Transparent Data Encryption	Yes	No
Failover clustering	Yes	Yes (2-node only)
Multiple-instance support	Yes (50 instances maximum)	Yes (16 instances maximum)
PowerPivot for SharePoint	Yes (R2 only)	No
Application and Multi-Server Management (R2 Only)	Yes	Yes (as a managed instance only)

Other SQL Server 2008 Editions

The Standard and Enterprise Editions of SQL Server 2008 are intended for server-based deployment of applications. In addition, the following editions are available for other specialized uses:

- ▶ Workgroup Edition
- ▶ Developer Edition
- ▶ Web Edition

- ▶ Express Edition
- ▶ Compact Edition

Workgroup Edition

SQL Server 2008 Workgroup Edition is intended for small organizations that need a database with no limits on database size or number of users but may not need the full capabilities of the Standard Edition. SQL Server 2008 Workgroup Edition can be used as a front-end web server or for departmental or branch office applications.

Workgroup Edition includes most of the core database features and capabilities of the SQL Server Standard Edition except for the following:

- ▶ It is limited to two CPUs and a maximum of 4GB of memory.
- ▶ It does not support failover clustering.
- ▶ Database mirroring support is limited to being a witness only.
- ▶ It does not include Analysis Services.
- ▶ It provides limited support for Integration Services and Reporting Services features.

Workgroup Edition can be installed in any of the following environments:

- ▶ Any Windows 2003 Server editions
- ▶ Any Windows 2008 Server editions
- ▶ Windows 7
- ▶ Windows Vista
- ▶ Windows XP

Developer Edition

The Developer Edition of SQL Server 2008 is a full-featured version intended for development and end-user testing only. It includes all the features and functionality of Enterprise Edition, at a much lower cost, but the licensing agreement prohibits production deployment of databases using Developer Edition.

To provide greater flexibility during development, Developer Edition can be installed in any of the following environments.

- ▶ Any Windows 2003 Server editions
- ▶ Any Windows 2008 Server editions
- ▶ Windows 7
- ▶ Windows Vista
- ▶ Windows XP

Web Edition

SQL Server 2008 Web Edition is a lower total-cost-of-ownership option, similar to the Workgroup Edition, but intended for small- to large-scale web hosts and websites.

Web Edition includes most of the core database features and capabilities of the SQL Server Standard Edition with the following key differences:

- ▶ It is limited to a maximum of 4 CPUs.
- ▶ Unlike the Workgroup Edition, memory in this edition is constrained only by the OS maximum memory limits.
- ▶ It does not support failover clustering.
- ▶ Database mirroring support is limited to being a witness only.
- ▶ It does not include Analysis Services.
- ▶ It includes only the basic version of SQL Server Management Studio (which lacks advanced features such as IntelliSense and version control support).
- ▶ It provides limited support for Integration Services and Reporting Services features.

Web Edition can be installed in any of the following environments.

- ▶ Any Windows 2003 Server editions
- ▶ Any Windows 2008 Server editions
- ▶ Windows 7
- ▶ Windows Vista
- ▶ Windows XP

Express Edition

SQL Server Express Edition is a free, lightweight, embeddable, and redistributable version of SQL Server 2008. It includes a stripped-down version of SQL Server Management Studio, called SQL Server Management Studio Express, for easily managing a SQL Server Express instance and its databases. The Express Edition of SQL Server 2008 is intended for users who are running applications that require a locally installed database, often on mobile systems, and who spend at least some time disconnected from the network. The core database engine of Express Edition is the same as the other SQL Server editions, so as your needs grow, your applications seamlessly work with the rest of the SQL Server product family.

The Express Edition can be installed in any of the following environments:

- ▶ Any Windows 2003 Server editions
- ▶ Any Windows 2008 Server editions
- ▶ Windows 7
- ▶ Windows Vista
- ▶ Windows XP

Express Edition supports most of the same features as the Workgroup Edition, with the following exceptions:

- ▶ It is limited to using a maximum of one CPU and 1GB of memory.
- ▶ It limits the maximum database size to 4GB.
- ▶ It does not include Full-Text Search, Reporting Services, or Analysis Services.
- ▶ It does not include SQL Server Integration Services.
- ▶ It supports Service Broker as a client only.
- ▶ It does not include SSMS.
- ▶ It can participate in replication only as a subscriber.

If you need a bit more than the Express Edition offers, but not as much as the Workgroup Edition, Microsoft also provides the Express Edition with Advanced Services. The Express Edition with Advanced Services includes support for Full-Text Search and limited support of Reporting Services for web reporting.

SQL Server Compact 3.5 Edition

SQL Server Compact 3.5 is a free, embedded version of SQL Server intended for building stand-alone and occasionally connected applications for mobile devices, desktops, and web clients on Windows platforms. The Compact 3.5 Edition provides general T-SQL compatibility and a cost-based Query Optimizer similar to that in SQL Server 2008. Developers who are familiar with SQL Server 2008 should feel comfortable developing for SQL Server Compact 3.5.

SQL Server Compact 3.5 Edition has a small footprint, requiring only about 2–3MB. It can connect directly with a SQL Server 2008 database through remote execution of T-SQL statements, and it also supports replication with SQL Server 2008 databases as a merge replication subscriber so that data can be accessed and manipulated offline and synchronized later with a server-based version of SQL Server 2008.

SQL Server 2008 R2 Premium Editions

SQL Server 2008 R2 introduces two new premium editions to meet the needs of large-scale datacenters and data warehouses:

- ▶ SQL Server 2008 R2 Datacenter
- ▶ SQL Server 2008 R2 Parallel Data Warehouse

SQL Server 2008 R2 Datacenter Edition is built on SQL Server 2008 R2 Enterprise and is designed to deliver a high-performing data platform that provides the highest levels of scalability for large application workloads, virtualization and consolidation, and management for an organization's database infrastructure. The Datacenter Edition provides the following key features:

- ▶ Application and Multi-Server Management for enrolling, gaining insights into, and managing over 25 instances
- ▶ Highest virtualization support for maximum ROI on consolidation and virtualization
- ▶ High-scale complex event processing with SQL Server StreamInsight

- ▶ Support for more than 8 processors and up to 256 logical processors for highest levels of scale
- ▶ Support for memory limits up to the OS maximum

SQL Server 2008 R2 Parallel Data Warehouse Edition is a highly scalable data warehouse appliance-based solution that delivers performance at low cost through a massively parallel processing (MPP) architecture and compatibility with hardware partners providing the ability to scale your data warehouse to tens and hundreds of terabytes. Following are some key features of the Parallel Data Warehouse Edition:

- ▶ Tens to hundreds of terabytes enabled by MPP architecture
- ▶ Advanced data warehousing capabilities such as Star Join Queries and Change Data Capture
- ▶ Integration with SSIS, SSRS, and SSAS
- ▶ Support for the industry standard data warehousing hub and spoke architecture and parallel database copy

SQL Server Licensing Models

In addition to feature sets, one of the determining factors in choosing a SQL Server edition is cost. With SQL Server 2008, Microsoft provides two types of licensing models: processor-based licensing and server-based licensing.

Processor-based licensing requires a single license for each physical CPU in the machine that is running a Microsoft Server product. This type of license includes unlimited client device access. Additional server licenses, seat licenses, and Internet connector licenses are not required. You must purchase a processor license for each installed processor on the server on which SQL Server 2008 will be installed, even if some processors will not be used for running SQL Server. The only exception is for systems with 16 or more processors that allow partitioning of the processors into groups so the SQL Server software can be delegated to a subset of the processors.

NOTE

For licensing purposes, Microsoft bases the number of CPUs in a machine on the number of CPU sockets on the motherboard, not the number of cores on the CPU chip itself. Thus, although a dual-core or quad-core processor chip may appear to the operating system as two or four CPUs, at the time of this writing, each of these types of chips is still considered a single CPU for licensing purposes if it occupies only a single CPU socket on the motherboard.

For those who prefer the more familiar server/client access license (CAL), or for environments in which the number of client devices connecting to SQL Server is small and known, two server/CAL-based licensing models are also available:

- ▶ **Device CALs**—A device CAL is required for a device (for example, PC, workstation, terminal, PDA, mobile phone) to access or use the services or functionality of Microsoft SQL Server. The server plus device CAL model is likely to be the more cost-effective choice if there are multiple users per device (for example, in a call center).
- ▶ **User CALs**—A SQL server user CAL is required for a user (for example, an employee, a customer, a partner) to access or use the services or functionality of Microsoft SQL Server. The server plus user CAL model is likely to be more cost effective if there are multiple devices per user (for example, a user who has a desktop PC, laptop, PDA, and so forth).

The server/CAL licensing model requires purchasing a license for the computer running SQL Server 2008 as well as a license for each client device or user that accesses any SQL Server 2008 installation. A fixed number of CALs are included with a server license and the server software. Additional CALs can be purchased as needed.

Server/per-seat CAL licensing is intended for environments in which the number of clients per server is relatively low, and access from outside the company firewall is not required. Be aware that using a middle-tier or transaction server that pools or multiplexes database connections does not reduce the number of CALs required. A CAL is still required for each distinct client workstation that connects through the middle tier. (Processor licensing might be preferable in these environments due to its simplicity and affordability when the number of clients is unknown and potentially large.)

The pricing listed in Table 1.2 is provided for illustrative purposes only and is based on pricing available at the time of publication. These estimated retail prices are subject to change and might vary from reseller pricing.

TABLE 1.2 SQL Server 2008 R2 Estimated Retail Pricing

Licensing Option	Enterprise Edition	Standard Edition	Workgroup Edition	Parallel Data Warehouse and Datacenter Editions
Processor Licensing	\$28,749 per processor	\$7,499 per processor	\$3,899 per processor	\$57,498 per processor
Server/per-seat CAL license with 5 workgroup CALs	N/A	N/A	\$739	N/A
Server/per-seat CAL license with 5 CALs	N/A	\$1,849	N/A	N/A
Server/per-seat CAL license with 25 CALs	\$13,969	N/A	N/A	N/A

Web Edition Licensing

The Express Edition of SQL Server 2008 is available via free download from www.microsoft.com/sql. Developers can redistribute it with their applications at no cost by simply registering for redistribution rights with Microsoft. The Express Edition does not require a CAL when it is used on a standalone basis. If it connects to a SQL Server instance running Enterprise Edition, Standard Edition, or Workgroup Edition, a separate user or device CAL is required for the device running Express Edition unless the SQL Server instance it connects to is licensed using the per-processor model.

Developer Edition Licensing

The Developer Edition of SQL Server 2008 is available for a fixed price of \$50. The Developer Edition is licensed per developer and must be used for designing, developing, and testing purposes only.

Express Edition Licensing

The Express Edition of SQL Server 2008 is available via free download from www.microsoft.com/sql. Developers can redistribute it with their applications at no cost by simply registering for redistribution rights with Microsoft. The Express Edition does not require a CAL when it is used on a standalone basis. If it connects to a SQL Server instance running Enterprise Edition, Standard Edition, or Workgroup Edition, a separate user or device CAL is required for the device running Express Edition unless the SQL Server instance it connects to is licensed using the per-processor model.

Compact Edition 3.5 Licensing

SQL Server 2008 Mobile Edition is available as a downloadable development product for mobile applications. You can deploy SQL Server Mobile to an unlimited number of mobile devices if they operate in standalone mode (that is, the device does not connect to or use the resources of any SQL Server system not present on the device). If the device connects to a SQL Server instance that is not on the device, a separate user or device CAL is required unless the SQL Server instance it connects to is licensed using the per-processor model.

Choosing a Licensing Model

Which licensing model should you choose? Per-processor licensing is generally required in instances in which the server will be accessed via the Web. This type of licensing includes servers used in Internet situations or servers that will be accessed from both inside and outside an organization's firewall. Per-processor licensing might also be appropriate and cost effective for internal environments in which there are a very large number of users in relation to the number of SQL Server machines. An additional advantage to the per-processor model is that it eliminates the need to count the number of devices connecting to SQL Server, which can be difficult to manage on an ongoing basis for a large organization.

Using the server/per-seat CAL model is usually the most cost-effective choice in internal environments in which client-to-server ratios are low.

Mixing Licensing Models

You can mix both per-processor and server/CAL licensing models in your organization. If the Internet servers for your organization are segregated from the servers used to support internal applications, you can choose to use processor licensing for the Internet servers and server/CAL licensing for internal SQL Server instances and user devices.

Keep in mind that you do not need to purchase CALs to allow internal users to access a server already licensed via a processor license: The processor licenses allow access to that server for all users.

Passive Server/Failover Licensing

In SQL Server 2008, two or more servers can be configured in a failover mode, with one server running as a passive server so that the passive server picks up the processing of the active server only in the event of a server failure. SQL Server 2008 offers three types of failover support:

- ▶ Database mirroring
- ▶ Failover clustering
- ▶ Log shipping

If your environment uses an active/passive configuration in which at least one server in the failover configuration does not regularly process information but simply waits to pick up the workload when an active server fails, no additional licenses are required for the passive server. The exception is if the failover cluster is licensed using the per-processor licensing model and the number of processors on the passive server exceeds the number of processors on the active server. In this case, additional processor licenses must be acquired for the number of additional processors on the passive computer.

In an active/active failover configuration, all servers in the failover configuration regularly process information independently unless a server fails, at which point one server or more takes on the additional workload of the failed server. In this environment, all servers must be fully licensed using either per-processor licensing or server/CAL licensing. Keep in mind that in some log shipping and database mirroring configurations, the standby (passive) server can be used as a read-only reporting server installation. Under this usage, the standby server is no longer “passive” and must be licensed accordingly.

Virtual Server Licensing

Virtualization is defined broadly as the running of software on a “virtual environment.” A virtual environment exists when an operating system is somehow emulated (that is, does not run directly on the physical hardware). When you’re running virtualization software on a system, one or several applications and their associated operating systems can run on one physical server inside their respective virtual environments.

Running SQL Server 2008 inside a virtual operating environment requires at least one license per virtual operating environment. Within each virtual operating environment, the license allows you to run one or more instances of SQL Server 2008. The license for a virtual operating environment can be a server/CAL license or a processor-based license. If using a processor-based license, you must purchase a processor license for each processor that the virtual machine accesses. The total number of physical and virtual processors used by the virtual operating system environments cannot exceed the number of software licenses assigned to that server. However, if you are running Enterprise Edition and all physical processors in the machine have been licensed, you may run an unlimited number of virtual operating environments on that same machine.

Multiple Instances of SQL Server

An option to virtualization is multi-instancing. With multi-instancing, multiple copies of SQL Server can be run concurrently in a single instance of an OS. Multi-instancing for SQL Server 2008 can take place both in a virtual environment or in a physical environment. Although multi-instancing offers a relatively high degree of isolation between copies of SQL Server 2008, this isolation takes place at the application level (instead of at the OS level).

In SQL Server 2008, the Workgroup and Standard Editions now allow you to run any number of instances of the server software in one physical or virtual operating system environment on the licensed server. Previously, only the Enterprise Edition of the server license allowed multi-instancing.

Summary

This chapter examined the various platforms that support SQL Server 2008 R2 and reviewed and compared the various editions of SQL Server 2008 that are available. Which platform and edition are appropriate to your needs depends on scalability, availability, performance, licensing costs, and limitations. The information provided in this chapter should help you make the appropriate choice.

Chapter 2, “What’s New in SQL Server 2008,” takes a closer look at the new features and capabilities provided with the various SQL Server 2008 editions.

CHAPTER 2

What's New in SQL Server 2008

IN THIS CHAPTER

- ▶ New SQL Server 2008 Features
- ▶ SQL Server 2008 Enhancements

SQL Server 2005 provided a number of significant new features and enhancements over what was available in SQL Server 2000. This is not too surprising considering there was a five-year gap between these major releases. Microsoft SQL Server 2008 is not as much of a quantum leap forward from SQL Server 2005, but it provides a number of new features and enhancements to further extend the performance, reliability, availability, programmability, and ease of use of SQL Server. This chapter explores the new features provided in SQL Server 2008 and SQL Server 2008 R2, as well as many of the enhancements to previously available features.

New SQL Server 2008 Features

So what does SQL Server 2008 have to offer over SQL Server 2005? Following is an overview of the new features provided in SQL Server 2008:

- ▶ **New storage features**—FILESTREAM storage, sparse columns and column sets, row-level and page-level data compression
- ▶ **New data types**—Date, Time, and DATETIME2 data types; Hierarchyid data type; spatial data types; user-defined table type
- ▶ **New Transact-SQL (T-SQL) constructs**—Compound operators, GROUPING SETS, MERGE statement, row constructors, table-valued parameters, INSERT over DML, new date and time functions
- ▶ **New performance features**—Filtered indexes and statistics, FORCESEEK query hint, hash values for

finding similar queries in the plan cache, Plan Guide Successful and Plan Guide Unsuccessful event classes, Guided/Misguided Plan Executions/sec Performance Monitor counters, LOCK ESCALATION option for ALTER TABLE, hot-add CPUs

- ▶ **New security features**—Transparent data encryption, Extensible Key Management, SQL Server Audit
- ▶ **New database administration features**—Backup compression, Change Data Capture, Change Tracking, the Data Collector, Policy-Based Management, SQL Server Extended Events, Resource Governor
- ▶ **New SQL Server management features**—Transact-SQL Debugger, IntelliSense, error list window, multiserver queries, PowerShell integration

SQL Server 2008 R2 further enhances SQL Server 2008 with the following new features:

- ▶ Two new premium editions to meet the needs of large-scale datacenters and data warehouses:
 - ▶ SQL Server 2008 R2 Datacenter
 - ▶ SQL Server 2008 R2 Parallel Data Warehouse
- ▶ SQL Server Utility for Multi-Server Management
- ▶ PowerPivot for Excel and SharePoint
- ▶ A number of new Reporting Services features including Report Builder 3.0, report parts, shared datasets, Sparklines and data bars, indicators, calculating aggregates of aggregates, maps, lookup functions

The following sections take a closer look at each of these new features and, where appropriate, provide references to subsequent chapters where you can find more information and detail about the new features.

New Storage Features

SQL Server 2008 provides a set of new features to reduce storage requirements and improve performance.

One of the new features is FILESTREAM storage. *FILESTREAM storage* is a property that can be applied to `varchar(max)` columns; it enables SQL Server applications to store unstructured data, such as documents and images, directly in the NTFS file system while still maintaining the behavior of a database column. The advantages of FILESTREAM storage are improved performance and increased size of BLOB data, expanding from the 2GB limit of image columns to the available space in the file system. For more information on using FILESTREAM storage, see Chapter 42, “What’s New for Transact-SQL in SQL Server 2008.”

Other storage features introduced in SQL Server 2008 are sparse columns and column sets. *Sparse columns* are ordinary columns that have an optimized storage format for null values. If you use sparse columns, you can also define a column set on the table that will return all sparse columns in the table. A *column set* is an untyped XML representation that combines all the sparse columns of a table into a structured output. For more information

on defining sparse columns and column sets, see Chapter 24, “Creating and Managing Tables.”

Row-level and page-level data compression also are introduced in SQL Server 2008. *Data compression* helps to reduce both storage and memory requirements as the data is compressed both on disk and when brought into the SQL Server data cache. Row-level compression isn't true data compression but implements a more efficient storage format for fixed-length data. Page-level compression is true data compression, using both column prefix and dictionary-based compression. For more information on implementing data compression, see Chapter 24.

New Data Types

SQL Server 2008 introduces a handful of new data types. Two of the most welcome of these are the new DATE and TIME data types. These new data types allow you to store date-only and time-only values. In addition, SQL Server now supports the DATETIME2 and DATETIMEOFFSET data types. DATETIME2 is a variation of the DATETIME data type that supports datetime values from 0001-01-01 to 9999-12-31 23:59:59.999999. DATETIMEOFFSET supports UTC-based datetime values that are time zone aware.

The new Hierarchyid data type is a common language runtime (CLR) user-defined type (UDT) that provides a mechanism for representing and storing a tree structure in a table in an efficient manner. This data type is useful for storing data that represents a parent child, tree-like structure such as an organizational structure or a graph of links between web pages.

Spatial data types are introduced in SQL Server 2008 as well. There are two new spatial data types: geometry and geography. The geometry data type supports planar, or Euclidean (flat-earth), data. The geography data type stores ellipsoidal (round-earth) data, such as GPS latitude and longitude coordinates. These new data types support the storage and manipulation of spatial data objects such as linestrings, points, and polygons.

SQL Server 2008 also introduces a new user-defined table type that can be used as parameters in stored procedures and functions, as well as for defining table variables in a batch or the body of a stored procedure or function.

For more information and examples on using the new SQL Server 2008 data types, see Chapter 42.

New Transact-SQL Constructs

What would a new SQL Server release be without new T-SQL commands and constructs to further expand the power and capabilities of the T-SQL language? SQL Server 2008 is no exception (although SQL Server 2008 R2 is an exception because no new T-SQL constructs are introduced in R2). The new constructs provided in SQL Server 2008 include

- ▶ **Compound operators**—New operators that provide a shorthand method of performing an operation and assigning a value to a local variable (for example, +=, *=).

- ▶ **GROUPING SETS**—New operator added to the GROUP BY clause to perform multiple grouping operations in a single query.
- ▶ **MERGE** statement—New DML statement that can perform INSERT, UPDATE, or DELETE operations on a target table based on the results of a join with a source table.
- ▶ **Row constructors**—An enhancement to the VALUES clause that allows multiple row inserts within a single INSERT statement. Also provides the ability to use the VALUES clause to create a pseudo table of values in a subquery or common table expression.
- ▶ **Table-valued parameters**—New parameter type that can be assigned the new user-defined table types. Table-valued parameters enable you to pass a table variable containing multiple rows of data to a stored procedure or function without the need to create a temporary table.

To coincide with the new DATE and TIME data types, SQL Server 2008 also introduces a few new date and time functions:

- ▶ **SYSDATETIME()**—Returns the current system datetime as a DATETIME2(7) value
- ▶ **SYSDATETIMEOFFSET()**—Returns the current system datetime as a DATETIMEOFFSET(7) value
- ▶ **SYSUTCDATETIME**—Returns the current system datetime as a DATETIME2(7) value representing the current UTC time
- ▶ **SWITCHOFFSET (DATETIMEOFFSET, time_zone)**—Changes the DATETIMEOFFSET value from the stored time zone offset to the specified time zone
- ▶ **TODATETIMEOFFSET (datetime, time_zone)**—Converts a local datetime value for the specified time zone to a DATETIMEOFFSET UTC value

For more information and examples on using the new SQL Server 2008 T-SQL constructs, see Chapter 42.

New Performance Features

SQL Server 2008 also introduces some new features and enhancements for monitoring, managing, and improving query performance. Among these new features are filtered indexes and statistics. A *filtered index* is a nonclustered index defined on a subset of data using a filter predicate to index only a portion of rows in the table. *Filtered statistics* are statistics defined on a subset of data in the table using a filter predicate. A well-designed filtered index can improve query performance, reduce index maintenance costs, and reduce index storage costs compared with full-table indexes, especially when columns contain a large number of rows with null or a single value that isn't searched on but can skew the index and statistics. For more information on creating and using filtered indexes and statistics, see Chapter 34, "Data Structures, Indexes, and Performance."

SQL Server 2008 provides FORCESEEK as a new table and query hint for controlling how SQL Server optimizes a query; it forces the optimizer to use only an index seek operation to access the data in the referenced table or view. For more information on using the FORCESEEK hint, see Chapter 35, "Understanding Query Optimization."

Plan guides were a feature introduced in SQL Server 2005. *Plan guides* can be used to optimize the performance of queries when you cannot or do not want to change the text of the query directly (for example, when queries in a third-party database application are not performing as expected). SQL Server 2008 provides additional features related to plan guides to make implementing and managing them easier. Among these features are new event classes (Plan Guide Successful and Plan Guide Unsuccessful) that can be monitored via SQL Server Profiler to determine when plan guides are being applied. There are also two new Performance Monitor counters (Guided/Misguided Plan Executions/sec) that you can use to monitor via Performance Monitor how often plan guides are being used or not being used.

SQL Server 2008 also now generates hash values for query plans in the plan cache. The `sys.dm_exec_query_stats` and `sys.dm_exec_requests` dynamic management views (DMVs) now provide query hash and query plan hash values that you can use to help find similar queries in the plan cache. Locating similar queries can help you determine the aggregate resource usage for similar queries and similar query execution plans so that you can better focus your query tuning efforts and help identify which queries may get the most benefit from using plan guides. For more information on query plans and using plan guides, see Chapter 35.

To provide greater control of locking, SQL Server 2008 offers the new `LOCK ESCALATION` table option. This option specifies the allowed methods of lock escalation for a table. The default is `AUTO`, which allows the Database Engine to select the appropriate lock escalation level for the query if a table is partitioned. You can also specify `TABLE` to force full table-level locking whether or not a table is partitioned. A third option, `DISABLE`, prevents escalation to a table-level lock in most cases. For more details on locking and the `LOCK ESCALATION` option, see Chapter 37, “Locking and Performance.”

One additional new feature in SQL Server 2008 Enterprise Edition is hot-add CPU. *Hot-add CPU* is the capability to dynamically add CPUs to a running system. Additional CPUs can be made available logically by online hardware partitioning, virtually through a virtualization layer, or even physically by adding new hardware on systems that support adding physical CPUs while the system is online. Hot-add CPU, which requires hardware support, is available only when you’re running Windows Server 2008 Datacenter or Enterprise Edition.

New Security Features

SQL Server 2005 provided the capability to encrypt data at the column level. However, this encryption was not transparent to the end users or applications. Encrypting and decrypting the data required coding changes to use the built-in encryption and decryption functions. SQL Server 2008 introduces transparent data encryption (TDE), which allows for encrypting the entire database without affecting client applications. The purpose of TDE is to protect sensitive data in the event a database file or backup is stolen. Encryption is done in real-time at the page level as the data is written to disk and decrypted as the data is read from disk. The encryption is based on a database encryption key (DEK), which is a symmetric key secured by using a certificate stored in the master database of the server or an asymmetric key protected by an Extensible Key Management (EKM) module.

Extensible Key Management, which is also new with SQL Server 2008, enables you to store the keys used to encrypt data separately from the data it protects. SQL Server 2008 EKM enables the encryption keys that protect the database files to be stored in a removable device such as a smartcard, USB device, or a software-based Extensible Key Management (EKM)/Hardware Security Module (HSM) module. EKM facilitates separation of duties by taking key management out of the hands of the database administrators.

For more information on implementing and using transparent data encryption and extensible key management, see Chapter 12, “Data Encryption.”

SQL Server already provides a number of existing audit methods (SQL Trace, C2 audit mode, DDL triggers). In addition to these, SQL Server 2008 adds an additional audit method: SQL Server Audit. SQL Server Audit, based on the new Extended Events feature, allows you to monitor server- or database-level events or groups of events. You can set up and monitor audit events at the server or database level and audit the audit actions themselves. For more information on SQL Server Audit, see Chapter 13, “Security and Compliance.”

New Database Administration Features

SQL Server 2008 introduced backup compression for Enterprise Edition. With SQL Server 2008 R2, backup compression is supported in Standard and all higher editions (every edition of SQL Server 2008 and later can restore a compressed backup, however). In addition to the space savings provided by compressed backups, compressing a backup also typically increases backup speed because it requires less device I/O. However, the I/O cost savings comes at the expense of increased CPU usage caused by the compression process. For more information on compressing backups, see Chapter 14, “Database Backup and Restore.”

Policy-Based Management is a new mechanism in SQL Server 2008 for managing one or more instances of SQL Server 2008. SQL Server Policy-Based Management can help to simplify management operations such as setting database options across multiple servers, checking SQL Server configurations, or enforcing naming conventions, helping to reduce the total cost of ownership (TCO) of administering multiple SQL Server instances. SQL Server Management Studio (SSMS) can be used to define and implement policies for managing SQL Server instances, databases, or other SQL Server objects as well as on-demand checking and enforcement of policies. Checking and enforcement of these policies can also be scheduled using SQL Server Agent. For more information on Policy-Based Management in SQL Server, see Chapter 22, “Administering Policy Based Management.”

Currently, several options are available for troubleshooting or getting information about SQL Server-generated events: SQL Server Profiler, SQL Server Log, dynamic management views and functions, SQL Trace, trace flags, Windows Application and System logs, performance counters, and so on. SQL Server 2008 introduces a new event infrastructure, Extended Events. *Extended Events* is a general-purpose event-handling system for server systems. Currently, the Extended Events infrastructure supports the correlation of data from SQL Server and, under certain conditions, the correlation of data from the operating system and database applications. Extended Events has the potential to make other trou-

troubleshooting options obsolete in future releases and become the common denominator for troubleshooting purposes. As mentioned previously, the new SQL Server Audit feature is based on Extended Events. For more information on configuring and using Extended Events for monitoring SQL Server 2008, see Chapter 39, “Monitoring SQL Server Performance.”

Resource Governor, another new technology in SQL Server 2008, enables you to manage and control the allocation of resources for SQL Server according to workload. Similarly sized queries or requests that can, and should be, treated the same are assigned to a workload group as the requests are received. Each workload group is associated to a pool of resources that represents the physical resources for SQL Server (currently, for SQL Server 2008, these resources are CPU and memory). Limits are specified on resource consumption for these incoming requests. In an environment where multiple distinct workloads are present on the same server, Resource Governor enables you to differentiate these workloads and allocate shared resources as they are requested, based on the limits you specify. For more information on implementing and configuring Resource Governor, see Chapter 40, “Managing Workloads with the Resource Governor.”

Change Data Capture (CDC) and Change Tracking are new features in SQL Server 2008 with similar names but different purposes. *CDC* is an asynchronous mechanism that captures all changes of a data row from the transaction log and stores them in change tables. The information captured is available in relational format and can be accessed by client applications such as extract, transform, and load (ETL) processes. All intermediate values of a row are stored. Using Change Data Capture, you can avoid using expensive techniques such as triggers, time stamp columns, and join queries to identify and capture the changes made to data.

Change Tracking, on the other hand, is a lightweight synchronous mechanism that tracks data modifications but records only the fact that a row has changed. Applications can use Change Tracking to identify which rows have changed for a user table and refresh their data stores with the latest values from these rows by requerying the table.

For more information on using CDC and Change Tracking, see Chapter 42.

New SQL Server Management Studio Features

SQL Server Management Studio (SSMS) was first introduced in SQL Server 2005. SSMS is a full-featured, robust SQL Server administration and development tool. However, there was clearly room for improvement, and SQL Server 2008 provides some long-awaited enhancements.

One of the most anticipated (and missed) features in SSMS was a built-in T-SQL debugger. Prior to SQL Server 2005, SQL Server Enterprise Manager had a built-in T-SQL Debugger. A lot of users were disappointed a T-SQL debugger was not included with this version of SSMS. To debug T-SQL, you needed to install Visual Studio (VS). Fortunately, a built-in debugger returns to SSMS in SQL Server 2008.

Another long-awaited feature for SSMS is IntelliSense. IntelliSense is a useful feature in the Query Editor for looking up language elements and object names without having to leave

the editor. IntelliSense can even automatically complete and insert language elements directly into your code.

In conjunction with IntelliSense, SSMS also provides the error list window. The *error list window* displays all errors and warnings produced by IntelliSense as you develop your code in the Database Engine Query Editor. You can double-click the error message entry to jump to the error location. As you fix errors, they are automatically removed from the error list window.

One other new capability built in to SSMS in SQL Server 2008 is *multiserver queries*. This feature allows you to execute T-SQL statements against multiple servers defined in a server group at the same time. If you open a Query Editor from the server group in the Registered Servers window, the T-SQL statements in the current Query Editor are executed against all the servers in the group. The results from the query can be merged into a single results pane or can be returned in separate results panes for each server.

For more details on these new features in SSMS, see Chapter 4, “SQL Server Management Studio.”

PowerShell Integration

SQL Server 2008 provides integrated support for Windows PowerShell, a powerful scripting shell that enables administrators and developers to automate server administration and application deployment. The Windows PowerShell language supports more complex logic than Transact-SQL scripts, enabling SQL Server administrators to build more robust and complex administration scripts.

SQL Server provides two snap-ins to Windows PowerShell for creating scripts to manage SQL Server:

- ▶ A SQL Server provider, which enables a simple navigation mechanism similar to file system paths where the drive is associated with a SQL Server management object model and the nodes are based on the object model classes. This allows you to use familiar commands such as `cd` and `dir` to navigate the paths similar to the way you navigate folders in a command prompt window.
- ▶ A set of cmdlets, which are commands used in Windows PowerShell scripts to specify a SQL Server action, such as running a SQLCMD script containing Transact-SQL or XQuery statements

For more information on managing SQL Server using PowerShell, see Chapter 17, “Administering SQL Server 2008 with PowerShell.”

New Premium SQL Server Editions

SQL Server 2008 R2 introduces two new premium-level editions of SQL Server: Datacenter Edition and Parallel Data Warehouse.

Built on SQL Server 2008 R2 Enterprise, SQL Server 2008 R2 Datacenter is designed to deliver a high-performing data platform that provides the highest levels of scalability for large application workloads, virtualization and consolidation, and management for an

organization's database infrastructure. Datacenter helps enable organizations to cost-effectively scale their mission-critical environment. Key features of Datacenter include

- ▶ Application and multiserver management for enrolling, gaining insights, and managing more than 25 instances
- ▶ Highest virtualization support for maximum return on investment (ROI) on consolidation and virtualization
- ▶ High-scale complex event processing with SQL Server StreamInsight
- ▶ Support for more than 8 processors and up to 256 logical processors

SQL Server 2008 R2 Parallel Data Warehouse is a highly scalable data warehouse appliance-based solution. Parallel Data Warehouse delivers performance at low cost through a massively parallel processing (MPP) architecture and compatibility with hardware partners, allowing you to scale your data warehouse to tens and even hundreds of terabytes. Key features provided by Parallel Data Warehouse include

- ▶ Advanced data warehousing capabilities such as Star Join Queries and Change Data Capture
- ▶ Integration with SSIS, SSRS, and SSAS
- ▶ Support for industry-standard data warehousing hub-and-spoke architecture and parallel database copy

SQL Server Utility for Multiserver Management

SQL Server 2008 R2 features new SSMS dashboards for observing information on more than one server from the same screen by utilizing the new SQL Server Utility. The SQL Server Utility models an organization's SQL Server-related entities in a unified view. Utility Explorer and SQL Server Utility viewpoints in SQL Server Management Studio provide administrators a holistic view of SQL Server resource health. Entities that can be viewed in the SQL Server Utility include

- ▶ Instances of SQL Server
- ▶ Data-tier applications
- ▶ Database files
- ▶ Volumes

SQL Server Utility is covered in more detail in Chapters 4 and 39.

PowerPivot for Excel and SharePoint

PowerPivot is a new tool that integrates SQL Server with Microsoft Excel and SharePoint to create a self-service business intelligence (BI) solution for the enterprise. PowerPivot for Excel and SharePoint are client and server components that integrate Analysis Services with Excel and SharePoint. PowerPivot for Excel is an add-in that allows you to create PowerPivot workbooks that can assemble and relate large amounts of data from different

sources. PowerPivot for SharePoint extends SharePoint 2010 and Excel Services to add server-side processing, collaboration, and document management support for the PowerPivot workbooks that you publish to SharePoint. Together, the PowerPivot client add-in and server components provide an end-to-end solution that furthers business intelligence data analysis for Excel users on the workstation and on SharePoint sites.

For more information on PowerPivot, see Chapter 51, “Analysis Services.”

New Reporting Services Features

SQL Server 2008 R2 introduces a number of new features for Reporting Services. The Reporting Services enhancements are probably the most significant aspect of the R2 release. One of the key changes in SQL Server 2008 R2 is an updated version of the Report Manager. The SQL Server 2008 R2 Report Manager provides an improved user experience via interface changes, including an updated color scheme and layout, in an effort to provide easier navigation for managing report properties and Report Server items. Following are some of the key enhancements to Report Manager in R2:

- ▶ An improved workflow for viewing and managing reports and Report Server items through the use of a new drop-down menu to access various configuration options for each report or Report Server item in a folder
- ▶ Elimination of the need to render a report before accessing and configuring report properties when in default view
- ▶ Increased screen space for the Report Viewer when rendering reports
- ▶ An updated Report Viewer toolbar, which includes some updates to the toolbar controls, as well as the capability to export report data to an Atom service document and data feeds

The set of new and enhanced features in SQL Server 2008 R2 for Reporting Services includes

- ▶ **Report parts**—You can store these reusable report items on a Report Server or on a SharePoint site that is integrated with a Report Server.
- ▶ **Sparklines and data bars**—These simple charts convey a lot of information in a little space, often inline with text.
- ▶ **Indicators**—These minimal gauges convey the state of a single data value at a glance. Indicators can be used by themselves in dashboards or free-form reports.
- ▶ **Calculation of aggregates of aggregates**—You can now create expressions that calculate an aggregate of an aggregate.
- ▶ **Improved report pagination**—Reporting Services provides more control over report pagination including dynamic updating of page names and numbers when a report is run, as well as disabling page breaks entirely.
- ▶ **Map reports**—Report Designer now provides a Map Wizard and Map Layer Wizard so that you can add maps and map layers to your report to help visualize data against a geographic background.

- ▶ **Shared datasets**—This Report Server feature can retrieve data from shared data sources that connect to external data sources, providing a way to share a query to help provide a consistent set of data for multiple reports.
- ▶ **Cache refresh plans**—These plans allow you to cache reports or shared dataset query results on first use or from a schedule.
- ▶ **Improved previewing of reports**—Report Builder 3.0 provides a better preview experience with the introduction of edit sessions that enable the reuse of cached datasets when you are previewing reports, which allows reports to render more quickly.

For more information on designing and deploying reports using Reporting Services and more information on the extensive set of new Reporting Services features in R2, see Chapter 53, “SQL Server 2008 Reporting Services.”

SQL Server 2008 Enhancements

In addition to the brand new features in SQL Server 2008, there are a number of enhancements to existing features provided by SQL Server 2008 and SQL Server 2008 R2. The following sections provide an overview of the major enhancements.

SQL Server Management Studio

In addition to the new SSMS features discussed previously, SSMS has also received a number of enhancements in SQL Server 2008; you are now able to do the following:

- ▶ Customize the columns displayed by the Object Explorer Details window.
- ▶ Display the properties of a selected item from Object Explorer Details at the bottom of the window.
- ▶ View a color-coded status bar at the bottom of the window for Transact-SQL and MDX code editors which provide information about the editor connection. The status bar changes color when a code editor opens multiple connections.
- ▶ Customize the tab name for items in the title bar of the code editor windows.
- ▶ Configure the number of rows returned when you open tables via the Object Browser.
- ▶ Create and manage plan guides via the Programmability folder in Object Browser.

Dynamic Management Views

SQL Server 2008 adds five new dynamic management views to return memory-related information about SQL Server:

- ▶ **sys.dm_os_memory_brokers**—Returns information about memory brokers, the components that track memory allocations
- ▶ **sys.dm_os_memory_nodes**—Returns memory allocation information for memory allocated through SQL Server Memory Manager

- ▶ **sys.dm_os_nodes**—Returns information about SQL OS memory nodes, internal structures of SQL OS that abstract hardware processor locality
- ▶ **sys.dm_os_process_memory**—Returns complete information about memory allocated to SQL Server process space
- ▶ **sys.dm_os_sys_memory**—Describes the memory state for the operation system

In addition, the `cpu_ticks_in_ms` column in the `sys.dm_os_sys_info` dynamic management view has been discontinued, and two new columns, `sqlserver_start_time_ms_ticks` and `sqlserver_start_time`, have been added.

Database Mirroring

SQL Server 2008 provides a number of enhancements to database mirroring, mostly related to performance of database mirroring, including compression of the transaction log records being streamed to the mirror database, asynchronous write-ahead on the incoming log stream and read-ahead during the undo phase, and improved use of the log send buffers. For more information on database mirroring and the improvements, see Chapter 20, “Database Mirroring.”

SQLCLR Enhancements

SQL Server 2008 extends the SQLCLR by extending the 8KB size limit for CLR user-defined types and CLR user-defined aggregates, supporting the definition of ordered table-valued functions, providing support for multiple input parameters for user-defined aggregates, and including the option to define static methods as user-defined functions.

For more information on the enhancements to SQL CLR, see Chapter 46, “Creating .NET CLR Objects in SQL Server 2008.”

Replication Enhancements

SQL Server 2008 introduces a number of usability and manageability enhancements for peer-to-peer replication and the Replication Monitor.

Peer-to-peer replication includes the following significant usability and manageability improvements:

- ▶ A new option, enabled by default, that allows the Distribution Agent to detect conflicts during synchronization and to stop applying changes at the affected row.
- ▶ The capability to add nodes to a replication topology without quiescing the topology.
- ▶ The capability to configure a topology visually in the Configure Peer-to-Peer Topology Wizard. The Topology Viewer enables you to perform common configuration tasks, such as adding new nodes, deleting nodes, and adding new connections between existing nodes.

The Replication Monitor includes the following usability improvements:

- ▶ Most of the Replication Monitor grids allow you to specify which columns to view, sort by multiple columns, and filter rows in the grid based on column values.

- ▶ The Common Jobs tab for the Publisher node has been renamed to Agents.
- ▶ The single Warnings and Agents tab for the publication node has been split into separate Warnings and Agents tabs to emphasize the difference between administering performance warnings and monitoring replication agents.

For more information on configuring and using replication in SQL Server 2008, see Chapter 19, “Replication.”

SQL Server Integration Services Enhancements

Integration Services in SQL Server 2008 received enhancements and improvements as well. Following are some of these enhancements:

- ▶ Improvements in the parallel execution of data flow pipeline paths on multiprocessor systems, going beyond the SQL Server 2005 limit of two engines.
- ▶ A new script environment. Visual Studio for Applications (VSA) has been replaced with Visual Studio Tools for Applications (VSTA). VSTA allows the development of scripts written on Visual C# and Visual Basic, providing support for the Script Task and Script Component. VSTA also supports debugging and adding managed assemblies to a script at design time.
- ▶ Increased performance and improved caching options for Lookup Transformations.
- ▶ Data profiling to improve data quality by identifying potential data quality problems.
- ▶ Support for the new Change Data Capture feature in SQL Server 2008, providing an effective method for performing incremental data loads from source tables to data marts and data warehouses.

For more information on using SQL Server Integration Services in SQL Server 2008, see Chapter 52, “SQL Server Integration Services.”

Service Broker Enhancements

SQL Server 2008 provides the following enhancements to Service Broker:

- ▶ Support for conversation priorities. This support allows administrators and developers to specify that messages for important Service Broker conversations are sent and received before messages from less important conversations to ensure that low-priority work does not block higher-priority work.
- ▶ The new `ssbdiagnose` command-prompt utility to analyze and diagnose Service Broker configurations and conversations.
- ▶ A new performance object and counters that report how often Service Broker dialogs request transmission objects and how often inactive transmission objects are written to work tables in `tempdb`.
- ▶ Support for Service Broker in SQL Server Management Studio via new Service Broker Elements in Object Explorer.

For more information on the new features and capabilities of Service Broker, see Chapter 49.

Analysis Services Enhancements

SQL Server 2008 also introduces some new features and enhancements to Analysis Services. Following are some of the primary improvements:

- ▶ A new Aggregation Designer makes it easier to browse and modify aggregation designs.
- ▶ Aggregation design and usage-based optimization wizards have been simplified and enhanced.
- ▶ New AMO warning messages alert users when they depart from design best practices or make logical errors in database design.
- ▶ Simplified and enhanced cube and dimension wizards help you create better cubes and dimensions in fewer steps.
- ▶ A new Attribute Relationship designer makes it easier to browse and modify attribute relationships.
- ▶ A new Key Columns dialog box makes editing key columns easier.
- ▶ Key columns can now be edited in the Properties panel.
- ▶ An updated Dimension Structure tab helps make modifying attributes and hierarchies easier.
- ▶ A new storage structure is available and performance has been enhanced in all backup and restore scenarios.
- ▶ When creating a mining structure, you can now divide the data in the mining structure into training and testing sets.
- ▶ You can now attach filters to a mining model and apply the filter during both training and testing. Applying a filter to the model lets you control the data used to train the model and lets you more easily assess the performance of the model on subsets of the data.
- ▶ Cross-validation is now available in the Mining Accuracy Chart view of the Data Mining Designer.
- ▶ SQL Server 2008 supports the creation, management, and use of data mining models from Microsoft Excel when you use the SQL Server 2008 Data Mining add-ins for Office 2007.
- ▶ You are able to add aliases to columns in a mining model to make it easier to understand column content and reference the column in DMX statements.

For more information on the new features and capabilities of SQL Server Analysis Services (SSAS), see Chapter 51.

Installation Enhancements

Starting with SQL Server 2008 Service Pack 1, you can now perform slipstream installations of SQL Server 2008. *Slipstream* is the integration of the original installation media files with a service pack and/or a cumulative update so that they can be installed in a single step.

SQL Server 2008 also provides the capability to selectively uninstall cumulative updates and/or service packs via the Programs and Features control panel.

For more information on installing and upgrading SQL Server 2008, see Chapters 8, “Installing SQL Server 2008,” and 9, “Upgrading to SQL Server 2008.”

Deprecated Features

In addition to the new and enhanced features in SQL Server 2008, it's important to note the features for which support has been discontinued. Table 2.1 lists the unsupported/deprecated features along with their replacements, if any.

TABLE 2.1 Deprecated Features in SQL Server 2008

Deprecated Feature	Replacement
sp_addalias	None
DUMP and LOAD statements	BACKUP and RESTORE
BACKUP LOG WITH NO_LOG and BACKUP LOG WITH TRUNCATE_ONLY	None; however, changing the database to simple recovery clears the transaction log
BACKUP TRANSACTION	BACKUP LOG
sp_helpdevice	sys.backupdevices catalog view
60, 65, and 70 compatibility levels	Support is provided only for compatibility levels 80 and higher
User groups (sp_addgroup, sp_changegroup, sp_dropgroup, sp_helpgroup)	Roles
Northwind and pubs databases	AdventureWorks database

To help keep track of deprecated features so that you can identify potential future upgrade and compatibility problems, SQL Server 2008 provides the SQL Server: Deprecated Features performance counter and the Deprecation Announcement and Deprecation Final Support event classes, which you can monitor via SQL Server Profiler or SQL Trace.

Summary

SQL Server 2008 provides a number of new and long-awaited features and enhancements. This chapter provides an overview of the new features and enhancements that ship with SQL Server 2008 and SQL Server 2008 R2. To learn more, refer to the other chapters referenced here.

However, before we get into covering the features and capabilities of SQL Server 2008 and SQL Server 2008 R2, we'll first take a look at some real-world production implementations of SQL Server to give you an idea of what is possible with SQL Server in both the online transaction processing (OLTP) world and in the decision support systems (DSS)/business intelligence (BI) realms.

CHAPTER 3

Examples of SQL Server Implementations

As you will see in this chapter, companies use SQL Server for many types of applications and on most tiers now. Gone are the days when you would second guess yourself choosing to use SQL Server over a competing database engine (such as Oracle or DB2 on a UNIX platform) to ensure you got optimal transactional throughput, high availability, and the highest performance. In fact, SQL Server outnumbers both of these database vendors in installed sites globally. Microsoft SQL Server has arrived!

The *SQL Server Unleashed* team has gathered a few showcase SQL Server-based applications to give you an example of what is possible with SQL Server in both the online transaction processing (OLTP) world and in the decision support systems (DSS)/business intelligence (BI) realms. Each example in this chapter comes from real-life database applications running in production environments at major organizations around the world. In general, all the examples in this book come from our direct customer experiences. We often translate those real-life customer implementations into AdventureWorks2008 or bigpubs2008 database terms so that you can easily re-create them for your own use.

This chapter describes two OLTP applications: one is a traditional ERP system using SQL Server as the database layer, and the other is an online shopping system with shopping carts and both high-availability and high-performance requirements.

IN THIS CHAPTER

- ▶ Application Terms
- ▶ OLTP Application Examples
- ▶ DSS Application Examples

On the DSS/BI side, this chapter presents a traditional conformed-dimension star schema data warehouse implementation for a high-tech company and then shows you what this looks like implemented as an online analytical processing (OLAP) cube created by Analysis Services.

Under the DSS/BI examples, this chapter describes a hybrid distributed reporting example that uses multiple SQL Server technologies to get the most out of a complex application environment in the healthcare industry.

Application Terms

Online transaction processing, or OLTP, is a class of applications that facilitate and manage transaction-oriented processing, typically for data entry, complex business processes (such as order entry), and retrieval transactions. The term *transaction* in the context of computer or database transactions is a finite set of changes that are grouped together and can be undone together if any one piece does not complete (or fails). Often, however, we speak of transactions as a business “unit of work” that can span multiple database transactions as one logical business transaction. The term *OLTP* has also been used to refer to processing in which the system responds immediately to user requests. An automated teller machine (ATM) application for a bank is a classic example of this type of OLTP transaction.

In many applications, efficient OLTP applications may depend on sophisticated transaction management software and/or database optimization tactics to facilitate the processing of large numbers of concurrent users and updates to an OLTP-oriented database. In a geographic-distributed database system, OLTP brokering programs are used to distribute transaction processing among multiple computers on a network. These days, central OLTP is often underneath the covers and integrated into most service-oriented architectures (SOAs) and exposed as web services that can be easily orchestrated for different application functionality.

Decision support systems (DSS) have been around since the late 1960s, beginning with model-driven DSS and running the gamut of financial planning systems, spreadsheets, and massive multidimensional databases more recently. We speak of data warehouses, data marts, executive information systems, OLAP cubes, and business intelligence when referring to DSS. All enable complex decision support capabilities, multidimensional data analysis, online analytical processing, business intelligence, spatial DSS, and complex querying and reporting capabilities.

DSS system categories are

- ▶ Data analysis systems that support the manipulation, aggregation, and transformation of data for a specific task or purpose

- ▶ Pure analysis information systems that enable a series of decision-oriented databases and small models
- ▶ Complex accounting and financial models that calculate and forecast behavior based on business events and financial results
- ▶ Predictive models that estimate the consequences of actions on the basis of simulation models
- ▶ Optimization models that provide insight and possible actions a business can take by generating an optimal solution consistent with a series of constraints

Microsoft has the capability to fully address the first three types and is only now venturing into predictive and optimization modeling. The examples in this chapter illustrate a classic data warehouse (star schema/snowflake, multidimensional, measures/facts), a small distributed data mart, and an OLAP cube.

For each example in this chapter, we try to describe the overall purpose of the application, the major use cases, and the technology and architecture on which they were deployed. Where appropriate, we might showcase a data model diagram, a relational schema, or a distributed topology that gives you some insight into why the implementation was done a specific way. You are likely to recognize some use cases that may be the same in your environment and therefore possibly apply the same techniques or solutions to serve you as well.

OLTP Application Examples

The following sections describe what the major Enterprise Resource Planning (ERP) vendor SAP AG has implemented using SQL Server for its database layer.

OLTP ERP Example

SAP business solutions are composed of a comprehensive range of products that empower an enterprise with a flexible, end-to-end solution. A critical challenge in implementing an SAP solution is the selection of a data platform to deliver the advanced features and capabilities needed to support the most demanding workloads. The Microsoft SQL Server database software (either SQL Server 2008 or SQL Server 2005) is the relational database management system (RDBMS) of choice for deploying secure, reliable, highly available, high-performing, and scalable SAP installations. Plus, SQL Server high-availability features can minimize downtime for any SAP implementation.

The company's flagship applications are the NetWeaver-based SAP ERP/Business Suites and SAP R/3 industry solutions. Since 1993, SAP and Microsoft have been working together to provide a deeply integrated Microsoft platform with SAP solutions. Microsoft is currently

the most selected platform for R/3 and SAP application deployments: more than 56,000 SAP application installations run on Windows, which is more than all other platforms combined. Of these, more than 23,000 SAP application installations worldwide are running with SQL Server as the RDBMS. In fact, this \$11.5 billion company uses its own software for its internal ERP purposes completely deployed on the Microsoft SQL Server platform.

As you can see in Figure 3.1, SAP's ERP footprint is a three-tier architecture consisting of a variety of client types, a horizontally scalable application server tier, and a highly available, high-performance database tier.

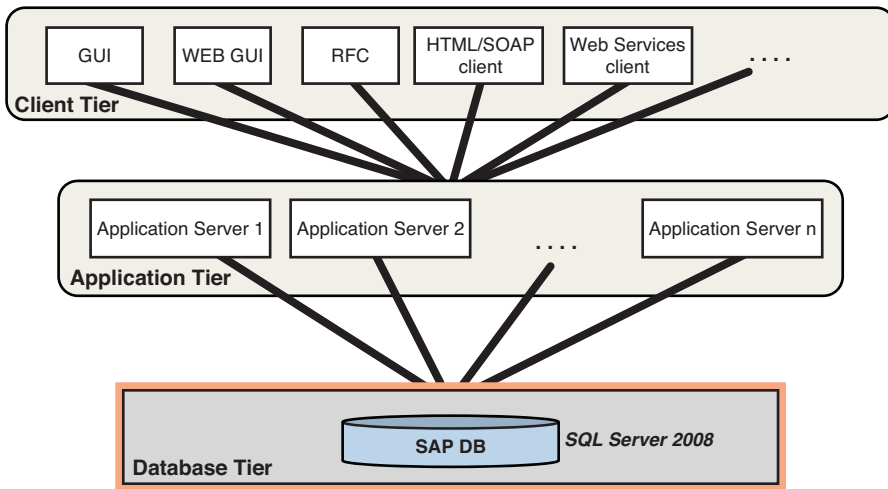

FIGURE 3.1 SAP multitier architecture with SQL Server as the database layer.

The SAP multitiered client/server architecture is composed of three levels:

- ▶ **Client/Presentation Tier**—This tier supports SAP graphic user interfaces (GUIs) such as SAP GUI, SAP WebGUI, and other products that connect to the SAP NetWeaver Application Server using one of the supported interfaces. The client tier also includes applications to access SAP using Web Services. For example, applications including smart clients and Microsoft Office applications can integrate SAP data, such as when the Microsoft Excel spreadsheet software is used with Web Services. Applications that use the SAP RFC interface are also part of the presentation tier. Especially in the Microsoft world, connecting to the application tier via RFC became common with the SAP .NET connector, which offers a bandwidth of .NET classes and methods that are mapped to SAP Business Application Programming Interfaces (BAPIs) that are accessible via RFC.

- ▶ **Application Tier**—This tier can contain multiple SAP NetWeaver Application Server instances. However, it needs to contain at least one application instance. If multiple instances are used in one system, each application instance is typically run on separate server hardware or virtual machines. The application tier and database tier can run on the same server hardware on small-scale systems and in some very large hardware configurations. The complete processing of the business transactions and workflow is handled on the application side. No business logic is pushed down for execution into the database layer. The database tier is used for data storage only. Technically, an SAP application instance is a collection of processes called *work processes* in SAP terminology. Based on a configuration profile for each individual instance, these work processes fulfill different tasks and requests. To share user contexts and user data, the work processes of one instance share larger areas of memory. The business logic itself was originally programmed in a 4GL language called ABAP; it has now been supplemented by the possibility to code business logic in Java as well.
- ▶ **Database Tier**—This tier supports the SAP database, including the SAP Business Suite or R/3 and other SAP applications hosted on SQL Server. The database tier typically runs one database schema for each SAP product using separate server hardware. The database servers can be connected to a storage area network (SAN), Network Attached Storage (NAS), or locally attached storage.

Each SAP application process establishes two connections to SQL Server (as shown in Figure 3.2). There is no sharing of connections between the different SAP processes of an instance. SAP does not use connection pooling. Every one of the processes establishes

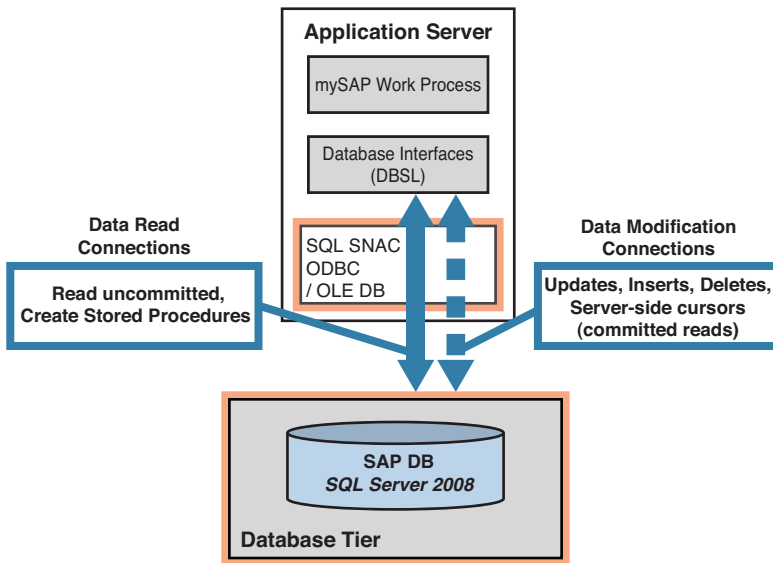

FIGURE 3.2 SAP multiple connections to SQL Server.

connections at startup and keeps them until the process is shut down or restarted. SAP uses Multiple Active Result Sets (MARS) and multiple open client-side cursors that can use the same connection. Each connection is used for different purposes. One performs uncommitted reads of the data or creates stored procedures as needed. The other connection is for data modifications such as updates, inserts, deletes, and server-side cursors. The application tier has been optimized around using these connections.

We featured this ERP application because SAP has proven to the world how rock solid SQL Server is and that the smallest company to companies as large as SAP itself can safely and confidently deploy on SQL Server without hesitation.

OLTP Shopping Cart Example

This shopping cart example features an Internet-based e-commerce implementation for a leading health and vitamin retailer. At the center of this high-availability application is the shopping cart and a global ordering and fulfillment capability. Approximately 5,000 to 10,000 users are online concurrently at any one time, and this application supports up to 50 million hits per day. A key to this application is that it is “stateless,” and all database calls are extremely simple and shallow. This web-facing application is built on JRUN but features SQL Server at the database layer, as shown in Figure 3.3.

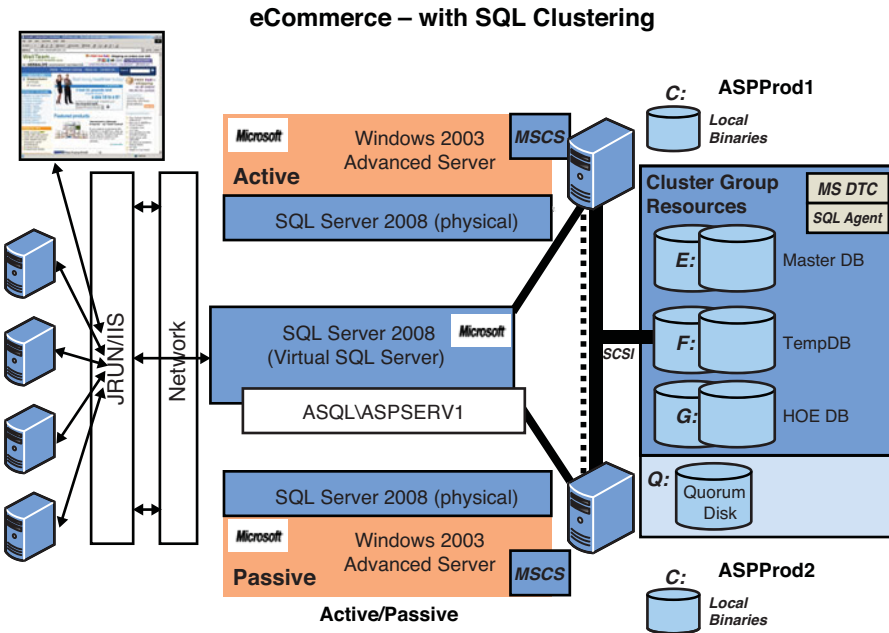

FIGURE 3.3 An e-commerce Internet application with a SQL Server database tier.

This e-commerce application is just a part of a much larger Application Service Provider (ASP) platform. This ASP company houses hundreds of other companies' applications in multiple data centers around the globe. To ensure high availability, this ecommerce application was built on a two-node Active/Passive SQL Clustering configuration. In the four years that this application has been running, the database tier has achieved a 99.99% uptime with rolling updates at both the operating system and SQL Server levels. The OLTP database on SQL Server is approximately 10TB and utilizes log shipping to create a reasonably current disaster recovery (DR) copy (that has never been utilized!). Ninety percent of the reporting is done off the DR copy (approximately one-hour old data on average). This is fully within the service-level requirements needed by the health and vitamin company.

It's important to note here is that if availability falls below 99.99 (four 9s), the ASP company must pay fairly large financial penalties as a part of its agreement with its customers. Each physical server in the cluster is a Dell 8 CPU server with 256GB RAM on SQL Server 2008 Enterprise editions on Windows 2003 Advanced Servers. This has been a rock-solid implementation from the very start.

DSS Application Examples

The DSS/BI examples start with a traditional star schema data warehouse deployment for a Silicon Valley high-tech company. The same data has also been deployed as an OLAP cube created by Analysis Services.

The last example, describes a hybrid distributed reporting system that, uses multiple SQL Server technologies such as data replication, database mirroring, and database snapshots to get the most out of a complex healthcare industry application environment.

DSS Example One

A Silicon Valley computer company implemented a traditional data warehouse using a star schema approach. A star schema provides multiple paths (dimensions) to the central data facts. As you can see in Figure 3.4, a decision support user can get to the Sales Units, Sales Price, and Sales Returns through Geographic, Time, and Product dimensions. This allows the user to ask questions such as "What were net sales for North America for a particular month for a specific computer product?" SQL Server Integration Services (SSIS) packages populate this data warehouse and conformed dimensions on a daily basis with deltas (new data changes only). The data warehouse is unavailable for about one hour each night as daily updates are rolled into this deployment.

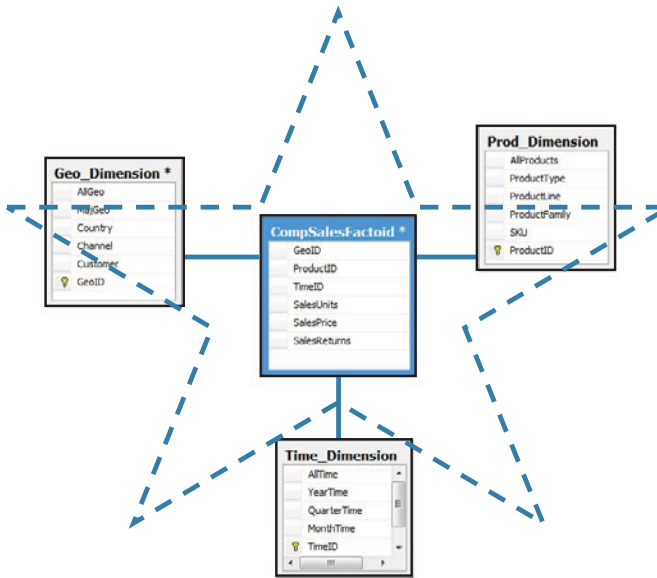

FIGURE 3.4 Star schema data warehouse for global computer sales.

This SQL Server instance is isolated from the OLTP application where the data is sourced. There are about 500–600 data warehouse users of this data globally. This data warehouse is approaching 5TB in size.

DSS Example Two

The same Silicon Valley computer company also implemented some of the same data in a more complex Analysis Services OLAP cube for data mining purposes. The company had many things it did not know about its sales data and wanted to do complex trending and forecasting to better understand the demand for products worldwide. Figure 3.5 shows the OLAP cube built in Analysis Services for this complex business intelligence purpose. Several demand forecasting and product sales trending models were developed to allow this company to predict sales by each of its products for each geographic region.

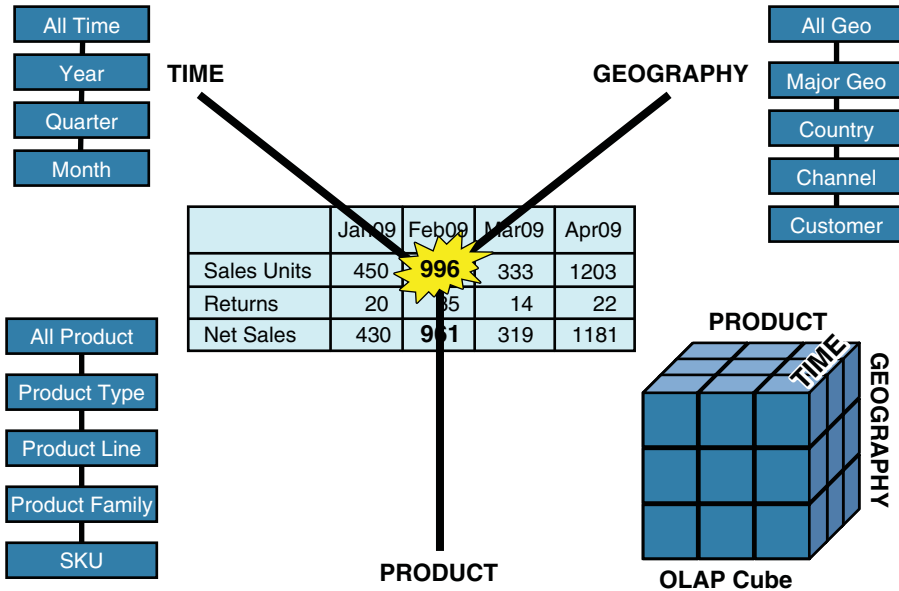

FIGURE 3.5 Multidimensional OLAP cube in Analysis Services.

DSS Example Three

This last example features a multitechnology hybrid data reporting solution that provides real-time reporting along with point-in-time reporting for a major healthcare organization in the Pacific Northwest. This solution starts with real-time data replication from its online transactional systems where all hospital transactions are taking place. This includes patient events, medications administered, surgeries done, hospital charges, and so on. By distributing this data to a highly available two-node SQL Cluster, the hospital is able to realize all its real-time reporting requirements that center around providing all known information for a particular patient in the hospital at any time. Figure 3.6 shows this OLTP-to-SQL cluster real-time, continuous data replication and the real-time reporting enabled by this data distribution.

Database Mirroring Topology with Snapshots

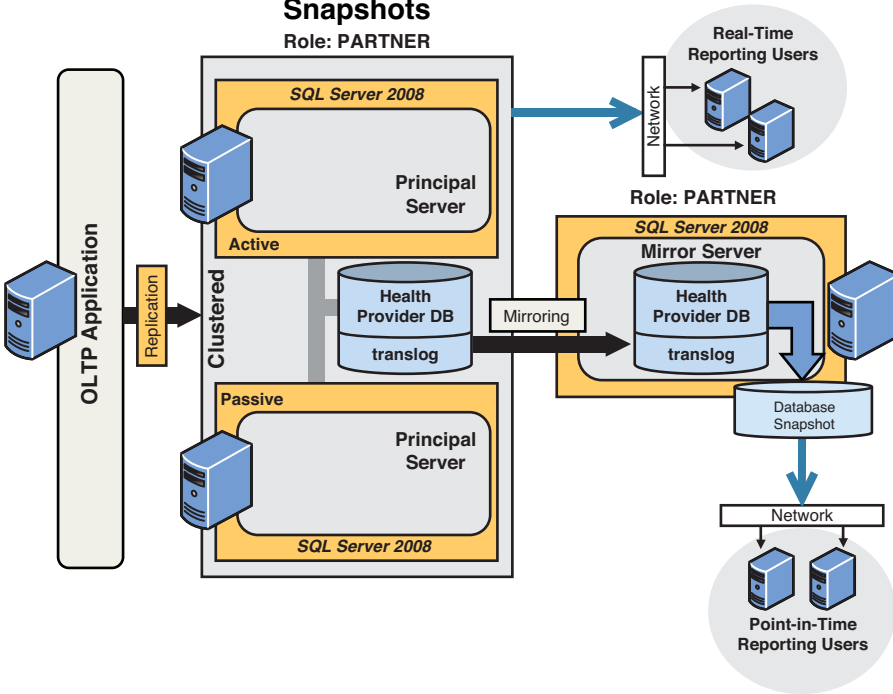

FIGURE 3.6 Hybrid SQL Server reporting configuration.

Another major reporting requirement for this health organization is not a real-time requirement, but rather a leisurely hourly snapshot, point-in-time reporting requirement. A much larger group of users must be served by this noncritical reporting need and cannot impact the real-time reporting environment in any way. To satisfy this point-in-time, noncritical reporting need, the health organization leveraged SQL Server database mirroring from the replicated SQL Server Health Provider DB. From the mirror, hourly database snapshots are created to satisfy all the point-in-time reporting needs of the organization. This configuration has been extremely stable since the SQL Server 2005 deployment.

Summary

This chapter described some truly interesting SQL Server–based implementations. These examples reflect how major software vendors such as SAP have utilized SQL Server as the core of their ERP data tier, how Internet-based companies rely on SQL Server to host their e-commerce applications, and how SQL Server can be used to fulfill various decision support and business intelligence needs of major corporations. We selected these examples because they are rock solid and reflect potentially similar scenarios that you may be faced with. It is this flexibility and reliability that will allow you to be successful as well.

The next chapter delves into the functionality of the SQL Server Management Studio environment.

This page intentionally left blank

CHAPTER 4

SQL Server Management Studio

SQL Server Management Studio (SSMS) is an integrated application that provides access to most of the graphical tools you can use to perform administrative and development tasks on SQL Server 2008. SSMS was introduced with SQL Server 2005 and replaced the Enterprise Manager, Query Analyzer, and Analysis Manager that were available in SQL Server 2000. Microsoft consolidated all those tools into one, with a focus on providing a tool that suits the needs of both developers and database administrators (DBAs).

SSMS is a complicated tool that provides an entry point to almost all of SQL Server's functionality. The functionality that is accessible from SSMS is entirely too much to cover in one chapter. The aim of this chapter is to give a basic overview of SSMS while touching on the features that are new to SQL Server 2008. Other chapters in this book discuss the components of SSMS and provide more detailed coverage.

What's New in SSMS

SSMS is loaded with new features in SQL Server 2008. This tool was introduced in SQL Server 2005, and it brought quite a bit of change with it. There is also quite a bit of change with SQL Server 2008, but the basic look-and-feel of the application remains much the same as it was in SQL Server 2005.

The standout features in the SQL Server 2008 SSMS include four new features geared toward the administrator and

IN THIS CHAPTER

- ▶ What's New in SSMS
- ▶ The Integrated Environment
- ▶ Administration Tools
- ▶ Development Tools

three new features geared toward the developer. Of course, all these features could be used by both administrators and developers.

The new administrator features in SSMS include a beefed-up Activity Monitor, a new Object Search option, a customizable Object Explorer Details window, and a new management tool named SQL Server Utility that was added with SQL Server 2008 R2. The Activity Monitor now contains four separate graphs that look like graphs displayed in Task Manager, and they pull information similar to what you might see in System Monitor. The Object Search option allows you to search for database objects by name while changes to the Object Explorer Details window significantly expand the amount of available information and allow the user to change the information that is displayed. Finally, the new SQL Server Utility allows for the capture of resource information across multiple servers and provides one unified view for the display of this information.

Enhancements that are focused on the developer include IntelliSense in the Query Editor, an integrated Transact-SQL (T-SQL) Debugger, and a Multiserver Query execution option. IntelliSense helps with the completion of T-SQL code as you write it. This feature was much anticipated for SQL Server 2005, but it never made it to the released code. That anticipation continued with SQL Server 2008, and fortunately, Microsoft has delivered. This feature should not disappoint, and it will ultimately improve your productivity.

A debugging tool that is integrated into SSMS is another great new feature. Those who have developed stored procedures with thousands of lines of code will particularly appreciate this new feature. You can set breakpoints, evaluate variables, and step through the code line by line. This debugging capability applies to all T-SQL in the query editor window.

Multiserver queries is the last standout feature offered with SQL Server 2008. This feature allows you to run a single query against more than one server. The results returned from each server are displayed in a single result window. If you're managing many servers, this feature can be a real timesaver.

This chapter further explores the new features in SSMS. It first examines the features at the environmental level, focusing on how SSMS behaves and how to best utilize the environment. Next, it looks at the administrative tools and what changes have been made to help you better manage your SQL Server environment. Finally, this chapter looks at the development tools available with SSMS and changes made to improve your SQL Server development experience.

The Integrated Environment

If you have been working with SQL Server for a long time, you may remember the SQL Enterprise Manager that came with SQL Server 6.5. In some respects, with SSMS, Microsoft has moved back to the paradigm that existed then. Like the SQL Server 6.5 Enterprise Manager, SSMS provides an integrated environment where developers and DBAs alike can perform the database tasks they need. Say goodbye to Query Analyzer, Analysis Manager, and a number of other disparate tools used in SQL Server 2000 and say hello to SSMS, which provides “one-stop shopping” for most of your database needs.

Window Management

Figure 4.1 shows a sample configuration for the SSMS main display. The environment and windows displayed are completely customizable, with the exception of the document window area. Figure 4.1 shows the document window area displaying the Object Explorer Details page. The Object Explorer Details page is the default, but other pages, such as a query editor window, can take the focus in this tab-oriented section of the SSMS display.

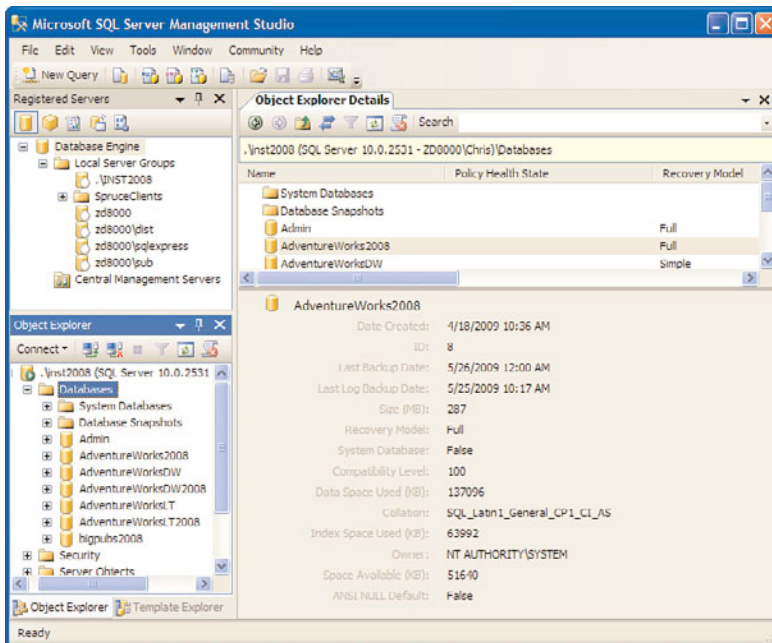

FIGURE 4.1 The SSMS main display.

The dialogs that form the rest of the SSMS display are referred to as *components* and include the Registered Servers and Object Explorer windows shown in Figure 4.1, as well as a number of other components that can be displayed via the View menu found at the top of the SSMS display. You can configure each of the component windows in a number of ways; for example, you can have them float, or you can hide, dock, autohide, or display them as tabbed documents in the document window area.

The configuration that you choose for your SSMS display depends on the type of work you do with SQL Server as well as the type of person you are. The Auto Hide feature causes the component window to shrink to a tab along the left or right side of the display. When you mouse over the tab, the window automatically expands and stays expanded as long as the mouse cursor remains in the component window area. Auto Hide helps maximize the working real estate available in the document window for query development and the

like. Docking many windows can clutter the screen, but this feature allows you to view many different types of information all at once. This is a matter of personal preference, and SSMS has made it very easy to change.

TIP

You can reposition the component windows by dragging and dropping them to the desired locations. When you are in the middle of a drag and drop, rectangular icons with arrows are displayed at different locations on the SSMS window surface. If you mouse over one of these arrowed icons to select the window location, you see the window destination highlighted. If you release your mouse button while the destination is highlighted, the window docks in that position.

Some users at first ignore the arrow icons and keep hovering the window over the location where they want the window to go. Hovering the window over the desired location does not allow you to effectively dock it. You should save yourself some time and aggravation and use the arrow icons for drag-and-drop positioning.

The SSMS window environment include nonmodal windows that are sizable. The nonmodal windows allows you to perform multiple tasks at one time without needing to open another instance of the SSMS application. In SQL Server 2000, the Enterprise Manager users were forced to open another instance of the application during many administrative tasks to be able to continue with other work. With SSMS, you can launch a backup with the Back Up Database dialog and then continue working with the Object Explorer or other components in SSMS while the backup is running. This capability is a great timesaver and helps improve overall productivity.

Your ability to size the dialog boxes is another user-friendly feature that may seem minor but is quite handy on certain windows. For example, the SQL Server 2000 Enterprise Manager Restore dialog had a fixed size. Viewing the backup set information in this relatively small (nonsizable) dialog box was a challenge. The Restore dialog in SQL Server 2008's SSMS can contain a slew of information related to the backup sets available for restore. The capability to size the windows allows for much more information to be displayed.

The tabbed document window area provides some usability improvements as well. This area, as described earlier, is fixed and is always displayed in SSMS. Component windows can be displayed in this area, along with windows for the Query Editor, diagrams, and other design windows. If desired, you can change the environment from a tabbed display to multiple-document interface (MDI) mode. In this mode, each document is opened in its own window within the document window. The MDI mode manages windows like the SQL Server 2000 Query Analyzer and may be more user-friendly for some people. You can

change to MDI mode by selecting Tools, Options and then selecting MDI Environment from the General page.

One particularly useful window that can be displayed in the document window is the Object Explorer Details page. This new window displays information relative to the node selected in the Object Explorer and includes options to produce detailed reports and graphs. The Object Explorer Details page is displayed in the document window by default when SSMS is launched, but you can also display it by pressing F7 or choosing Object Explorer Details from the View menu.

The Object Explorer Details page has been vastly improved in SQL Server 2008. If you're familiar with the previous version, you can see in Figure 4.1 that there is much more information displayed in SQL Server 2008 than there was in 2005. The nice part is that you can customize the information that is displayed and save those changes so that they are used the next time you open SSMS. For example, when you right-click on a column heading (such as Name), you see all the columns available for display. Only a handful are displayed by default, but more than 30 available columns relate to databases. The columns that are available depend on the type of object selected in the Object Explorer window.

TIP

You can copy some or all of the information shown in the Object Explorer Details window and paste it into another application such as Excel for a quick and easy report. For example, you can select the Databases node in Object Explorer, highlight the data shown in the Object Explorer Details page, press Ctrl+C to copy the data, and then paste it into Excel. All the columns related to database (including Headings) are captured and give you an easy way to review information about all your databases.

Another significant change in the Object Explorer Details page is the Object Search box. The Object Search box, located at the top of the Object Explorer Details page (next to the Search label), allows you to search for objects by name. You can use wildcards (for example, Product%), or you can type a specific name you are looking for. The results are displayed in the Object Explorer Details page. Keep in mind that the objects that are searched depend on what is selected in the Object Explorer window. For example, if you highlight the Databases node, you search all the databases on your SQL Server instance. If you select a specific database, only that database is searched.

TIP

In SQL Server 2000, you could select multiple objects for scripting by selecting the items from the Object Explorer tree in Enterprise Manager. You cannot use the Object Explorer tree to perform this operation with SQL Server 2008, and this has generated some confusion. The solution is the Object Explorer Details page, which provides a means for performing multiple selections of the objects it displays. You can hold down the Ctrl key and click only those items you want to script. After you select the items you want, you simply right-click one of the selected items and choose the preferred scripting method. This method also works with scheduled jobs displayed in the Object Explorer Details page. SQL Server 2000 did not offer this capability.

Integrated Help

SSMS offers an expanded set of help facilities as well as improved integration into the application environment. The Help sources have been expanded to include both local and online resources. Local help is similar to the Help resources available in past versions and references files installed on your machine during the installation process. Local help includes the local SQL Server Books Online resources. Local help files are static and are updated only if another documentation installation is run on the local machine.

Online help provides access to content that is not static and can be updated with the latest changes. Three default online resources are provided by default:

- ▶ **MSDN Online**—MSDN Online contains the latest version of the MSDN documentation, including the latest quarterly releases.
- ▶ **Codezone Community**—Codezone Community includes a set of third-party websites that have partnered with Microsoft and provide a wealth of information from sources outside Microsoft.
- ▶ **Questions**—The Questions option allows you to search the forum archives for answers to questions that others have already asked. It also allows you to post your own questions.

The help resources you use on your machine are configurable. You can choose to search online resources first, followed by local help, or you can choose an option that searches local help resources first, followed by online resources. You can also choose specific Codezone online resources to search, or you can eliminate the search of all online resources. Figure 4.2 shows the online help Options window, which allows you to configure your Help options. You access this dialog by selecting Tools, Options.

The Help resources you select are used when you search for content within the Help facility. When you use both local and online resources options, you see results from multiple locations in your search results. Figure 4.3 shows a sample Books Online Document Explorer window with results from a search on “Management Studio.” Notice that the panel on the right side of the window lists entries under Local Help, MSDN Online, Codezone Community, and Questions. Each of these sections contains search results that

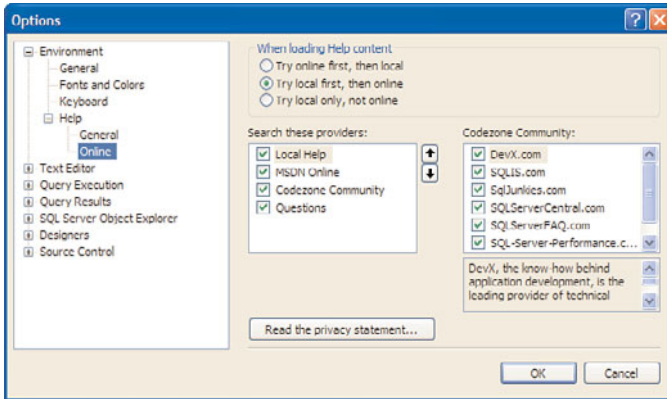

FIGURE 4.2 Setting Help options.

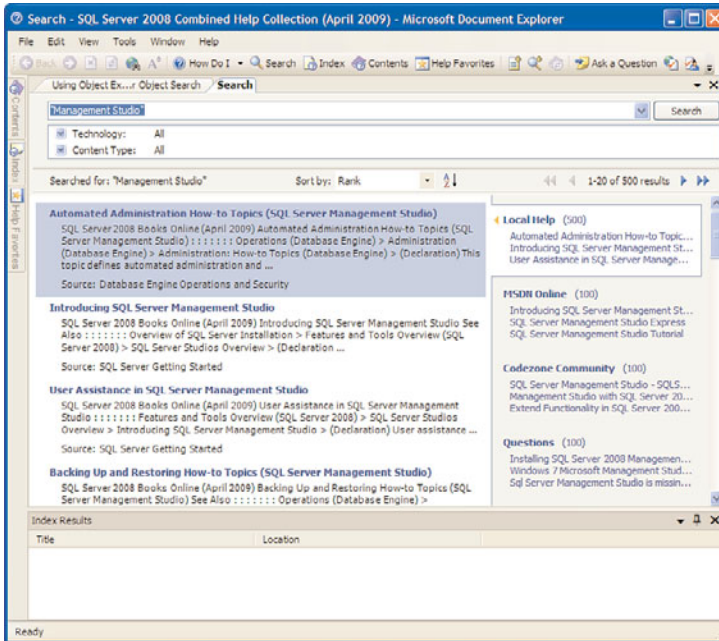

FIGURE 4.3 A Books Online search.

you can access by simply clicking on that area. The number of search results for each section is displayed in parentheses after the section name.

One other significant change to the help facilities in SSMS is the addition of Dynamic Help. Dynamic Help is a carryover from the Visual Studio environment. It is a help facility

that automatically displays topics in a Help window that are related to what you are doing in SSMS. For example, if you are working in a query window and type the word `SELECT` to start your query, the Dynamic Help window displays several topics related to the `SELECT` statement. If you are working in the Object Explorer, it displays Help topics related to the Object Explorer.

NOTE

There is some processing overhead associated with Dynamic Help. You may find that your SSMS environment runs a bit slower when you use this feature.

Dynamic Help is one of the component windows that you can dock or position on the SSMS surface. To use Dynamic Help, you select `Help, Dynamic Help`. Figure 4.4 shows an example of the SSMS environment with the Dynamic Help window docked on the right side of the window. The Dynamic Help topics in this example are relative to the `SELECT` keyword that is typed in the query editor window in the middle of the screen.

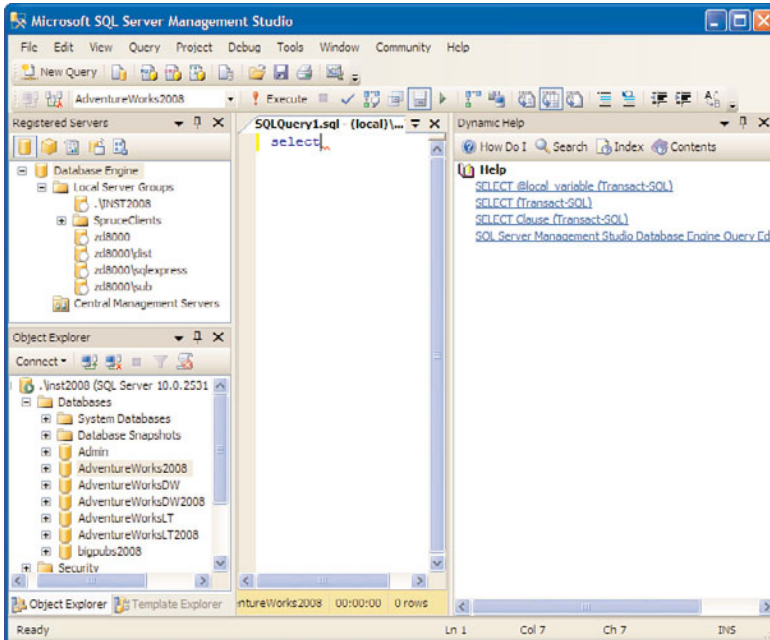

FIGURE 4.4 Dynamic Help.

Administration Tools

The tools available with SSMS can be broadly categorized into tools that are used for administering SQL Server and tools that are used for developing or authoring new SQL Server objects. As a matter of practice, developers use some of the administrative tools, and administrators use some of the development tools.

SSMS comes with an expanded set of tools to help with SQL Server administrative tasks. It builds on the functionality that was available in SQL Server 2005 and adds some new tools and functionality to help ease the administrative burden.

Registered Servers

Registered servers is a concept in SQL Server 2008 that represents a division between managing servers and registering servers. With the SQL Server 2000 Enterprise Manager, the Microsoft Management Console (MMC) tree was displayed on the left side of the Enterprise Manager screen, and it contained servers that had been registered via that tree. Any registered servers or groups were listed in the tree, along with any of the associated objects.

Registered servers are managed and displayed in the Registered Servers component window. Figure 4.5 shows an example of the Registered Servers window, with several server groups and their associated registered servers. You can add new groups or servers any time so that you have a handy way of organizing the servers you work with.

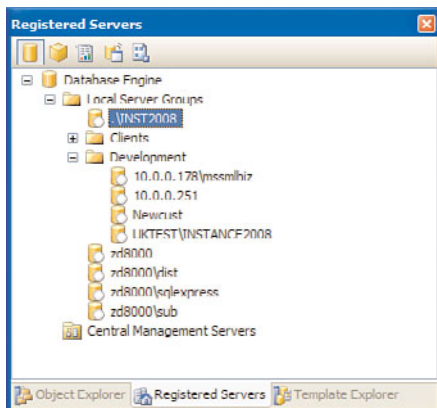

FIGURE 4.5 The Registered Servers window.

The servers listed in Figure 4.5 are all Database Engine servers. These server types are the conventional SQL Server instances, like those you could register in the SQL Server 2000 Enterprise Manager. You can also register several other types of servers. The icons across the top of the Registered Servers window indicate the types of servers that can be registered. In addition to Database Engine servers, you can also register servers for Analysis Services, Reporting Services, SQL Server Mobile, and Integration Services. The Registered Servers window gives you one consolidated location to register all the different types of servers available in SQL Server 2008. You simply click the icon associated with the appropriate server type, and the registered servers of that type are displayed in the Registered Servers tree.

NOTE

The SQL Server 2008 Registered Servers window enables you to register servers that are running SQL Server 2005, SQL Server 2000, and SQL Server 7.0. You can manage all the features of SQL Server 2005 and SQL Server 2000 with SQL Server 2008 tools. You can also have both sets of tools on one machine. The SQL Server 2000, SQL Server 2005, and SQL Server 2008 tools are compatible and function normally together.

Management tools from prior SQL Server versions cannot be used to manage SQL Server 2008 instances. For example, the SQL Server 2000 Enterprise Manager cannot be used to manage SQL Server 2008. You can connect the Query Analyzer to a SQL Server 2008 instance and run queries, but the Object Explorer and other tools are not compatible with SQL Server 2008.

When a server is registered, you have several options available for managing the server. You can right-click the server in the Registered Servers window to start or stop the related server, open a new Object Explorer window for the server, connect to a new query window, or export the registered servers to an XML file so that they can be imported on another machine.

TIP

The import/export feature can be a real timesaver, especially in environments where many SQL servers are managed. You can export all the servers and groups registered on one machine and save the time of registering them all on another machine. For example, you can right-click the Database Engine node, select Export, and then choose a location to store the XML output file. Then all you need to do to register all the servers and groups on another machine is move the file to that machine and import the file.

Object Explorer

The Object Explorer window that existed in the SQL Server 2000 Query Analyzer was integrated into SSMS in SQL Server 2005. SQL Server 2008 continues to use an integrated Object Explorer that behaves like SQL Server 2005.. The most significant feature for those folks managing a large number of database objects is the capability to populate the Object Explorer tree asynchronously. This may not hit home for folks who deal with smaller databases, but it can be a real time saver for those that are dealing with many databases on a single SQL Server instance or for those that work with databases that have a significant number of database objects. The Object Explorer tree in SSMS displays immediately and allows navigation in the tree and elsewhere in SSMS while the population of the tree is taking place.

The Object Explorer is adaptive to the type of server it is connected to. For a Database Engine server, the databases and objects such as tables, stored procedures, and so on are displayed in the tree. If you connect to an Integration Services server, the tree displays information about the packages defined on that type of server. Figure 4.6 shows an example of the Object Explorer with several different types of SQL Server servers displayed in the tree. Each server node has a unique icon that precedes the server name, and the type of server is also displayed in parentheses following the server name.

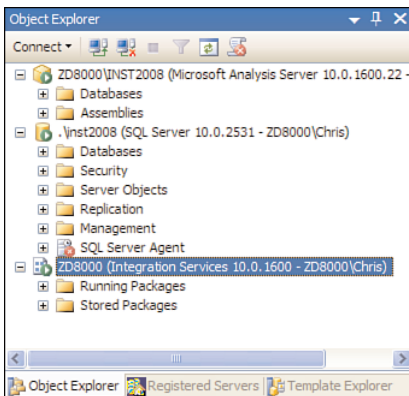

FIGURE 4.6 Multiple server types in Object Explorer.

The objects displayed in the Object Explorer tree can be filtered in SQL Server 2008. The number of filters is limited, but those that are available can be helpful. For example, you can filter the tables displayed in Object Explorer based on the name of the table, the

schema that it belongs to, or the date on which it was created. Again, for those who deal with large databases and thousands of database objects, this feature is very helpful.

Administrators also find the enhanced scripting capabilities in the Object Explorer very useful. The scripting enhancements are centered mostly on the administrative dialog boxes. These dialogs now include a script button that allows you to see what SSMS is doing behind the scenes to effect your changes. In the past, the Profiler could be used to gather this information, but it was more time-consuming and less integrated than what is available now.

Figure 4.7 shows an example of an administrative dialog, with the scripting options selected at the top. You can script the commands to a new query window, a file, the Windows Clipboard, or a job that can be scheduled to run at a later time.

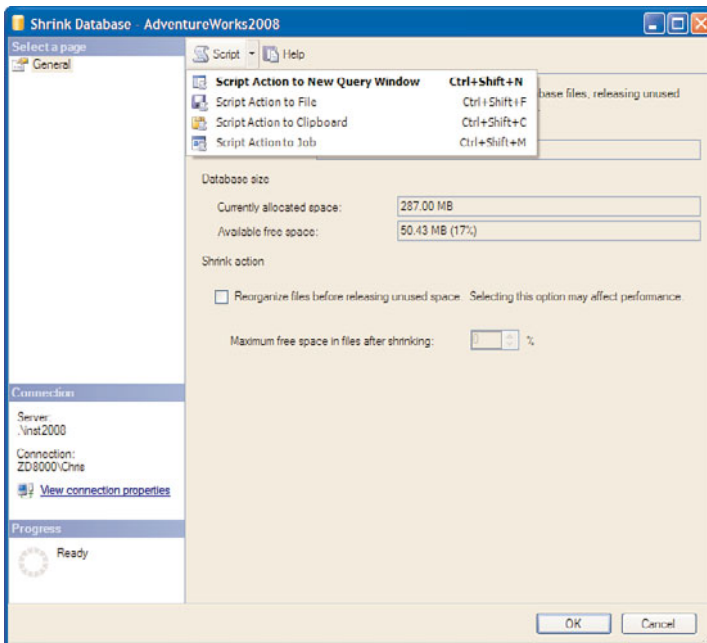

FIGURE 4.7 Scripting from administrative dialogs.

Aside from these features, many of the features and much of the functionality associated with the Object Explorer is similar to what was found in SQL Server 2000 and is almost identical to what was found in SQL Server 2005. Keep in mind that there are some additional nodes in the Object Explorer tree and that some of the objects are located in different places. For example, the Management node now contains nodes for Policy Management, Data Collection, and the Resource Governor, which are all new in SQL Server 2008.

One often-overlooked Object Explorer feature is the reports option that was added in SQL Server 2005 and still exists in SQL Server 2008. This option is available by right-clicking on a node in the Object Explorer. Reports are not available for every node in the Object Explorer tree, but many of them do have this option. Most reports are found in the top-level nodes in the tree. For example, if you right-click on a database in the Object Explorer tree and then select Reports and Standard Reports, you see more than a dozen available reports. These reports include Disk Usage, Backup and Restore Events, Top Transactions by Age, and a host of others. Graphs are included with some reports, and you can export or print all these reports. Figure 4.8 shows an example of the Disk Usage report for the AdventureWorks2008 database.

FIGURE 4.8 A Disk Usage Object Explorer Details report.

The graphs are easy to read, and some sections of the report can be expanded to provide more detail. Bullets at the bottom of a report are nodes that can be expanded. For example, the bullet Disk Space Used by Data Files at the bottom of Figure 4.8 can be expanded to display details about each of the data files.

Activity Monitor

The Activity Monitor has seen some dramatic changes in SQL Server 2008. These changes build on the foundation established in SQL Server 2005 and help provide much more information related to the performance of your SQL Server instance.

Before we get into the details of the Activity Monitor, let's make sure you know where to find it. It is no longer found in the Management node of the Object Explorer. Instead, you right-click on the name of the server instance in the Object Explorer, and you see a selection for Activity Monitor.

When the Activity Monitor launches, you see a new display with four different graphs, as shown in Figure 4.9. The graphs include % Processor Time (from SQL Server), Waiting Tasks, Database I/O and Batch Requests. These graphs give you a quick performance snapshot for your SQL Server in one spot without having to launch System Monitor or some other monitoring tool to view this kind of information.

You also find more detailed performance information below the graphs. This information is grouped into four categories: Processes, Resource Waits, Data File I/O and Recent Expensive Queries. Clicking on the expand button for one of these categories presents the details you are looking for. These details contain drop-down headings that allow you to filter the results and view only the information you need.

FIGURE 4.9 SQL Server 2008 Activity Monitor.

The Processes Details window contains information similar to what was displayed in the SQL Server 2005 Activity Monitor. These details include information similar to what is returned with the `sp_who` system stored procedure. The server process ID (SPID) is listed in a column named Session ID, and the related information for each SPID is displayed in the remaining columns. If you right-click on a particular process, you can see the details of that process. You can then kill that process or launch the SQL Server Profiler to trace the activity for the process. Figure 4.10 shows an example of the expanded Processes details window.

The Resource Waits window (that is displayed below the Process window) can help you identify bottlenecks on your server. It details the processes waiting for other resources on the server. The amount of time a process is waiting and the wait category (what the process is waiting for) are found in this display. If you click on the Cumulative Wait Time column, the rows are sorted by this column and you can find the wait category that has been waiting the longest. This sorting capability applies to all the columns in the display.

Spid	User	Login	Database	Task State	Comm.	Applic.	Wait Time (ms)	Wait Type	Wait Resou	Dis By	I/O Bl	Memory Use (KB)

FIGURE 4.10 Processes Details window in the Activity Monitor.

The Data File I/O window lists each database and its related database files. The amount of disk I/O experienced by each of the files is detailed in the columns of this display. You can isolate the database and files that are most heavily hit with read or write activity as well as the databases that may be suffering from poor I/O response with this screen.

Finally, the Recent Expensive Queries window displays information similar to what you can obtain using catalog views. It provides statistics for all the databases on the instance and is a quick and easy way to find and tune expensive SQL statements. If you right-click on a row in the display and click Edit Query Text, you can see the entire SQL text associated with the query. You are able to click on one of the column headings such as CPU to sort the display according to the metric you feel defines cost. Best of all, you can right-click on a row and choose Show Execution Plan, and you have the Query Plan ready for analysis.

NOTE

When you mouse over the column headers in the detailed windows, ToolTips give you more information about the columns. This information includes the system view that the information is gathered from and where you can look in Books Online to obtain further information.

Log File Viewer

The Log File Viewer is another nonmodal window that is essential for administering your SQL Server. Like the Activity Monitor, it houses information that was previously displayed in the document window in the SQL Server 2000 Enterprise Manager. It can display log files that are generated from several different sources, including Database Mail, SQL Server Agent, SQL Server, and Windows NT.

The Log File Viewer can be launched from the related node in the SSMS Object Explorer. For example, you can select the Management node and expand SQL Server Error Logs. If you double-click one of the error logs listed, a new Log File Viewer window is launched, displaying the SQL Server log file entries for the log type selected (see Figure 4.11).

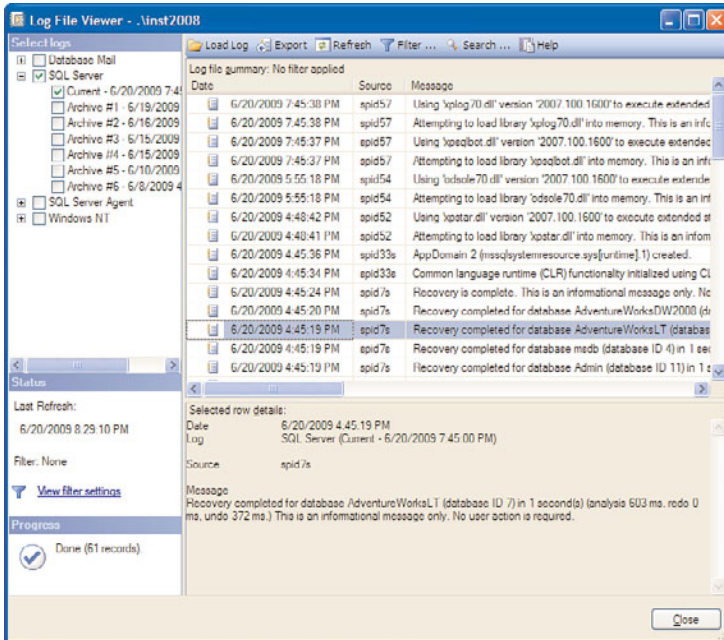

FIGURE 4.11 SQL Server logs displayed in the Log File Viewer.

NOTE

By default, entries are shown in the SQL Server Log File Viewer from newest to oldest. This is different from the default order in the SQL Server 2000 Enterprise Manager, which displayed the log file entries from oldest to newest.

One of the first things you notice when you launch the Log File Viewer is that a tree structure at the top-left corner of the screen shows the log files you are viewing. You can see that there are four different log types available: Database Mail, SQL Agent, SQL Server, and Windows NT. You can choose to display multiple log files within a given log type (for example, the current SQL Server log and Archive #1), or you can select logs from different sources. For example, you can display all the current log entries for SQL Server and the current log entry for the SQL Server Agent.

When multiple logs are selected, you can differentiate between the rows shown on the right side of the Log File Viewer by looking at the Log Source column and the Log Type column. The Log Source values match up with the names shown in the tree structure where the log was selected. The Log Type column shows the type of log, such as SQL Agent or SQL Server. Rows from the different log types are displayed together and sorted according to the date on which the row was created. The sort order cannot be changed.

TIP

You can rearrange the order of the columns shown in the Log File Viewer. You simply click the column header and drag the column to the desired location. When you are viewing rows for more than one log type or multiple logs, it is best to drag the Log Type and Log Source columns to a location that is easily viewed so that you can distinguish between the entries.

Other noteworthy features in the Log File Viewer include the capability to filter and load a log from an external source. You can filter on dates, users, computers, the message text, and the source of the message. You can import log files from other machines into the view by using the Load Log facility. This facility works hand-in-hand with the Export option, which allows you to export the log to a file. These files can be easily shared so that others can review the files in their own Log File Viewer.

SQL Server Utility

The SQL Server Utility was added in SQL Server 2008 R2 and is geared toward multiserver management. It provides several new hooks in the SSMS environment that improve visibility and control across multiple SQL Server environments. Access to these new hooks is provided through a new Utility Explorer that can be displayed within your SSMS environment. This Utility Explorer has a tree-like structure similar to the Object Explorer, and it provides rich content related to the health and integrity of the SQL Server environments you have selected to manage using the SQL Server Utility. Figure 4.12 shows an example of the type of information the Utility Explorer can display.

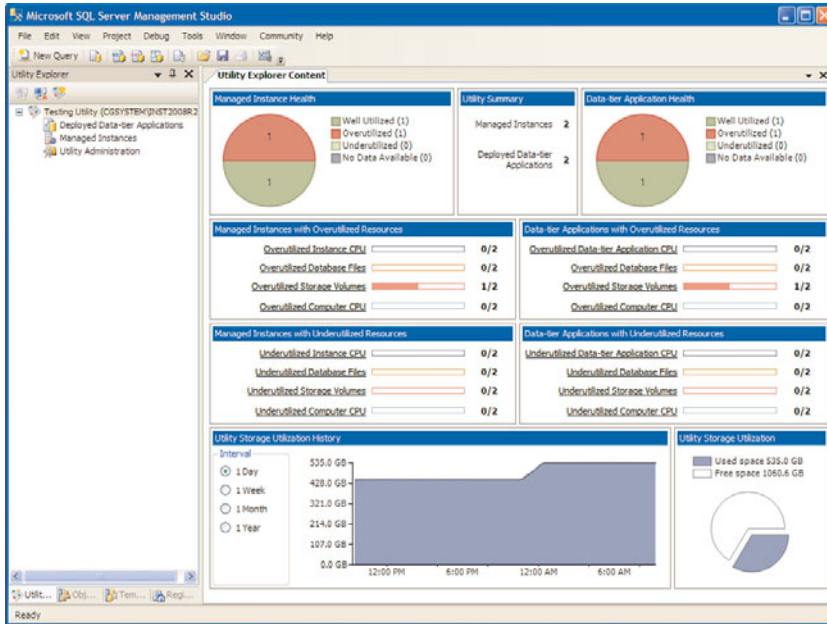

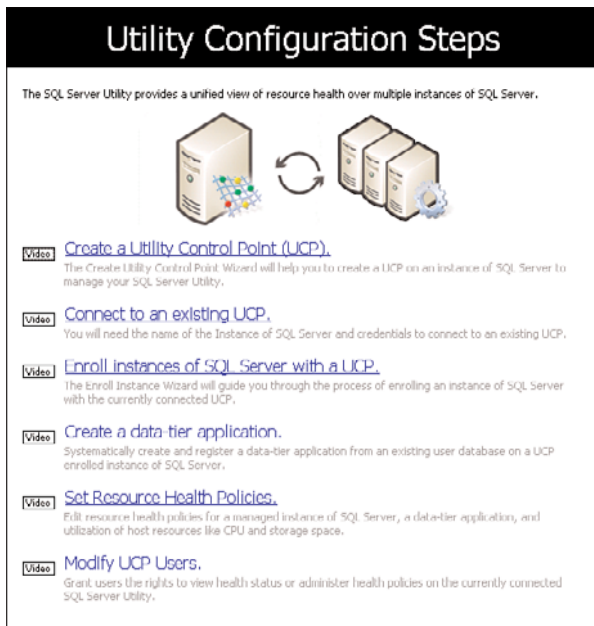

FIGURE 4.12 Utility Explorer content.

The SQL Server Utility must first be configured to facilitate the display of information in the Utility Explorer. The configuration is relatively straightforward, but you must meet several requirements before starting it. The following requirements apply to the utility control point (UCP), which is the SQL Server instance capturing the information and the SQL Server instances being managed by the UCP:

- ▶ SQL Server must be version 10.50 or higher.
- ▶ The SQL Server instance type must be Database Engine.
- ▶ The SQL Server Utility must operate within a single Windows domain or domains with two-way trust relationships.
- ▶ On Windows Server 2003, the SQL Server Agent service account must be a member of Performance Monitor User group.
- ▶ The SQL Server service accounts on the UCP and all managed instances of SQL Server must have read permission to Users in Active Directory.

In addition, the UCP must be running the Data Center, Developer, or Enterprise Edition of SQL Server.

When you have met these requirements, you are ready to start using the SQL Server Utility. The first steps are to establish a UCP and to enroll SQL Server instances for the UCP to manage. This is accomplished by selecting View on the SSMS menu bar and then selecting Utility Explorer. A content pane is displayed in SSMS that contains options for configuring the SQL Server Utility (see Figure 4.13). It also contains links to video that can guide you through each step.

Utility Configuration Steps

The SQL Server Utility provides a unified view of resource health over multiple instances of SQL Server.

- Video** [Create a Utility Control Point \(UCP\).](#)
The Create Utility Control Point Wizard will help you to create a UCP on an instance of SQL Server to manage your SQL Server Utility.
- Video** [Connect to an existing UCP.](#)
You will need the name of the Instance of SQL Server and credentials to connect to an existing UCP.
- Video** [Enroll instances of SQL Server with a UCP.](#)
The Enroll Instance Wizard will guide you through the process of enrolling an instance of SQL Server with the currently connected UCP.
- Video** [Create a data-tier application.](#)
Systematically create and register a data-tier application from an existing user database on a UCP enrolled instance of SQL Server.
- Video** [Set Resource Health Policies.](#)
Fill resource health policies for a managed instance of SQL Server, a data-tier application, and utilization of host resources like CPU and storage space.
- Video** [Modify UCP Users.](#)
Grant users the rights to view health status or administer health policies on the currently connected SQL Server Utility.

FIGURE 4.13 Utility Configuration Steps.

The first thing to do when configuring the SQL Server Utility is to click on the Create a Utility Control Point (UCP) link on the Getting Started tab. This initiates a wizard that will guide you through a five-step process that creates the UCP. The first wizard screen that outlines these steps is shown in Figure 4.14.

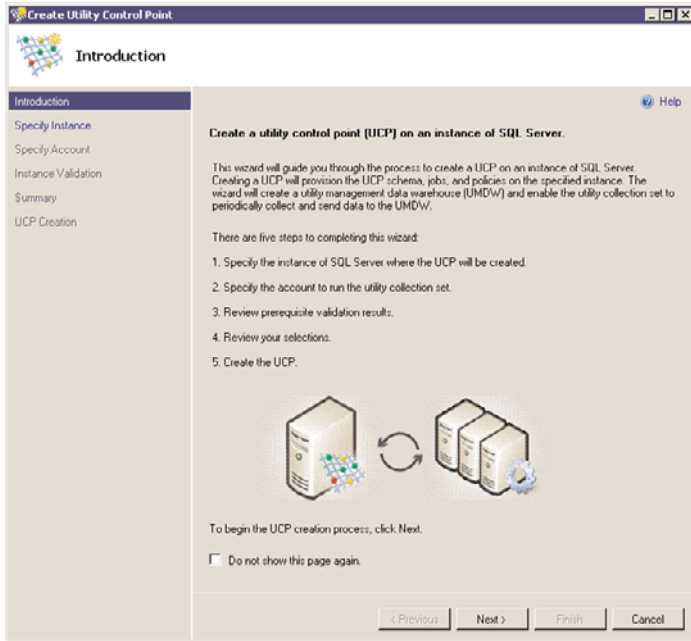

FIGURE 4.14 Create Utility Control Point Wizard screen.

The first step of the wizard is the most critical because you choose the SQL Server Instance that will be the UCP. The SQL Server instance you select in this step will store the information related to the UCP and any other instances enrolled within that UCP. The information collected by the UCP is stored in a database named `sysutility_mdw` created on the UCP instance. This database drives the health and status information displayed in the Utility Explorer.

After you complete the wizard steps to create a UCP, the UCP appears in the Utility Explorer Tree, and summary information about the UCP is displayed in the Utility Explorer Content tab. The UCP is the top-most node in the tree and contains other child nodes that contain the different types of information managed by the UCP. An example of the Utility Explorer tree is shown in Figure 4.15.

The first child node displayed in the Utility Explorer tree is named `Deployed Data-tier Applications`. A data-tier application, or DAC, is a single entity that contains all the database objects and related instance objects used by an application. This includes tables, stored procedures, SQL Server Logins, and so on. DACs can be created from a Visual Studio 2010 data-tier application project or by using the Extract Data-Tier Application Wizard in SSMS. The full scope of DAC capabilities is beyond the scope of this chapter, but it is important to see how they fit into the Utility Explorer Display.

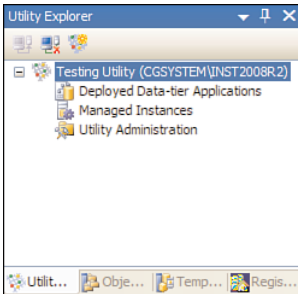

FIGURE 4.15 Utility Explorer tree.

NOTE

Two different SQL Server features use the same *DAC* acronym. The aforementioned *data-tier application* is one of them, but a *dedicated administrator connection* is also referred to as a DAC.

4

After creating a DAC deployment package, you can deploy it to another SQL Server instance. This deployment creates the related database, the database objects along with the related server objects. If the server to which the DAC is deployed is managed by the UCP, you can show the deployed DAC information by clicking on the *Deployed Data-tier Applications* node of the Utility Explorer.

The next node in the Utility Explorer tree, named *Managed Instances*, contains information about SQL Server instances enrolled in the UCP. Enrolling an instance essentially means you want to manage the instance through the UCP and gather information about it. You can easily enroll this instance by right-clicking on the *Managed Instances* node and selecting *Enroll Instance*.

Each instance enrolled in the UCP is listed at the top of the Utility Explorer Content tab. When a managed instance is selected from this list, a set of resource and policy information is made available in the lower half of the window. The available tabs in this window which define the type of information that is captured include *CPU Utilization*, *Storage Utilization*, *Policy Details* and *Property Details*. Figure 4.16 shows two managed instances and the related *CPU Utilization* graphs for the top-most SQL Server instance.

The last node, *Utility Administration*, can be used to manage policy, security, and data warehouse settings for a SQL Server Utility. These settings drive the SQL Server Utility summary screen and set thresholds across the entities defined in the utility. Figure 4.17 shows an example of the *Policy* information that can be managed with *Utility Administration*.

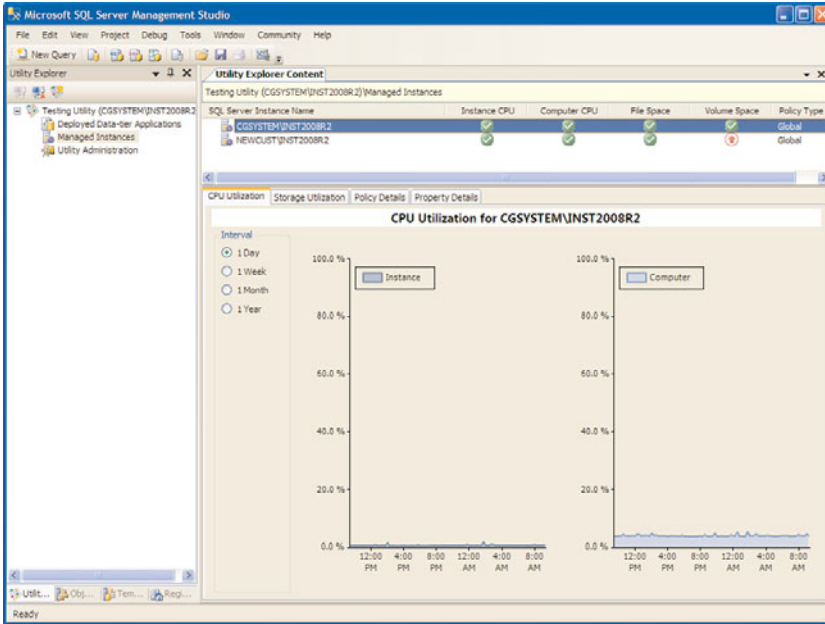

FIGURE 4.16 Managed Instances.

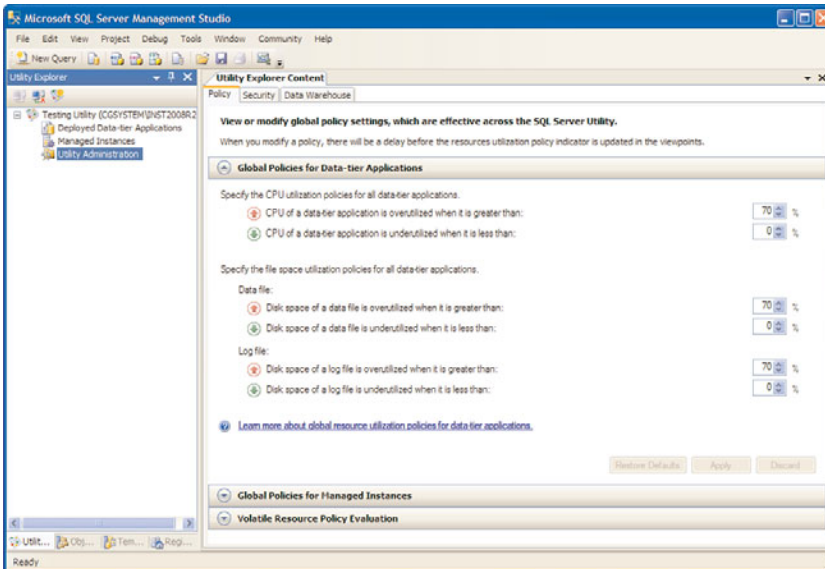

FIGURE 4.17 Utility Administration.

The Policy tab is one of three tabs available on the Utility Administration window. You can see in Figure 4.17 that there are also Security and Data Warehouse tabs. The Security tab allows you to manage permissions for logins that can administer or read from the UCP. Logins can be assigned to the Utility Reader role on this screen, which allows them to connect to the SQL Server Utility and read information from the Utility Explorer in SSMS. The Data Warehouse tab allows you to adjust the amount of time data will be retained in the UCP data warehouse. The default time period is one year.

Over time, the amount of data collected in the UCP data warehouse can be substantial. By default, each managed instance enrolled in the UCP sends configuration and performance data to the UCP every 15 minutes. Consequently, the space used by the utility management data warehouse (UMDW) needs to be monitored. The UMDW database, named `sysutility_mdw`, is listed as a user database in the Object Explorer.

Development Tools

SSMS delivers an equally impressive number of features for database developers. Many of the features were available with SQL Server 2005, but SQL Server 2008 has added some new ones as well. T-SQL Debugging, IntelliSense in the Query Editor, and multiserver queries are a few of those new tools for developers found in SQL Server 2008. These new tools and the other essential developer tools from SSMS are discussed in the following sections.

The Query Editor

The Query Editor sits at the top of the list for development tools in SSMS. The Query Editor, as its name indicates, is the editing tool for writing queries in SSMS. It contains much of the functionality that was contained in SQL Server 2000's Query Analyzer. The capability to write T-SQL queries, execute them, return results, generate execution plans, and use many of the other features you may be familiar with in Query Analyzer are also available with the Query Editor.

One main difference with the Query Editor is that it has been integrated into the SSMS environment. In SQL Server 2000, the Query Analyzer was a separate application with its own independent interface. In SQL Server 2008, SSMS houses the query-editing capabilities along with all the administrative capabilities.

NOTE

The biggest upside to the integration of the query-editing tool into the SSMS environment is that you can find almost anything you need to administer or develop on your SQL Server database in one spot. There is no need to jump back and forth between applications. One possible downside, however, is that SSMS may be much more than some database developers need.

Clicking the New Query button, opening a file, and selecting the Script to File option from a list of database objects in the Object Explorer are just a few of the ways to launch the Query Editor. Figure 4.18 shows the query editor window with a sample SELECT statement from the AdventureWorks2008 database. The query editor window is displayed on the right side of the screen and the Object Explorer on the left side.

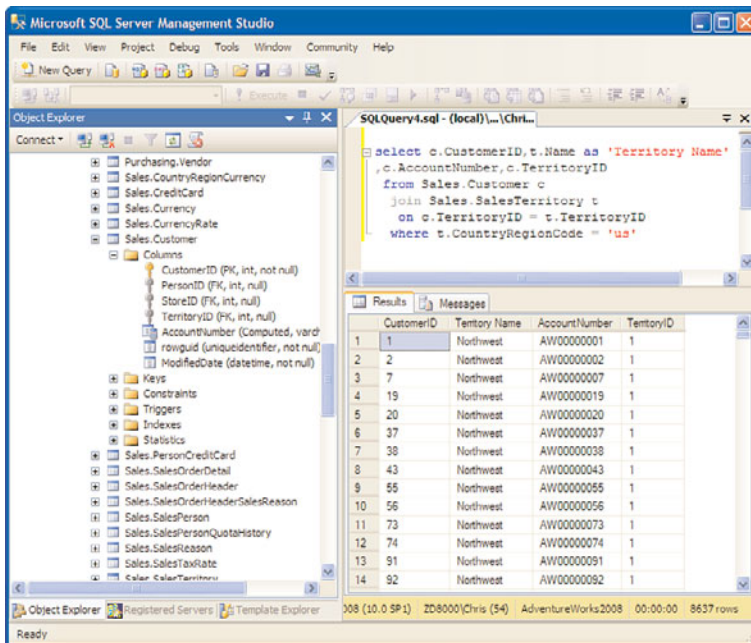

FIGURE 4.18 The query editor window in SSMS.

The basic editing environment within the Query Editor is similar to Query Analyzer. The top portion of the query editor window contains the query. The bottom portion contains the results of an executed query. The results can be displayed as text, displayed in a grid format, or output as XML. However, in the Query Editor, windows are by default managed differently than with Query Analyzer. Multiple query editor windows are displayed in a tabbed format; in comparison, Query Analyzer displayed a separate window for each query.

TIP

The tabbed document display has some advantages, but you can set an option in SSMS that causes the Query Editor to behave much like the Query Analyzer. To do this, you select Tools, Options to launch the Options dialog. The default page has a section named Environmental Layout. If you choose the MDI Environment option, you set SSMS in MDI mode instead of the tabbed layout.

IntelliSense

IntelliSense has finally made it to the SQL Server Query Editor. This much-anticipated tool was slated for SQL Server 2005, but it was pulled before making it to the marketplace. Fortunately, it made it to SQL Server 2008, and it was worth the wait. This is especially true for those developers who have been working with Visual Studio or other Microsoft development tools that have this feature.

IntelliSense is a handy tool that helps you complete queries as you are typing them in the query editor window. Start typing and you will see. For example, type `SELECT * FROM A` in the query editor window, and a drop-down appears in the query editor window after you start typing the first letter after the `FROM` clause. The drop-down, in this case, contains the databases and tables from which you can select data. If you type in a stored procedure name to execute, a drop-down shows you the parameters that the stored procedure accepts. Type `SYS.` in the query editor window, and you see a drop-down of all the objects available in the `SYS` schema. This includes catalog views and the related columns that these views contain. If you type in a query that is incorrect, IntelliSense places a red squiggly line under the part of the query that is syntactically incorrect.

The value of this tool will become more apparent as you use it. It can be confusing at times, but it will ultimately speed up your development time. It can also reduce the number of times you need to go to Books Online or some other help source and will make your development life easier.

NOTE

IntelliSense works only with SQL Server 2008 databases. If you start typing a query against a database from a prior version, the handy IntelliSense drop-downs do not appear.

Query Editor Types

The Query Editor in SQL Server 2008 enables you to develop different types of queries. You are not limited to database queries based on SQL. You can use the Query Editor to develop all types of SQL Server Scripts, including those for SQL Server Analysis Services (SSAS) and SQL Server Mobile Edition. The SSAS queries come in three different flavors: multidimensional expressions (MDX), data mining expressions (DMX), and XML for analysis (XMLA). Only one selection exists for creating SQL Server Mobile Edition scripts.

You see these new query options when you create a new query. When you select New from the SSMS menu, you can choose what type of query to create. You use the Database Engine Query choice to create a T-SQL query against the Database Engine. The other new query options correspond to SSAS and SQL Server Mobile Edition. The SSMS toolbar has icons that correspond to each type of query that can be created.

Each query type has a code pane that works much the same way across all the different types of queries. The code pane, which is the topmost window, color-codes the syntax that is entered, and it has sophisticated search capabilities and other advanced editing features that make it easy to use.

Disconnected Editing

SQL Server 2008 is able to use the code editor without a database connection. When creating a new query, you can choose to connect to a database or select Cancel to leave the code pane disconnected. To connect to the database later, you can right-click in the code pane window and select the Connect option. You can also disconnect the Query Editor at any time or choose the Change Connection option to disconnect and connect to another database all at once.

Along with disconnected editing are some changes to the Windows behavior that are worth noting. The biggest changes relate to the behavior of query windows currently open at the time a file is opened for editing. With SQL Server 2000 Query Analyzer, the currently selected window would be populated with the contents of the file you were opening. Prior to this replacement, a prompt would be displayed asking whether you wanted to save your results. If the query window was empty, the contents would be replaced without the prompt for saving.

With SQL Server 2008, a new query window is opened every time a new file is opened. The new window approach is faster but can lead to many more open windows in the document window. You need to be careful about the number of windows/connections you have open. Also, you need to be aware that the tabbed display shows only a limited number of windows. Additional connections can exist even if their tabs are not in the active portion of the document window.

Editing sqlcmd Scripts in SSMS

sqlcmd is a command-line utility introduced in SQL Server 2008. You can use it for ad hoc interactive execution of T-SQL statements and scripts. It is basically a replacement for the ISQL and OSQL commands used in versions prior to SQL Server 2005. (OSQL still works with SQL Server 2008, but ISQL has been discontinued.)

You can write, edit, and execute sqlcmd scripts within the Query Editor environment. The Query Editor in SSMS treats sqlcmd scripts in much the same way as other scripts. The script is color-coded and can be parsed or executed. This is possible only if you place the Query Editor in SQLCMD mode, which you do by selecting Query, SQLCMD Mode or selecting the SQLCMD mode icon from the SSMS toolbar.

Figure 4.19 shows a sample sqlcmd script in SSMS that can be used to back up a database. This example illustrates the power and diversity of a sqlcmd script that utilizes both T-SQL

and `sqlcmd` statements. It uses environment variables set within the script. The script variables `DBNAME` and `BACKUPPATH` are defined at the top of the script with the `SETVAR` command. The `BACKUP` statement at the bottom of the script references these variables, using the convention `$(variablename)`, which substitutes the value in the command.

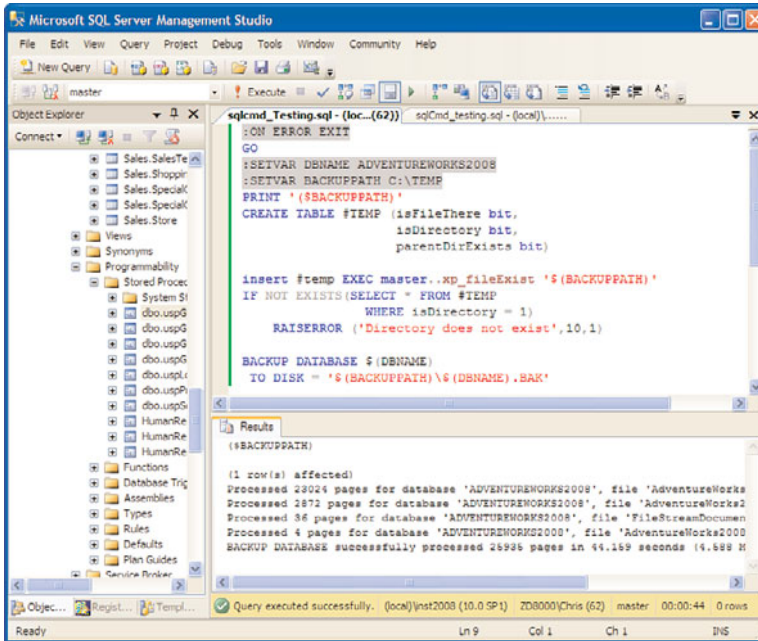

FIGURE 4.19 Editing a `sqlcmd` script in SSMS.

`sqlcmd` scripts that are edited in SSMS can also be executed within SSMS. The results are displayed in the results window of the query editor window, just like any other script. After you test a script, you can execute it by using the `sqlcmd` command-line utility. The `sqlcmd` command-line utility is a powerful tool that can help automate script execution. For more information on using `sqlcmd` in SSMS, refer to the Books Online topic “Editing SQLCMD Scripts with Query Editor.” The `sqlcmd` command-line utility is discussed in more detail in Chapter 5, “SQL Server Command-Line Utilities.”

Regular Expressions and Wildcards in SSMS

SSMS has a robust search facility that includes the use of regular expressions. Regular expressions provide a flexible notation for finding and replacing text, based on patterns within the text. Regular expressions are found in other programming languages and applications, including the Microsoft .NET Framework. The regular expressions in SSMS work in

much the same way as these other languages, but there are some differences in the notation.

The option to use regular expressions is available whenever you are doing a find or replace within an SSMS script. You can use the find and replace option in the code pane or results window. You can use the Find and Replace option from the Edit menu or press either the Ctrl+F or Ctrl+H shortcut keys to launch the Find and Replace dialog box. Figure 4.20 shows an example of the Find and Replace dialog that utilizes a regular expression. This example is searching for the text *Customer*, preceded by the @ character and not followed by the *Id* characters. This kind of search could be useful for searching a large stored procedure where you want to find the customer references but don't want to see the variables that contain *customer* in the first part of the variable name.

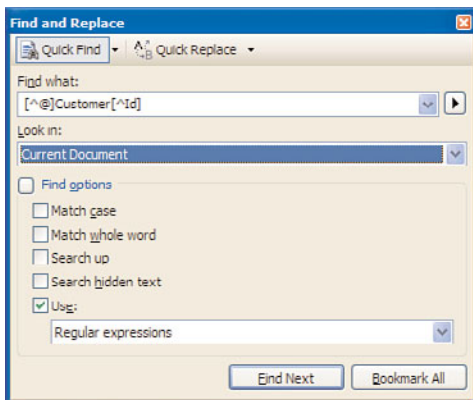

FIGURE 4.20 A find and replace with regular expressions.

You use regular expressions only when the Use check box in the Find and Replace dialog is selected. When this option is selected, you can choose either Regular Expressions or Wildcards. Wildcard searches work much the same way in SSMS as they do in file searches. For example, if you want to find any references to the word *zip*, you could enter **zip** in the Find What text box. The wildcard options are limited but very effective for simple searches.

Regular expressions have a much more extensive number of available search options. When you choose the option to use regular expressions, the arrow button is enabled to the right of the text box where you enter your search text. If you click this button, you are given an abbreviated list of regular expression characters that you can use in your searches. A brief description of what each character represents in the search is listed next to the character. For a complete list of characters, you can choose the Complete Character List option at the bottom of the list. This option brings you to the Books

Online topic “How to: Search with Regular Expressions,” which gives a comprehensive review of all the characters.

Enhanced Performance Output

The Query Editor in SSMS has an extensive set of options available for capturing and distributing performance-related data. It contains many of the familiar performance features that you may have grown accustomed to in SQL Server 2000 Query Analyzer—plus more. If you’re familiar with the SQL Server 2005 performance output, you will find that the SQL Server 2008 performance output has changed very little. The Execution Plan tab that is displayed in the results window and the Results and Messages tab are still there in SQL Server 2008. The Execution Plan tab can be populated with two different types of plans: estimated plans and actual plans. The actual execution plan shows the plan that was used in generating the actual query results. The actual plan is generated along with the results when the Include Actual Execution Plan option is selected. This option can be selected from the SSMS toolbar or from the Query menu. Figure 4.21 shows an example of an actual execution plan generated for a query against the AdventureWorks2008 database.

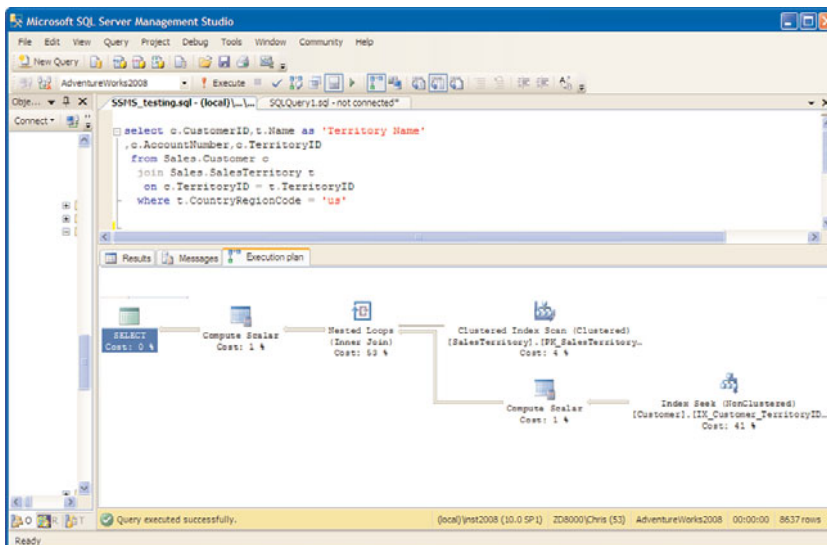

FIGURE 4.21 Displaying an actual execution plan in Query Editor.

The familiar tree-like structure that was also present in SQL Server 2000 is still used in SQL Server 2005 and SQL Server 2008. The ToolTips displayed when you mouse over a node in the execution plan include additional information; you can see that information in a

more static form in the Properties window if you right-click the node and select Properties. The display is generally easy to read and should be read from right to left.

NOTE

The Manage Indexes and Manage Statistics options available in the SQL Server 2000 Query Analyzer are not present in the Query Editor in SQL Server 2008. Those options in Query Analyzer were accessible by right-clicking a node in the query plan. You can use the Database Engine Tuning Advisor (DTA) in SQL Server 2008 to analyze the Query Editor statements or open the Table Designer to manage the indexes on a specific table.

Query plans generated in the Query Editor are easy to distribute in SQL Server 2008. You have several options for capturing query plan output so that you can save it or send it to someone else for analysis. If you right-click an empty section of the Execution Plan window, you can select the Save Execution Plan As option, which allows you to save the execution plan to a file. By default, the file has the extension `.sqlp1an`. This file can be opened using SSMS on another machine to display the graphical output.

The query plan can also be output in XML format and distributed in this form. You make this happen by using the `SET SHOWPLAN_XML ON` option. This option generates the estimated execution plan in a well-defined XML document. The best way to do this is to turn off the display of the actual execution plan and execute the `SET SHOWPLAN_XML ON` statement in the code pane window. Next, you set the Query Editor to return results in grid format and then execute the statements for which you want to generate a query plan. If you double-click the grid results, they are displayed in the SSMS XML editor. You can also save the results to a file. If you save the file with the `.sqlp1an` extension, the file displays the graphical plan when opened in SSMS.

Using the Query Designer in the Query Editor

A graphical query design tool is accessible from the query editor window where you write your queries. This is a great option that was missing in SQL Server 2000. With SQL Server 2000, you could access a graphical query designer by opening a table in Enterprise Manager and selecting Query, but this option was disconnected from the Query Analyzer environment, where the queries were authored. This tool was introduced in SQL Server 2005 and remains generally unchanged in SQL Server 2008.

With SQL Server 2008, you can right-click in the query editor window and choose Design Query in Editor. A dialog box appears, allowing you to add tables to the graphical query designer surface. The selected tables are shown in a window that allows you to select the columns you want to retrieve. Selected columns appear in a `SELECT` statement displayed at the bottom of the Query Designer window. Figure 4.22 shows an example of the Query Designer window that contains two tables from the AdventureWorks2008 database. The two tables selected in this figure are related, as indicated by the line between them.

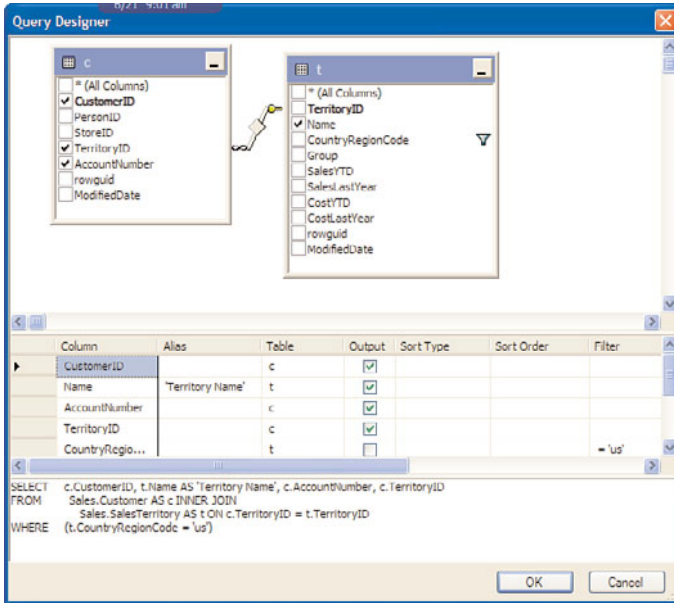

FIGURE 4.22 Designing queries in the Query Editor.

The T-SQL statements are generated automatically as you select various options on the Query Designer screen. If you select Sort Type, an `ORDER BY` clause is added. If you choose an alias for a column, it is reflected in the T-SQL. If tables are related, the appropriate joins are generated.

When you click OK on the Query Designer window, the related T-SQL is automatically placed in the query editor window. You can edit the T-SQL as needed or use it as is. You can imagine the time savings you can achieve by using this tool.

TIP

The Query Designer has a very impressive feature that allows you to view a T-SQL query visually. If you copy a valid T-SQL statement, open the Query Designer, and paste the T-SQL into the SQL pane at the bottom of the Query Designer, it tries to resolve the T-SQL into a graphical display. The tables in the `FROM` clause are shown in the designer panel, and information related to the selected columns is listed as well. The Query Designer cannot resolve all T-SQL statements and may fail to generate a visual display for some complex T-SQL.

Managing Projects in SSMS

Project management capabilities like those available in Visual Studio are available in SSMS. Queries, connections, and other files that are related can be grouped into projects. A project or set of projects is further organized or grouped as a solution. This type of organization is the same as in the Visual Studio environment.

Projects and solutions are maintained and displayed with the Solution Explorer. The Solution Explorer contains a tree-like structure that organizes the projects and files in the solution. It is a component window within SSMS that you launch by selecting View, Solution Explorer. Figure 4.23 shows an example of the Solution Explorer. The solution in this example is named EmployeeUpgrade, and it contains two projects, named Phase1 and Phase2. Each project contains a set of connections, a set of T-SQL scripts, and a set of miscellaneous files.

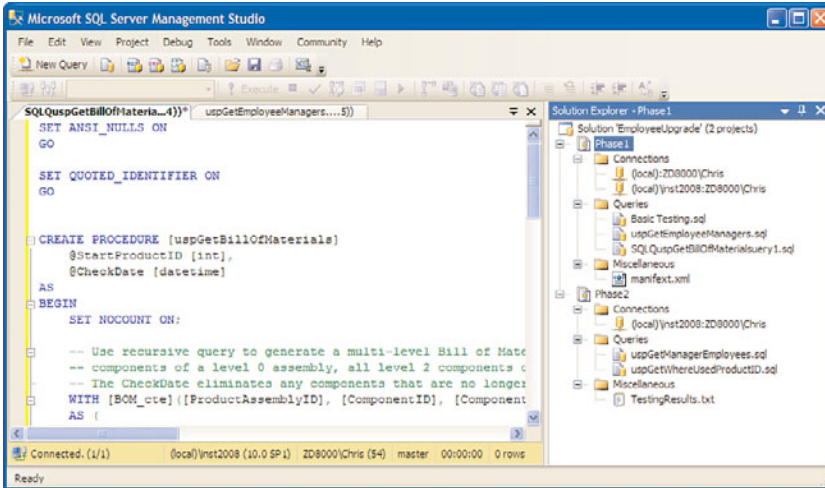

FIGURE 4.23 Solutions and projects listed in the Solution Explorer.

The first thing to do when using the project management capabilities in SSMS is to add a project. To do this, you select File, New, and when the New dialog appears, you select Project to add a new project. When adding the new project, you are given a choice of the type of project, and you must select either SQL Server Scripts, Analysis Services Scripts, or SQL Mobile Scripts. Each one of these project types is geared toward the respective SQL Server technology.

The solution that is related to the project is created at the same time that the project is created. The Solution Name is entered at the bottom of the New Project window and an option to create a separate directory for the solution is provided. There is no option to create the solution separately.

After the project is added, you can add the related connections and files. To add a new connection, you simply right-click the Connections node. The Connections entries allow you to store SQL Server connection information that relates to the project you are working on. For example, you could have a connection to your test environment and another

connection to the production environment that relates to the project. When a connection is included in the project, you can double-click it, and a new query window for that connection is established.

SQL script files are added to a project in a similar fashion to connections: You right-click the **Queries** node and select the **New Query** option. A new query editor window appears, allowing you to enter the T-SQL commands. Any T-SQL script is viable for this category, including those that relate to database objects such as stored procedures, triggers, and tables.

You can also add existing files to a project. To do this, you right-click the project node, select **Add**, and then select **Existing Item**. The file types listed in the drop-down at the bottom of the **Add Existing Item** dialog include SQL Server files (*.sql), SQL deadlock files (*.xd1), XML files (*.xml), and execution plan files (*.sqlplan). SQL Server files are added, by default, to the **Queries** node. All the other file types are added to the **Miscellaneous** node. The connection entries are not stored in a separate file but are contained in the project file itself.

Integrating SSMS with Source Control

SSMS has the capability to integrate database project files into a source control solution. Source control provides a means for protecting and managing files. Source control applications typically contain features that allow you to track changes to files, control and track who uses the files, and provide a means for tagging the files with a version stamp so that the files can be retrieved at a later time, by version.

SSMS can integrate with a number of different source control applications. Visual SourceSafe is Microsoft's basic source control solution, but other source control applications can be used instead. The source control client application must be installed on the machine on which SSMS is running. When the installation is complete, you can set the source control application that SSMS will use within SSMS. To do this, you select **Tools**, **Options** and navigate to the **Source Control** node. The available source control clients are listed in the **Current Source Control Plug-in** drop-down.

The link between SSMS and the source control application is the database solution. After a solution is created, it can be added to the source control. To add a solution to a source control application, you open the **Solution Explorer** and right-click the solution or any of the projects in the solution. You then see the **Add Solution to Source Control** option. You must then log in to the source control application and select a source control project to add the solution to.

When the solution is added to a source control application, all the related projects and project files are added as well. The projects and files in the source control application have additional options available in the **Solution Explorer**. Figure 4.24 shows a sample solution added to a source control application. A subset of the source control options available when you right-click project files are shown in this figure as well.

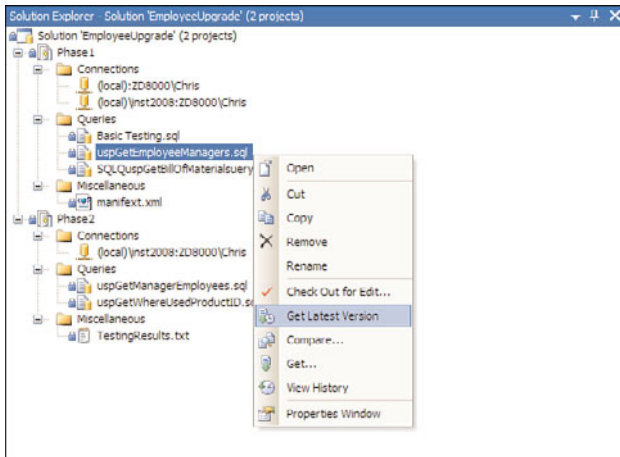

FIGURE 4.24 Source control options in the Solution Explorer.

The options related to source control are listed toward the bottom of the options list. The options that are available depend on the status of the selected file. For example, if a file has been checked out, additional options are displayed that relate to checking the file back in. Following are some of the common source control options:

- ▶ **Check Out for Edit**—This option allows you to get a copy of the file from the source control application so that you can modify the file. When you check out the file, the source control provider can keep track of the user who has checked out the file, and it can also prevent other users from checking out the file.
- ▶ **Check In**—This option copies the locally modified file into the source control solution. The file must first be checked out for editing before you can use the Check In option. A new version for the file is established, and any prior versions of the file are retained as well.
- ▶ **Get Latest Version**—This option gets a read-only copy of the latest version of the project file from the source control application. The file is not checked out with this option.
- ▶ **Compare**—This option enables you to compare versions of source control files. The default comparison that is shown is between the file in the source control application and the local file on your machine.
- ▶ **Get**—This option is similar to the Get Latest Version option, but it retrieves a read-only copy of the file. With this option, a dialog box appears, allowing you to select the file(s) that you want to retrieve.
- ▶ **View History**—This option lists all versions of the files checked into the source control application. The History dialog box has many options that you can use with the different versions of the file. You can view differences between versions of the

files, view the contents of a specific version, generate reports, or get an older version of the file.

- ▶ **Undo Checkout**—This option changes the checkout status in the source control application and releases the file to other source control users. Any changes made to the local copy of the file are not added to the source control version.

Other source control options are available via the Source Control menu in SSMS. You select an item in the Solution Explorer and then select File, Source Control. You can use this menu to check the status of a file by using the SourceSafe Properties option, set source control properties, launch the source control application, and perform other source control operations.

Using SSMS Templates

Templates provide a framework for the creation of database objects in SSMS. They are essentially boilerplate files that help generate scripts for common database objects. They can speed up the development of these scripts and help enforce consistency in the generation of the underlying database objects.

The Template Explorer is a component window available in SSMS and replaces the Template tab available in the SQL Server 2000 Query Analyzer. Figure 4.25 shows the Template Explorer and the available SQL Server template folders. Separate templates also exist for Analysis Services and SQL Server Mobile Edition. You can view them by selecting the related icon at the top of the Template Explorer.

You access the available templates by expanding the template folder in the Template Explorer tree. For example, if you expand the Index folder, you see six different types of index templates. If you double-click one of the templates, a new query editor window appears, populated with the template script. Figure 4.26 shows the template script displayed when you open the Create Index Basic template.

The template script contains template parameters that have the following format within the script:

```
<parameter_name, data_type, value>
```

You can manually replace these parameters in the script, or you can use the Specify Values for Template Parameters option from the Query menu to globally replace the parameters in the script with the desired values. Selecting Query, Specify Values for Template Parameters launches the Specify Values for Template Parameters dialog box, which enables you to enter the parameter values (see Figure 4.27).

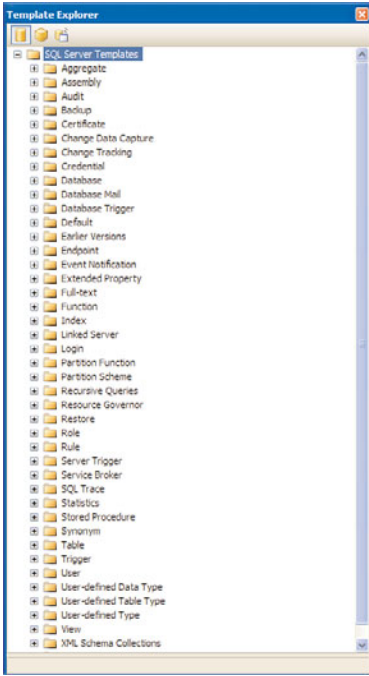

FIGURE 4.25 The SSMS Template Explorer.

```

-- =====
-- Create index basic template
-- =====
USE <database_name>, <sysname>, AdventureWorks
GO

CREATE INDEX <index_name>, <sysname>, ind_test>
ON <schema_name>, <sysname>, Person.<table_name>, <sysname>, Address>
(
    <column_name1>, <sysname>, PostalCode>
)
GO
    
```

FIGURE 4.26 The template script for creating a basic index.

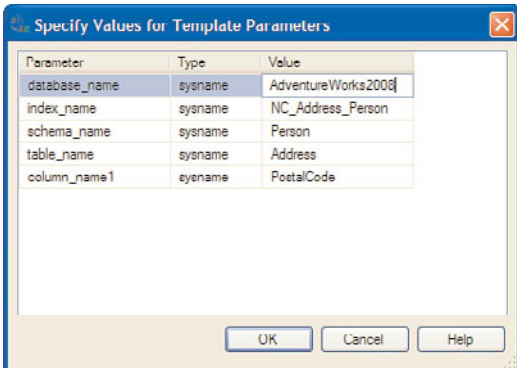

FIGURE 4.27 The Specify Values for Template Parameters dialog box.

TIP

When you use the Specify Values for Template Parameters option, some parameters may be missed if the parameter text has been altered. For example, if you add a carriage return after *parameter_name*, the Parameters dialog box does not list that parameter. It is best to leave the template script unchanged before you specify values for the parameters. You should make changes to the script after the values have been specified.

After you enter the parameter values and click OK, the values are reflected in the script. For example, the values shown in Figure 4.27 for the basic index template result in the following script:

```
-- =====  
-- Create index basic template  
-- =====  
USE AdventureWorks2008  
GO  
CREATE INDEX NC_Address_Person  
ON Person.Address  
(  
    PostalCode  
)  
GO
```

You also have the option of creating your own custom templates. These templates can contain parameters just like those available with the default templates. You can also create your own template folder that will be displayed in the Template Explorer tree. To create a new template folder, you right-click the SQL Server Templates node in the Template Explorer tree and select New, Folder. A new folder appears in the tree, and you can specify a new folder name. Figure 4.28 shows the Template Explorer with a set of custom templates found under the *_mytemplates* folder. The code pane in this figure shows the contents of a new custom template named *sys.objectSelectWithParameters*. This custom template contains two parameter declarations: *object_type* and *modify_date*. When you select the Specify Values for Template Parameters options for this custom template, you have the opportunity to change the values, just as you can with the default templates.

NOTE

When you double-click a template in the Template Explorer tree, you create a script based on the template. Changes made to the script do not affect the template; they affect only the script generated from the template. To change the actual template, you need to right-click the template and select Edit. After you complete your changes, you need to make sure to save the template.

Also, you should keep in mind that there is no requirement to have parameters in your templates. Templates are handy tools for accessing any code snippet you might use. After the code snippet is added as a template, you can open a new query editor window based on the template or simply drag and drop the template from the Template Explorer to an existing query editor window, and the code for the template is pasted into the window.

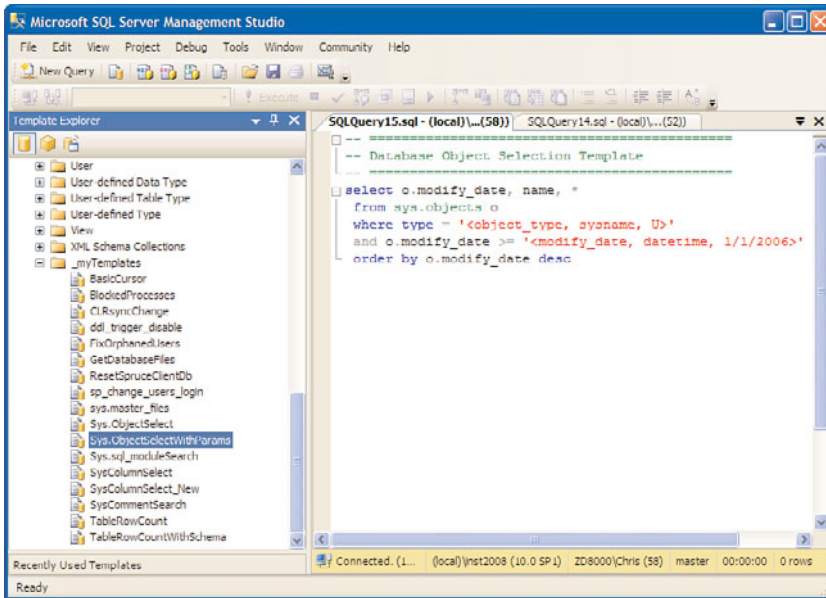

FIGURE 4.28 A custom template example.

T-SQL Debugging

Finally, you are able to debug T-SQL from within the SQL Server development environment. Yes, you could do this kind of thing using Visual Studio, but database developers should be able to debug in the environment where they generally develop their SQL statements—within SSMS. SQL Server 2008 provides this capability, and it works well.

The trickiest part of debugging may be starting the debugger. It is not all that difficult but may be less than obvious for some. For example, let's say you want to debug a stored procedure. To do this, you right-click on the stored procedure in the Object Explorer and select Script Stored Procedure As, Execute To, New Query Editor Window, and a script for executing the procedure is generated. If the stored procedure has parameters, you add the SQL to assign a value to those parameters to the script. Now you are ready to debug this script and the related stored procedure.

To initiate debugging, you click on the green arrow on the SQL Server menu bar. When you start debugging, several new debugging windows are added to the SSMS display, and the query editor window shows a yellow arrow in the left margin next to the line in the script

that is about to be run. You can now use the debug toolbar at the top of the SSMS screen to step through your code. If you click the Step Into button, the current statement executes, and the script progresses to the next available statement. Figure 4.29 shows an example of the T-SQL Debugging Environment while debugging is in progress. The debugging environment enables you to view values assigned to variables, review the call stack, set breakpoints, and perform debugging much like you would do in development environments such as Visual Studio.

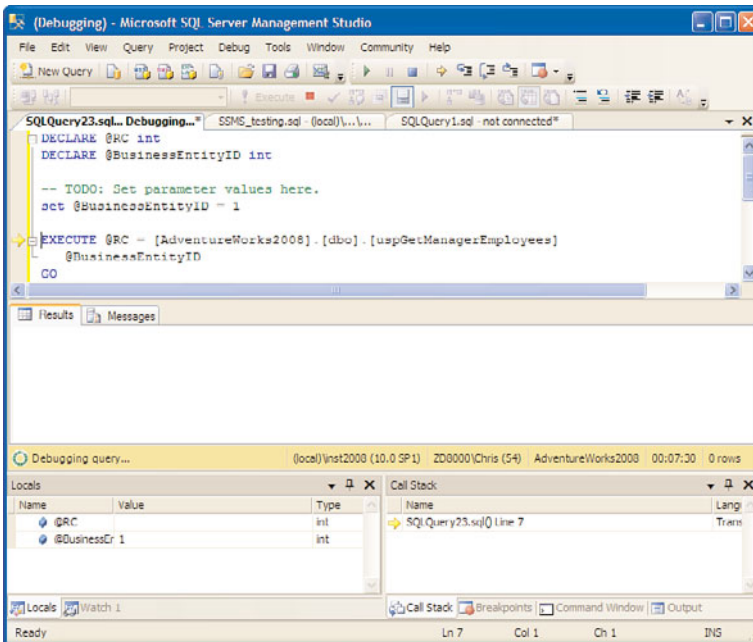

FIGURE 4.29 The T-SQL Debugging Environment.

Multiserver Queries

Another slick new option available with SQL Server 2008 is the capability to execute a script on multiple servers at once. Multiserver queries allow the contents of a single query editor window to be run against all the servers defined in a given registered server group. After the group is created and servers are registered in the group, you can right-click on the group and select the New Query option to create a query window that can be run against all the servers in the group. Click on the Execute button, and the query is run against all the servers. Figure 4.30 shows a server group named MyTestGroup containing three servers registered in that group, a sample query to run against these servers, and a single result window that shows the results of the query for all servers in the group.

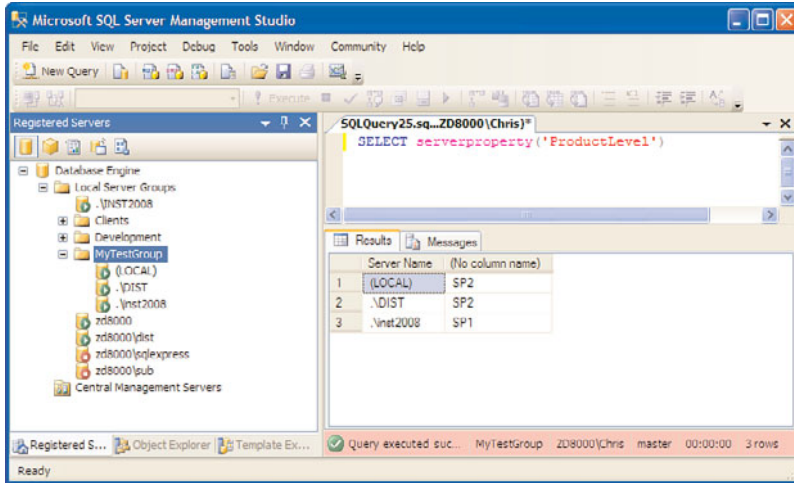

FIGURE 4.30 Multiserver query execution.

Multiserver queries are relatively easy to use. The results window includes a Server Name column that allows you to determine which server the result came from. These queries are backward compatible and allow you to run against prior versions of SQL Server, including SQL Server 2005. The only caveat is that you must first create a registered server group and the related registered servers before you run the query, but you already know that this task is also relatively easy.

Summary

The number of tools and features available in SSMS is extensive and can be daunting when you first enter the environment. Remember that you can customize this environment and hide many of the windows that are displayed. You can start with a fairly simple SSMS configuration that includes the Object Explorer and a query editor window. This configuration may allow you to accomplish a majority of your SQL Server tasks. As you become more familiar with the environment, you can introduce new tools and features to help improve your overall productivity.

The discussion of SSMS does not end with this chapter. Further details related to SSMS are covered throughout this book. You can use the new features described in this chapter as a starting point and look to other chapters for more detailed discussion of database features accessible through SSMS.

Chapter 5 looks at the SQL Server utilities that can be run from the command prompt. These tools allow you to perform some of the same tasks available in SSMS. The capability to launch these utilities from the command line can be useful when you're automating tasks or accessing SQL Server when a GUI tool such as SSMS is not available.

CHAPTER 5

SQL Server Command-Line Utilities

This chapter explores various command-line utilities that ship with SQL Server. These utilities give administrators a different way to access the database engine and its related components. In some cases, they provide functionality that is also available with SQL Server's graphical user interface (GUI). Other command-line utilities provide functionality that is available only from the command prompt. For each utility, this chapter provides the command syntax along with the most commonly used options. For the full syntax and options available for the utility, see SQL Server Books Online.

NOTE

This chapter focuses on command-line utilities that are core to SQL Server and the SQL Server database engine. Several other command-line utilities that are used less frequently or geared toward other SQL Server services are not covered in this chapter. These utilities include `dtexec` and `dtutil`, which can be used with SQL Server Integration Services (SSIS). Reporting Services has the `rs`, `rsconfig`, and `rskeymgmt` command-line utilities. Lastly, there are several executable files documented as utilities in Books Online (such as `ssms`, which opens the SQL Server Management Studio) that have limited parameters and are basically used to launch their related applications.

Table 5.1 lists the command-line utilities discussed in this chapter. This table lists the physical location of each utility's

IN THIS CHAPTER

- ▶ What's New in SQL Server Command-Line Utilities
- ▶ The **sqlcmd** Command-Line Utility
- ▶ The **dta** Command-Line Utility
- ▶ The **tablediff** Command-Line Utility
- ▶ The **bcp** Command-Line Utility
- ▶ The **sqldiag** Command-Line Utility
- ▶ The **sqlservr** Command-Line Utility

executable. The location is needed to execute the utility in most cases, unless the associated path has been added to the Path environmental variable.

TABLE 5.1 Command-Line Utility Installation Locations

Utility	Install Location
sqlcmd	x:\Program Files\Microsoft SQL Server\100\Tools\Binn
dta	x:\Program Files\Microsoft SQL Server\100\Tools\Binn
tablediff	x:\Program Files\Microsoft SQL Server\100\COM
bcp	x:\Program Files\Microsoft SQL Server\100\Tools\Binn
sqldiag	x:\Program Files\Microsoft SQL Server\100\Tools\Binn
sqlservr	x:\Program Files\Microsoft SQL Server\MSSQL10.MSSQLSERVER\MSSQL\Binn

NOTE

The `tablediff` utility is installed when SQL Server replication is installed. If you can't find the `tablediff.exe` in the location specified in Table 5.1, check to see whether the replication was installed.

When you are testing many of these utilities, it is often easiest to set up a batch file (.BAT) that contains a command to change the directory to the location shown in Table 5.1. After you make this directory change, you can enter the command-line utility with the relevant parameters. Finally, you should enter a PAUSE command so that you can view the output of the utility in the command prompt window. Following is an example you can use to test the `sqlcmd` utility (which is discussed in more detail later in this chapter):

```
CD "C:\Program Files\Microsoft SQL Server\100\Tools\Binn"
SQLCMD -S(local) -E -Q "select @@servername"
pause
```

After you save the commands in a file with a .BAT extension, you can simply double-click the file to execute it. This approach is much easier than retyping the commands many times during the testing process.

What's New in SQL Server Command-Line Utilities

The SQL Server command-line utilities available in SQL Server 2008 are basically the same as those offered with SQL Server 2005. This has some key benefits for those who are familiar with the 2005 utilities. Very little has changed in the syntax, and batch files or scripts you have used with these utilities in the past should continue to work unchanged.

A few command-line utilities have been added in SQL Server 2008, however, and some have been removed. The `sqlps` utility is new to SQL Server 2008. This utility can be used to run PowerShell commands and scripts. The `sqlps` utility and the PowerShell Windows-based command-line management tool are discussed in detail in Chapter 17, “Administering SQL Server 2008 with PowerShell.”

Utilities removed from SQL Server 2008 include `sac`. The `sac` utility can be used in SQL Server 2005 to import or export settings available in the graphical Surface Area Configuration (SAC) tool. Both the `sac` command-line utility and SAC graphical tool have been removed. Similar functionality is now available via policy-based management and the Configuration Manager tool.

The sqlcmd Command-Line Utility

The `sqlcmd` command-line utility is the next generation of the `isql` and `osql` utilities that you may have used in prior versions of SQL Server. It provides the same type of functionality as `isql` and `osql`, including the capability to connect to SQL Server from the command prompt and execute T-SQL commands. The T-SQL commands can be stored in a script file, entered interactively, or specified as command-line arguments to `sqlcmd`.

NOTE

The `isql` and `osql` command-line utilities are not covered in this chapter. The `isql` utility was discontinued in SQL Server 2005 and is not supported in SQL Server 2008. The `osql` utility is still supported but will be removed in a future version of SQL Server. Make sure to use `sqlcmd` in place of `osql` to avoid unnecessary reworking in the future.

The syntax for `sqlcmd` follows:

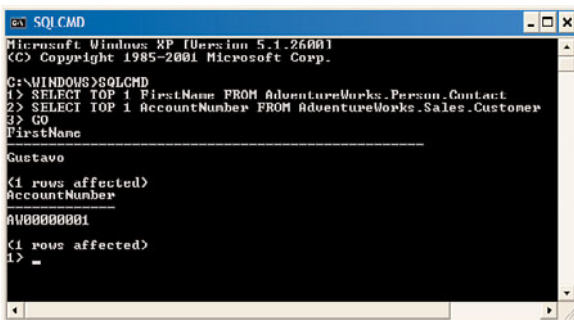

```
sqlcmd
[ { { -U login_id [ -P password ] } | -E trusted connection } ]
[ -z new_password ] [ -Z new_password_and_exit ]
[ -S server_name [ \ instance_name ] ] [ -H wksta_name ] [ -d db_name ]
[ -l login_time_out ] [ -A dedicated_admin_connection ]
[ -i input_file ] [ -o output_file ]
[ -f <codepage> | i: <codepage> [ < , o: <codepage> ] ]
[ -u unicode output ] [ -r [ 0 | 1 ] msgs to stderr ]
[ -R use client regional settings ]
[ -q "cmdline query" ] [ -Q "cmdline query" and exit ]
[ -e echo input ] [ -t query_time_out ]
[ -I enable Quoted Identifiers ]
[ -v var = "value"...] [ -x disable variable substitution ]
[ -h headers ][ -s col_separator ] [ -w column_width ]
[ -W remove trailing spaces ]
```

```
[ -k [ 1 | 2 ] remove[replace] control characters ]
[ -y display_width ] [-Y display_width ]
[ -b on error batch abort ] [ -V severitylevel ] [ -m error_level ]
[ -a packet_size ][ -c cmd_end ]
[ -L [ c ] list servers[clean output] ]
[ -p [ 1 ] print statistics[colon format]]
[ -X [ 1 ] ] disable commands, startup script, environment variables [and exit]
[ -? show syntax summary ]
```

The number of options available for `sqlcmd` is extensive, but many of the options are not necessary for basic operations. To demonstrate the usefulness of this tool, we look at several different examples of the `sqlcmd` utility, from fairly simple (using few options) to more extensive.

Executing the `sqlcmd` Utility

Before we get into the examples, it is important to remember that `sqlcmd` can be run in several different ways. It can be run interactively from the command prompt, from a batch file, or from a Query Editor window in SSMS. When run interactively, the `sqlcmd` program name is entered at the command prompt with the required options to connect to the database server. When the connection is established, a numbered row is made available to enter the T-SQL commands. Multiple rows of T-SQL can be entered in a batch; they are executed only after the `GO` command has been entered. Figure 5.1 shows an example with two simple `SELECT` statements that were executed interactively with `sqlcmd`. The connection in this example was established by typing `sqlcmd` at the command prompt to establish a trusted connection to the default instance of SQL Server running on the machine on which the command prompt window is opened.

```
Microsoft Windows [Version 5.1.2600]
(C) Copyright 1985-2001 Microsoft Corp.

C:\WINDOWS\SQLCMD
1> SELECT TOP 1 FirstName FROM AdventureWorks.Person.Contact
2> SELECT TOP 1 AccountNumber FROM AdventureWorks.Sales.Customer
3> GO
-----
FirstName
-----
Gustavo
(1 rows affected)
AccountNumber
-----
AW00000001
(1 rows affected)
1> _
```

FIGURE 5.1 Executing `sqlcmd` interactively.

The capability to edit and execute `sqlcmd` scripts was added to SSMS with SQL Server 2005. A `sqlcmd` script can be opened or created in a Query Editor window within SSMS. To edit these scripts, you must place the editor in SQLCMD Mode. You do so by selecting Query, SQLCMD Mode or by clicking the related toolbar button. When the editor is put in SQLCMD Mode, it provides color coding and the capability to parse and execute the

commands within the script. Figure 5.2 shows a sample `sqlcmd` script opened in SSMS in a Query Editor window set to SQLCMD Mode. The shaded lines are `sqlcmd` commands.

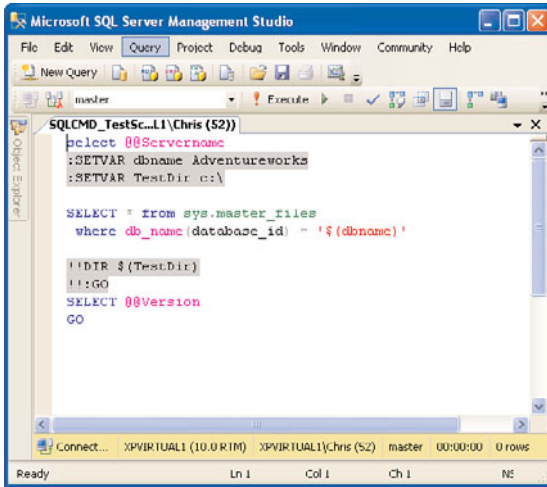

FIGURE 5.2 Executing and editing `sqlcmd` scripts in SSMS.

The most common means for executing `sqlcmd` utility is via a batch file. This method can provide a great deal of automation because it allows you to execute a script or many scripts by launching a single file. The examples shown in this section are geared toward the execution of `sqlcmd` in this manner. The following simple example illustrates the execution of `sqlcmd`, using a trusted connection to connect to the local database, and the execution of a simple query that is set using the `-Q` option:

```
sqlcmd -S (local) -E -Q"select getdate()"
```

You can expand this example by adding an output file to store the results of the query and add the `-e` option, which echoes the query that was run in the output results:

```
sqlcmd -S (local) -E -Q"select getdate()" -o c:\TestOutput.txt -e
```

The contents of the `c:\TestOutput.txt` file should look similar to this:

```
select getdate()
-----
2008-09-10 20:29:05.645
(1 rows affected)
```

Using a trusted connection is not the only way to use `sqlcmd` to connect to a SQL Server instance. You can use the `-U` and `-P` command-line options to specify the SQL Server user and password. `sqlcmd` also provides an option to specify the password in an environmental variable named `sqlcmdPASSWORD`, which can be assigned prior to the `sqlcmd` execution and eliminates the need to hard-code the password in a batch file.

sqlcmd also provides a means for establishing a dedicated administrator connection (DAC) to the server. The DAC is typically used for troubleshooting on a server that is having problems. It allows an administrator to get onto the server when others may not be able to. If the DAC is enabled on the server, a connection can be established with the `-A` option and a query can be run, as shown in the following example:

```
sqlcmd -S (local) -A -Q"select getdate()"
```

If you need to manage more complex T-SQL execution, it is typically easier to store the T-SQL in a separate input file. The input file can then be referenced as a sqlcmd parameter. For example, say that you have the following T-SQL stored in a file named `C:\TestsqlcmdInput.sql`:

```
BACKUP DATABASE Master
  TO DISK = 'c:\master.bak'
```

```
BACKUP DATABASE Model
  TO DISK = 'c:\model.bak'
```

```
BACKUP DATABASE MSDB
  TO DISK = 'c:\msdb.bak'
```

The sqlcmd execution, which accepts the `C:\TestsqlcmdInput.sql` file as input and executes the commands within the file, looks like this:

```
sqlcmd -S (local) -E -i"C:\TestsqlcmdInput.sql" -o c:\TestOutput.txt -e
```

The execution of the preceding example backs up three of the system databases and writes the results to the output file specified.

Using Scripting Variables with sqlcmd

sqlcmd provides a means for utilizing variables within sqlcmd input files or scripts. These scripting variables can be assigned as sqlcmd parameters or set within the sqlcmd script. To illustrate the use of scripting variables, let's change our previous backup example so that the database that will be backed up is a variable. A new input file named `c:\BackupDatabase.sql` should be created, and it should contain the following command:

```
BACKUP DATABASE $(DatabaseToBackup)
  TO DISK = 'c:\$(DatabaseToBackup).bak'
```

The variable in the preceding example is named `DatabaseToBackup`. Scripting variables are referenced using the `$()` designators. These variables are resolved at the time of execution, and a simple replacement is performed. This allows variables to be specified within quotation marks, if necessary. The `-v` option is used to assign a value to a variable at the command prompt, as shown in the following example, which backs up the `model` database:

```
sqlcmd -S (local) -E -i"C:\BackupDatabase.sql" -v DatabaseToBackup = model
```

If multiple variables exist in the script, they can all be assigned after the `-v` parameter. These variables should not be separated by a delimiter, such as a comma or semicolon. Scripting variables can also be assigned within the script, using the `:SETVAR` command. The input file from the previous backup would be modified as follows to assign the `DatabaseToBackup` variable within the script:

```
:SETVAR DatabaseToBackup Model
BACKUP DATABASE $(DatabaseToBackup)
TO DISK = 'c:\$(DatabaseToBackup).bak'
```

Scripts that utilize variables, `sqlcmd` commands, and the many available options can be very sophisticated and can make your administrative life easier. The examples in this section illustrate some of the basic features of `sqlcmd`, including some of the features that go beyond what is available with `osql`.

The dta Command-Line Utility

`dta` is the command-line version of the graphical Database Engine Tuning Advisor. Both the command-line utility and graphical tool provide performance recommendations based on the workload provided to them. The syntax for `dta` is as follows:

```
Dta [ -? ] |
[
  [ -S server_name[ \instance ] ]
  {
    { -U login_id [-P password ] }
    | -E
    { -D database_name [ ,...n ] }
    [ -d database_name ]
    [ -Tl table_list | -Tf table_list_file ]
    { -if workload_file | -it workload_trace_table_name }
    { -s session_name | -ID session_ID }
    [ -F ]
    [ -of output_script_file_name ]
    [ -or output_xml_report_file_name ]
    [ -ox output_XML_file_name ]
    [ -rl analysis_report_list [ ,...n ] ]
    [ -ix input_XML_file_name ]
    [ -A time_for_tuning_in_minutes ]
    [ -n number_of_events ]
  }
  [ -m minimum_improvement ]
  [ -fa physical_design_structures_to_add ]
  [ -fp partitioning_strategy ]
  [ -fk keep_existing_option ]
```

```

        [ -fx drop_only_mode ]
    [ -B storage_size ]
    [ -c max_key_columns_in_index ]
    [ -C max_columns_in_index ]
        [ -e | -e tuning_log_name ]
        [ -N online_option ]
        [ -q ]
        [ -u ]
    [ -x ]
    [ -a ]
]

```

An extensive number of options is available with this utility, but many of them are not required to do basic analysis. At a minimum, you need to use options that provide connection information to the database, a workload to tune, a tuning session identifier, and the location to store the tuning recommendations. The connection options include `-S` for the server name, `-D` for the database, and either `-E` for a trusted connection or `-U` and `-P`, which can be used to specify the user and password.

The workload to tune is either a workload file or workload table. The `-if` option is used to specify the workload file location, and the `-it` option is used to specify a workload table. The workload file must be a Profiler trace file (`.trc`), SQL script (`.sql`) that contains T-SQL commands, or SQL Server trace file (`.log`). The workload table is a table that contains output from a workload trace. The table is specified in the form `database_name.owner_name.table_name`.

The tuning session must be identified with either a session name or session ID. The session name is character based and is specified with the `-s` option. If the session name is not provided, a session ID must be provided instead. The session ID is numeric and is set using the `-ID` option. If the session name is specified instead of the session ID, the `dta` generates an ID anyway.

The last options required for a basic `dta` execution identify the destination to store the `dta` performance recommendations, which can be stored in a script file or in XML. The `-of` option is used to specify the output script filename. XML output is generated when the `-or` or `-ox` option is used. The `-or` option generates a filename if one is not specified, and the `-ox` option requires a filename. The `-F` option can be used with any of the output options to force an overwrite of a file with the same name, if one exists.

To illustrate the use of `dta` with basic options, let's look at an example of tuning a simple `SELECT` statement against the `AdventureWorks2008R2` database. To begin, you use the following T-SQL, which is stored in a workload file named `c:\myScript.sql`:

```

USE AdventureWorks2008R2 ;
GO
select *
from Production.transactionHistory
where TransactionDate = '9/1/04'

```

The following example shows the basic dta execution options that can be used to acquire performance recommendations:

```
dta -S xpvirtual1 -E -D AdventureWorks2008R2 -if c:\MyScript.sql
-s MySessionX -of C:\MySessionOutputScript.sql -F
```

NOTE

dta and other utilities executed at the command prompt are executed with all the options on a single line. The preceding example and any others in this chapter that are displayed on more than one line should actually be executed at the command prompt or in a batch file on a single line. They are broken here because the printed page can accommodate only a fixed number of characters.

The preceding example utilizes a trusted connection against the AdventureWorks2008R2 database, a workload file named c:\MyScript.sql, and a session named MySessionX, and it outputs the performance recommendations to a text file named c:\MySessionOutputScript.sql. The -F option is used to force a replacement of the output file if it already exists. The output file contains the following performance recommendations:

```
se [AdventureWorks2008R2]
go

CREATE NONCLUSTERED INDEX [_dta_index_TransactionHistory_5]
ON [Production].[TransactionHistory]
(
    [TransactionDate] ASC
)
INCLUDE ( [TransactionID],
[ProductID],
[ReferenceOrderID],
[ReferenceOrderLineID],
[TransactionType],
[Quantity],
[ActualCost],
[ModifiedDate])
WITH (SORT_IN_TEMPDB = OFF, IGNORE_DUP_KEY = OFF,
DROP_EXISTING = OFF, ONLINE = OFF) ON [PRIMARY]
go
```

In short, the dta output recommends that a new index be created on the TransactionDate column in the TransactionHistory table. This is a viable recommendation, considering that there was no index on the TransactionHistory.TransactionDate column, and it was used as a search argument in the workload file.

Many other options (that go beyond basic execution) can be used to manipulate the way `dta` makes recommendations. For example, a list can be provided to limit which tables the `dta` looks at during the tuning process. Options can be set to limit the amount of time that the `dta` tunes or the number of events. These options go beyond the scope of this chapter, but you can gain further insight into them by looking at the graphical DTA, which contains many of the same types of options. You can refine your tuning options in the DTA, export the options to an XML file, and use the `-ix` option with the `dta` utility to import the XML options and run the analysis.

The `tablediff` Command-Line Utility

The `tablediff` utility enables you to compare the contents of two tables. It was originally developed for replication scenarios to help troubleshoot nonconvergence, but it is also very useful in other scenarios. When data in two tables should be the same or similar, this tool can help determine whether they are the same, and if they are different, it can identify what data in the tables is different.

The syntax for `tablediff` is as follows:

```
tablediff
[ -? ] |
{
    -sourceserver source_server_name[\instance_name]
    -sourcedatabase source_database
    -sourcetable source_table_name
    [ -sourceschema source_schema_name ]
    [ -sourcepassword source_password ]
    [ -sourceuser source_login ]
    [ -sourcelocked ]
    -destinationserver destination_server_name[\instance_name]
    -destinationdatabase subscription_database
    -destinationtable destination_table
    [ -destinationschema destination_schema_name ]
    [ -destinationpassword destination_password ]
    [ -destinationuser destination_login ]
    [ -destinationlocked ]
    [ -b large_object_bytes ]
    [ -bf number_of_statements ]
    [ -c ]
    [ -dt ]
    [ -et table_name ]
    [ -f [ file_name ] ]
    [ -o output_file_name ]
    [ -q ]
    [ -rc number_of_retries ]
    [ -ri retry_interval ]
}
```

```
[ -strict ]
[ -t connection_timeouts ]
}
```

The `tablediff` syntax requires source and destination connection information to perform a comparison. This information includes the servers, databases, and tables that will be compared. Connection information must be provided for SQL Server authentication but can be left out if Windows authentication can be used. The source and destination parameters can be for two different servers or the same server, and the `tablediff` utility can be run on a machine that is neither the source nor the destination.

To illustrate the usefulness of this tool, let's look at a sample comparison in the AdventureWorks2008R2 database. The simplest way to create some data for comparison is to select the contents of one table into another and then update some of the rows in one of the tables. The following `SELECT` statement makes a copy of the `AddressType` table in the AdventureWorks2008R2 database to the `AddressTypeCopy` table:

```
select *
into Person.AddressTypeCopy
from Person.AddressType
```

In addition, the following statement updates two rows in the `AddressTypeCopy` table so that you can use the `tablediff` utility to identify the changes:

```
UPDATE Person.AddressTypeCopy
SET Name = 'Billing New'
WHERE AddressTypeId = 1
```

```
UPDATE Person.AddressTypeCopy
SET Name = 'Shipping New',
    ModifiedDate = '20090918'
WHERE AddressTypeId = 5
```

The `tablediff` utility can be executed with the following parameters to identify the differences in the `AddressType` and `AddressTypeCopy` tables:

```
tablediff -sourceserver "(local)" -sourcedatabase "AdventureWorks2008R2"
-sourceschema "Person" -sourcetable "AddressType"
-destinationserver "(local)" -destinationdatabase "AdventureWorks2008R2"
-destination schema "Person" -destinationtable "AddressTypeCopy"
-f c:\TableDiff_Output.txt
```

The destination and source parameters are the same as in the previous example, except for the table parameters, which have the source `AddressType` and the destination `AddressTypeCopy`. The execution of the utility with these parameters results in the following output to the command prompt window:

User-specified agent parameter values:

```
-sourceserver (local)
-sourcedatabase AdventureWorks2008R2
-sourceschema Person
-sourcetable AddressType
-destinationserver (local)
-destinationdatabase AdventureWorks2008R2
-destinationschema Person
-destinationtable AddressTypeCopy
-f c:\TableDiff_Output
```

Table [AdventureWorks2008R2].[Person].[AddressType] on (local) and Table [AdventureWorks2008R2].[Person].[AddressTypeCopy] on (local) have 2 differences.

Fix SQL written to c:\TableDiff_Output.sql.

```
Err      AddressTypeID  Col
Mismatch      1      Name
Mismatch      5      ModifiedDate Name
The requested operation took 0.296875 seconds.
```

The output first displays a summary of the parameters used and then shows the comparison results. In this example, it found the two differences that are due to updates performed on AddressTypeCopy. In addition, the `-f` parameter used in the example caused the `tablediff` utility to output a SQL file that can be used to fix the differences in the destination table. The output file from this example looks as follows:

```
— Host: (local)
— Database: [AdventureWorks2008R2]
— Table: [Person].[AddressTypeCopy]
SET IDENTITY_INSERT [Person].[AddressTypeCopy] ON
UPDATE [Person].[AddressTypeCopy]
  SET [Name]='Billing'
  WHERE [AddressTypeID] = 1
UPDATE [Person].[AddressTypeCopy]
  SET [ModifiedDate]='2002-06-01 00:00:00.000',
  [Name]='Shipping' WHERE [AddressTypeID] = 5
SET IDENTITY_INSERT [Person].[AddressTypeCopy] OFF
```

NOTE

The `tablediff` utility requires the source table to have at least one primary key, identity, or ROWGUID column. This gives the utility a key that it can use to try to match a corresponding row in the destination table. If the `-strict` option is used, the destination table must also have a primary key, identity, or ROWGUID column.

Keep in mind that several different types of comparisons can be done with the `tablediff` utility. The `-q` option causes a quick comparison that compares only record counts and looks for differences in the schema. The `-strict` option forces the schemas of each table to be the same when the comparison is run. If this option is not used, the utility allows some columns to be of different data types, as long as they meet the mapping requirements for the data type (for example, `INT` can be compared to `BIGINT`).

The `tablediff` utility can be used for many different types of comparisons. How you use this tool depends on several factors, including the amount and type of data you are comparing.

The bcp Command-Line Utility

You use the `bcp` (bulk copy program) tool to address the bulk movement of data. This utility is bidirectional, allowing for the movement of data into and out of a SQL Server database.

`bcp` uses the following syntax:

```
bcp {[[database_name.][owner.]]{table_name | view_name} | "query" }
    {in | out | queryout | format} data_file
    [-mmax_errors] [-fformat_file] [-x] [-eerr_file]
    [-Ffirst_row] [-Llast_row] [-bbatch_size]
    [-n] [-c] [-N] [-w] [-V (60 | 65 | 70 | 80)] [-6]
    [-q] [-C { ACP | OEM | RAW | code_page } ] [-tfield_term]
    [-rrow_term] [-iinput_file] [-ooutput_file] [-apacket_size]
    [-Sserver_name[\iinstance_name]] [-Ulogin_id] [-Ppassword]
    [-T] [-v] [-R] [-k] [-E] [-h"hint [,...n]" ]
```

Some of the commonly used options—other than the ones used to specify the database, such as user ID, password, and so on—are the `-F` and `-L` options. These options allow you to specify the first and last row of data to be loaded from a file, which is especially helpful in large batches. The `-t` option allows you to specify the field terminator that separates data elements in an ASCII file. The `-E` option allows you to import data into SQL Server fields that are defined with identity properties.

TIP

The `BULK INSERT T-SQL` statement and `SSIS` are good alternatives to `bcp`. The `BULK INSERT` statement is limited to loading data into SQL Server, but it is an extremely fast tool for loading data. `SSIS` is a sophisticated GUI that allows for both data import and data export, and it has capabilities that go well beyond those that were available in SQL Server 2000's Data Transformation Services (DTS).

This section barely scratches the surface when it comes to the capabilities of bcp. For a more detailed look at bcp, refer to the section, “Using bcp” in Chapter 52, “SQL Server Integration Services.”

The sqldiag Command-Line Utility

sqldiag is a diagnostic tool that you can use to gather diagnostic information about various SQL Server services. It is intended for use by Microsoft support engineers, but you might also find the information it gathers useful in troubleshooting a problem. sqldiag collects the information into files that are written, by default, to a folder named SQLDIAG, which is created where the file sqldiag.exe is located (for example, C:\Program Files\Microsoft SQL Server\100\Tools\bin\SQLDIAG\). The folder holds files that contain information about the machine on which SQL Server is running in addition to the following types of diagnostic information:

- ▶ SQL Server configuration information
- ▶ SQL Server blocking output
- ▶ SQL Server Profiler traces
- ▶ Windows performance logs
- ▶ Windows event logs

The syntax for sqldiag changed quite a bit in SQL Server 2005, but very little has changed in SQL Server 2008. Some of the options that were used in versions prior to SQL Server 2005 are not compatible with the current version. The full syntax for sqldiag is as follows:

```
sqldiag
  { [/?] }
  |
  { [/I configuration_file]
    [/O output_folder_path]
    [/P support_folder_path]
    [/N output_folder_management_option]
    [/C file_compression_type]
    [/B [+]start_time]
    [/E [+]stop_time]
    [/A SQLdiag_application_name]
    [/T { tcp [ ,port ] | np | lpc | via } ]
    [/Q] [/G] [/R] [/U] [/L] [/X] }
  |
  { [START | STOP | STOP_ABORT] }
  |
  { [START | STOP | STOP_ABORT] /A SQLdiag_application_name }
```

NOTE

Keep in mind that many of the options for sqldiag identify how and when the sqldiag utility will be run. The utility can be run as a service, scheduled to start and stop at a specific time of day, and it can be configured to change the way the output is generated. The details about these options are beyond the scope of this chapter but are covered in detail in SQL Server Books Online. This section is intended to give you a taste of the useful information that this utility can capture.

By default, the sqldiag utility must be run by a member of the Windows Administrators group, and this user must also be a member of the sysadmin fixed SQL Server role. To get a flavor for the type of information that sqldiag outputs, open a command prompt window, change the directory to the location of the sqldiag.exe file, and type the following command:

```
sqldiag
```

No parameters are needed to generate the output. The command prompt window scrolls status information across the screen as it collects the diagnostic information. You see the message “SQLDIAG Initialization starting...” followed by messages that indicate what information is being collected. The data collection includes a myriad of system information from MSINF032, default traces, and SQLDumper log files. When you are ready to stop the collection, you can press Ctrl+C.

If you navigate to the sqldiag output folder, you find the files created during the collection process. In this output folder, you should find a file with MSINF032 in its name. This file contains the same type of information that you see when you launch the System Information application from Accessories or when you run MSINF032.EXE. This is key information about the machine on which SQL Server is running. This information includes the number of processors, the amount of memory, the amount of disk space, and a slew of other hardware and software data.

You also find a file named *xxx_sp_sqldiag_Shutdown.out*, where *xxx* is the name of the SQL Server machine. This file contains SQL Server-specific information, including the SQL Server error logs, output from several key system stored procedures, including *sp_helpdb* and *sp_configure*, and much more information related to the current state of SQL Server.

You find other files in the sqldiag output directory as well. Default trace files, log files related to the latest sqldiag execution, and a copy of the XML file containing configuration information are among them. Microsoft documentation on these files is limited, and you may find that the best way to determine what they contain is simply to open the files and review the wealth of information therein.

The sqlservr Command-Line Utility

The `sqlservr` executable is the program that runs when SQL Server is started. You can use the `sqlservr` executable to start SQL Server from a command prompt. When you do that, all the startup messages are displayed at the command prompt, and the command prompt session becomes dedicated to the execution of SQL Server.

CAUTION

If you start SQL Server from a command prompt, you cannot stop or pause it by using SSMS, Configuration Manager, or the Services applet in the Control Panel. You should stop the application only from the command prompt window in which SQL Server is running. If you press Ctrl+C, you are asked whether you want to shut down SQL Server. If you close the command prompt window in which SQL Server is running, SQL Server is automatically shut down.

The syntax for the `sqlserver` utility is as follows:

```
sqlservr [-sinstance_name] [-c] [-dmaster_path] [-f]
         [-eerror_log_path] [-lmaster_log_path] [-m]
         [-n] [-Ttrace#] [-v] [-x] [-gnumber] [-h]
```

Most commonly, you start SQL Server from the command prompt if you need to troubleshoot a configuration problem. The `-f` option starts SQL Server in minimal configuration mode. This allows you to recover from a change to a configuration setting that prevents SQL Server from starting. You can also use the `-m` option when you need to start SQL Server in single-user mode, such as when you need to rebuild one of the system databases.

SQL Server functions when started from the command prompt in much the same way as it does when it is started as a service. Users can connect to the server, and you can connect to the server by using SSMS. What is different is that the SQL Server instance running in the command prompt appears as if it is not running in some of the tools. SSMS and SQL Server Service Manager show SQL Server as being stopped because they are polling the SQL Server service, which is stopped when running in the command prompt mode.

TIP

If you simply want to start the SQL Server service from the command prompt, you can use the `NET START` and `NET STOP` commands. These commands are not SQL Server specific but are handy when you want to start or stop SQL Server, especially in a batch file. The SQL Server service name must be referenced after these commands. For example, `NET START MSSQLSERVER` starts the default SQL Server instance.

Summary

SQL Server provides a set of command-line utilities that allow you to execute some of the available SQL Server programs from the command prompt. Much of the functionality housed in these utilities is also available in graphical tools, such as SSMS. However, the capability to initiate these programs from the command prompt is invaluable in certain scenarios.

Chapter 6, “SQL Server Profiler,” covers a tool that is critical for performance tuning in SQL Server 2008. SQL Server Profiler provides insight by monitoring and capturing the activity occurring on a SQL Server instance. It is a “go-to” tool for many DBAs and developers because of the wide variety of information that it can capture.

This page intentionally left blank

CHAPTER 6

SQL Server Profiler

This chapter explores the SQL Server Profiler, one of SQL Server's most powerful auditing and analysis tools. The SQL Server Profiler gives you a basic understanding of database access and helps you answer questions such as these:

- ▶ Which queries are causing table scans on my invoice history table?
- ▶ Am I experiencing deadlocks, and, if so, why?
- ▶ What SQL queries is each application submitting?
- ▶ Which were the 10 worst-performing queries last week?
- ▶ If I implement this alternative indexing scheme, how will it affect my batch operations?

SQL Server Profiler records activity that occurs on a SQL Server instance. The tool has a great deal of flexibility and can be customized for your needs. You can direct SQL Server Profiler to record output to a window, file, or table. You can specify which events to trace, the information to include in the trace, how you want that information grouped, and what filters you want to apply.

What's New with SQL Server Profiler

The SQL Server 2008 Profiler is essentially the same as the SQL Server 2005 profiler. This is not surprising because many new features that were added with SQL Server 2005 addressed gaps identified in previous versions. The changes made in SQL Server 2008 are generally minor and include several new trace events, one new trace column, and several other minor changes to the profiler GUI screens.

IN THIS CHAPTER

- ▶ What's New with SQL Server Profiler
- ▶ SQL Server Profiler Architecture
- ▶ Creating Traces
- ▶ Executing Traces and Working with Trace Output
- ▶ Saving and Exporting Traces
- ▶ Replaying Trace Data
- ▶ Defining Server-Side Traces
- ▶ Profiler Usage Scenarios

SQL Server Profiler Architecture

SQL Server 2008 has both a server and a client-side component for tracing activity on a server. The SQL trace facility is the server-side component that manages queues of events initiated by event producers on the server. Extended stored procedures can be used to define the server-side events that are to be captured. These procedures, which define a SQL trace, are discussed later in this chapter, in the section, “Defining Server-Side Traces.”

The SQL Profiler is the client-side tracing facility. It comes with a fully functional GUI that allows for real-time auditing of SQL Server events. When it is used to trace server activity, events that are part of a trace definition are gathered at the server. Any filters defined as part of the trace definition are applied, and the event data is queued for its final destination. The SQL Profiler application is the final destination when client-side tracing is used. The basic elements involved in this process are shown in Figure 6.1.

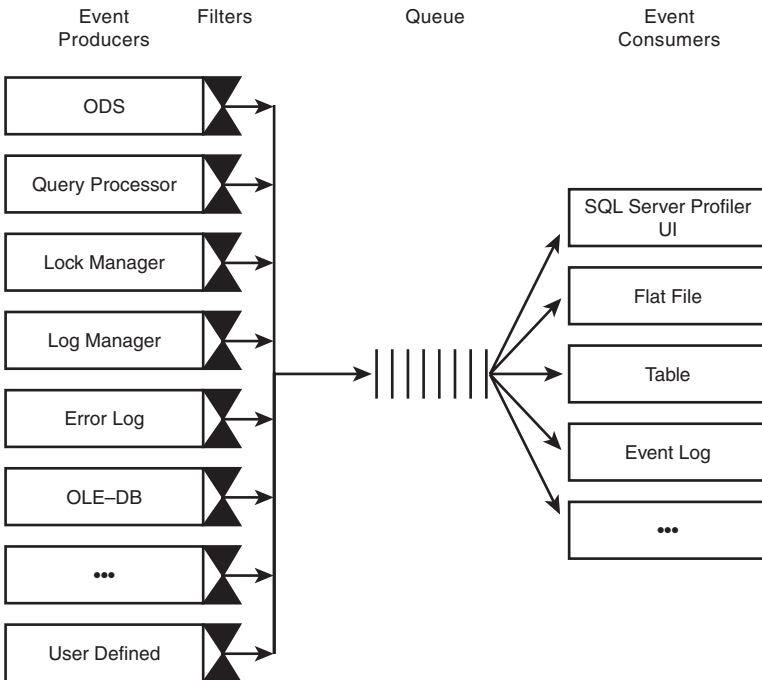

FIGURE 6.1 SQL Server Profiler's architecture.

This figure illustrates the following four steps in the process when tracing from the SQL Server Profiler:

1. Event producers, such as the Query Processor, Lock Manager, ODS, and so on, raise events for the SQL Server Profiler.
2. The filters define the information to submit to SQL Server Profiler. A producer will not send events if the event is not included in the filter.

3. SQL Server Profiler queues all the events.
4. SQL Server Profiler writes the events to each defined consumer, such as a flat file, a table, the Profiler client window, and so on.

In addition to obtaining its trace data from the event producers listed in step 1, you can also configure SQL Profiler so that it obtains its data from a previously saved location. This includes trace data saved in a file or table. The “Saving and Exporting Traces” section, later in this chapter, covers using trace files and trace tables in more detail.

Creating Traces

Because SQL Server Profiler can trace numerous events, it is easy to get lost when reading the trace output. You need to roughly determine the information you require and how you want the information grouped. For example, if you want to see the SQL statements that each user is submitting through an application, you could trace incoming SQL statements and group them by user and by application.

When you have an idea about what you want to trace, you should launch the SQL Server Profiler by selecting Start, then SQL Server 2008, then Performance Tools, and finally SQL Server Profiler. You also can launch it from within SSMS from the Tools menu. When you launch the Profiler, you are presented with an application window that is basically empty. To start a new trace, you select the File menu and choose New Trace. In the connection dialog that is displayed, you can enter the connectivity information for the server you want to trace. After the connection is established, the General tab of the Trace Properties window (see Figure 6.2) is displayed.

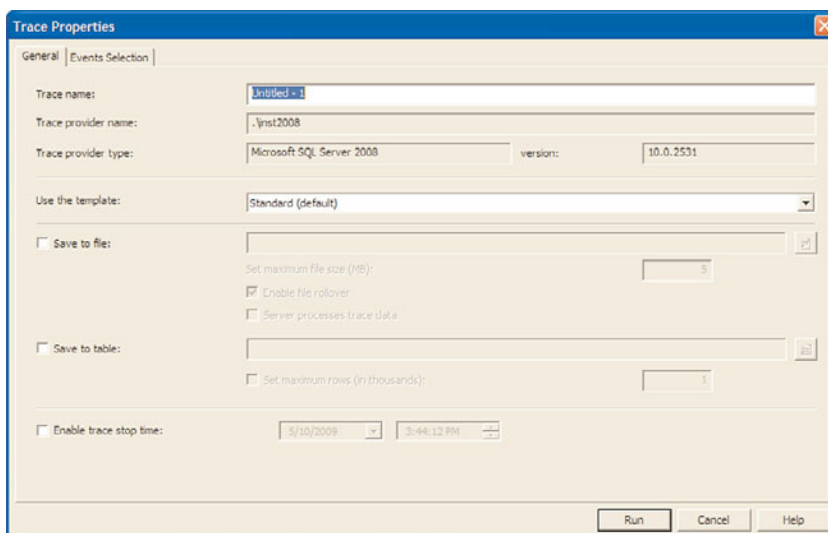

FIGURE 6.2 General trace properties.

The first place you should look when creating a new trace is at the trace templates. These templates contain predefined trace settings that address some common auditing needs. They have preset events, data columns, and filters targeted at specific profiling scenarios. The available trace templates, found in the template drop-down on the General tab of the Trace Properties window, are listed in Table 6.1.

TABLE 6.1 SQL Profiler Templates

Template	Description
SP_Counts	Tracks all the stored procedures as they start. No event except for the stored procedure starting is traced.
Standard	Traces the completion of SQL statements and Remote Procedure Calls (RPCs) as well as key connection information.
TSQL	Traces the start of SQL statements and RPCs. This template is useful for debugging client applications where some of the statements are not completing successfully.
TSQL_Duration	Traces the total execution time for each completed SQL statement or RPC.
TSQL_Grouped	Traces the start of SQL statements and RPCs, grouped by Application, NTUser, LoginName, and ClientProcessId.
TSQL_Locks	Traces the completion of SQL statements along with the key lock information that can be used to troubleshoot lock timeouts, deadlocks, and lock escalation issues.
TSQL_Replay	Captures profiling information that is useful for replay. This template contains the same type of information as the standard template, but it adds more detail, including cursor and RPC output details.
TSQL_SPs	Traces stored procedures in detail, including the start and completion of each stored procedure. The SQL statements within each procedure are traced as well.
Tuning	Performs a streamlined trace that tracks only the completion of SQL statements and RPCs. The completion events provide duration details that can be useful for performance tuning.

Keep in mind that the templates that come with SQL Server 2008 are not actual traces. They simply provide a foundation for you in creating your own traces. After you select a template, you can modify the trace setting and customize it for your own needs. You can then save the modified template as its own template file that will appear in the template drop-down list for future trace creation.

Trace Name is another property you can modify on the General tab. Trace Name is a relatively unimportant trace property for future traces. When you create a new trace, you can specify a name for the trace; however, this trace name will not be used again. For instance, if you have a trace definition you like, you can save the trace definition as a template file. If you want to run the trace again in the future, you can create a new trace and select the template file that you saved. You will not be selecting the trace to run based on the trace name you entered originally. Trace Name is useful only if you are running multiple traces simultaneously and need to distinguish between them more easily.

TIP

Do yourself a favor and save your favorite trace definitions in your own template. The default set of templates that come with SQL Server are good, but you will most likely want to change the position of a column or add an event that you find yourself using all the time. It is not hard to adjust one of the default templates to your needs each time, but if you save your own template with exactly what you need, it makes the task all the more easy. After you save your own template, you can set it as the default template, and it will be used by default every time you start the Profiler.

The Save to File and Save to Table options on the General tab of the Trace Properties page allow you to define where the trace output is stored. You can save the output to a flat file or SQL Server table. These options are discussed in more detail later in the chapter, in the section “Saving and Exporting Traces.”

The last option on the General tab of the Trace Properties window is the Enable Trace Stop Time option. This scheduling-oriented feature allows you to specify a date and time at which you want to stop tracing. This capability is handy if you want to start a trace in the evening before you go home. You can set the stop time so that the trace will run for a few hours but won't affect any nightly processing that might occur later in the evening.

Events

The events and data columns that will be captured by your Profiler trace are defined on the Events Selection tab. An example of the Events Selection tab is shown in Figure 6.3.

The Events Selection tab consolidates the selection of events, data columns, and filters on one screen. One of the biggest advantages of the SQL Server 2008 Events Selection tab is that you can easily determine which data columns will be populated for each event by looking at the columns that have check boxes available for the event. For example, the Audit Login event has check boxes for Text Data, ApplicationName, and others but does not have a check box available for CPU, Reads, Writes, and other data columns that are not relevant to the event. For those data columns that have check boxes, you have the

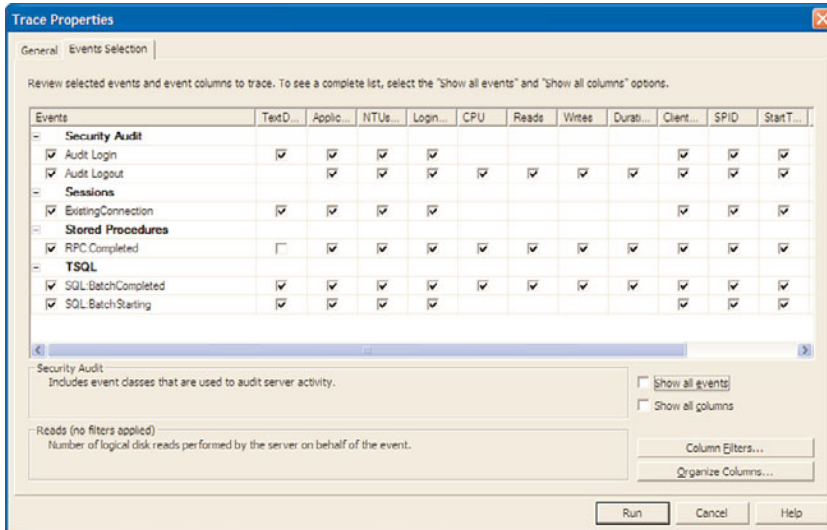

FIGURE 6.3 The Events Selection tab.

option of unchecking the box so that the data column will not be populated for the event when the trace is run.

You may find that adding events in SQL Server 2008 is a bit confusing. When you select a template, the event categories, selected events in those categories, and selected columns are displayed in the Events Selection tab. Now, if you want to add additional events, how do you do it? The answer to this question lies in the Show All Events check box in the lower-right corner of the Events Selection tab. When you click this check box, all the available event categories are listed on the screen. The events and columns that you had previously selected may or may not be visible on the screen. They are not lost, but you may need to scroll down the Events Selection tab to find the event categories that contain the events you had selected prior to selecting the Show All Events check box.

You will also notice that all the events in the categories in which you had events selected are displayed. In other words, if you had only 2 events selected in the Security Audit category and then selected the Show All Events check box, you see all 42 events listed. The only 2 events selected are the ones you had selected previously, but you need to wade through many events to see them. One upside to this kind of display is that you can easily view all the events for a category and the columns that relate to the events. One possible downside is that the Events Selection tab can be very busy, and it may take a little extra time to find what you are looking for.

TIP

If you capture too many events in one trace, the trace becomes difficult to review. Instead, you can create several traces, one for each type of information that you want to examine, and run them simultaneously. You can also choose to add or remove events after the trace has started. Keep in mind that you can pause a running trace, change the selected events, and restart the trace without losing the output that was there prior to pausing the trace.

Your ability to select and view events is made easier by using the tree control available on each event. The tree control allows you to expand or compress an event category. When you click the + icon next to a category, all the events are displayed. When you click the – icon, the event category is collapsed to a single row on the display. When an event has been selected for use within a category, the category name is shown in bold. If you want to add all the events in a category to your trace, you can simply right-click the category name and choose the Select Event Category option. You can also remove all events in a category by right-clicking the category name and choosing the Deselect Event Category option.

Understanding what each of the events captures can be a challenging task. You can refer to “SQL Server Event Class Reference” in Books Online for a detailed description, or you can use the simple Help facility available on the Events Selection tab. The Events Selection tab has a Help facility that describes each of the events and categories. The Help text is displayed on the Events Selection tab below the list of available events. When you mouse over a particular event or event category, a description of that item is shown. This puts the information you need at your fingertips.

NOTE

If you are going to use SQL Server Profiler, you should spend some time getting to know the events first and the type of output that Profiler generates. You should do this first in a development environment or standalone environment where the Profiler’s effect on performance does not matter. It’s a good idea to start a trace with a few events at a time and execute some relevant statements to see what is displayed for each event. You will soon realize the strength of the SQL Server Profiler and the type of valuable information it can return.

Data Columns

The columns of information captured in a Profiler trace are determined by the Data Columns selected. The Events Selection tab has the functionality you need to add columns, organize the columns, and apply filters on the data returned in these columns. As mentioned earlier, you can select and deselect the available columns for a particular event by using the check boxes displayed for the listed events. To understand what kind of

information a column is going to return, you can simply mouse over the column, and Help for that item is displayed in the second Help box below the event list. Figure 6.4 shows an example of the Help output. In this particular case, the mouse pointer is over the ApplicationName column returned for the SQL:BatchCompleted event. The first Help box displays information about the SQL:BatchCompleted event, and the second Help box shows information about the data column.

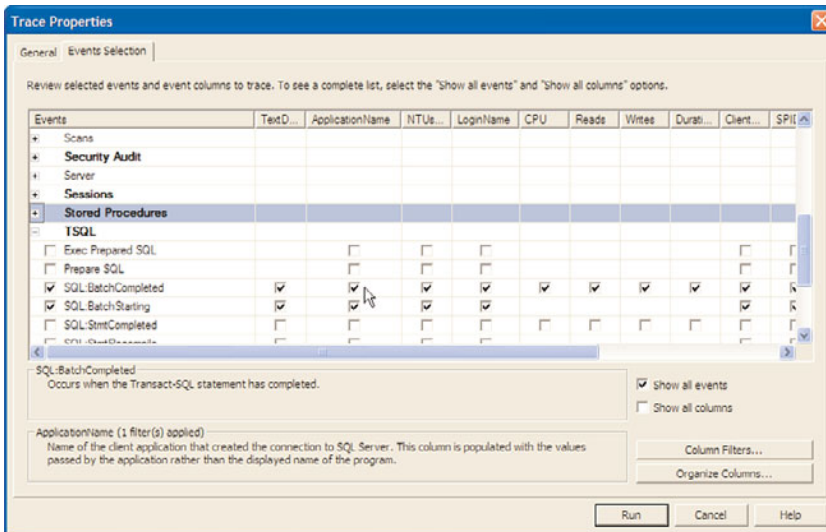

FIGURE 6.4 Help for data columns on the Events Selection tab.

Keep in mind that there is a default set of columns displayed for each event. You can view additional columns by selecting the Show All Columns check box. When you choose this option, an additional set of columns is displayed in the Events Selection tab. The additional columns are shown with a dark gray background, and you may need to scroll to the right on the Events Selection tab to be able to see them. Figure 6.5 shows an example of the additional columns displayed for the Performance event when the Show All Columns option is used. Some of the additional columns available for selection in this example are BigintData1 and BigintData2.

To organize the columns you have selected, you can choose the Organize Columns selection on the Events Selection tab. This Organize Columns window allows you to change the order of the columns in the trace output as well as group the data by selected columns. Figure 6.6 shows an example of the Organize Columns window with the groups and columns selected by default when you use the TSQL_Grouped template.

To change the order of a column, you simply select the column in the list and use the Up or Down buttons to move it. The same movement can be done with columns selected for grouping. You add columns to groups by selecting the column in the data list and clicking the Up button until the column is moved out of the Columns list and into the Groups

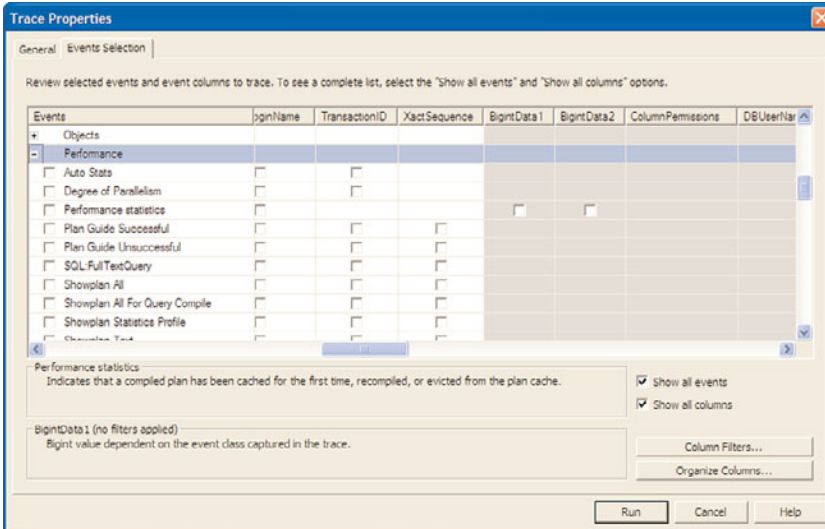

FIGURE 6.5 Additional columns displayed with the Show All Columns option.

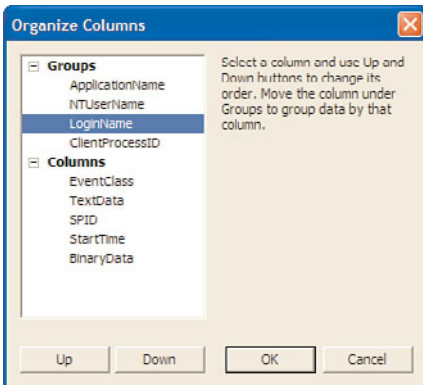

FIGURE 6.6 Organizing columns in the Events Selection tab.

list. For example, in Figure 6.6, you can group the SPID column by selecting it and clicking the Up button until it moves into the Groups tree structure instead of the Columns tree structure.

TIP

You can select a particular column for all events by right-clicking the column header in the Events Selection tab and choosing the Select Column option. This causes all the check boxes on the grid to be selected. To remove a column from all events, you right-click the column header and choose Deselect Column.

The number of columns selected for grouping and the order of the columns are both important factors in the way the trace data will be displayed. If you choose only one column for grouping, the trace window displays events grouped by the values in the grouped data column and collapses all events under it. For example, if you group by DatabaseId, the output in the trace window grid displays DatabaseId as the first column, with a + sign next to each DatabaseId that has received events. The number displayed to the right of the event in parentheses shows the number of collapsed events that can be viewed by clicking on the + sign. Figure 6.7 shows an example of the trace output window that has been grouped by DatabaseId only. The database with a DatabaseId equal to 6 is shown at the bottom of the grid in this example. The grid has been expanded, and some of the 20 events that were captured for this DatabaseId are shown.

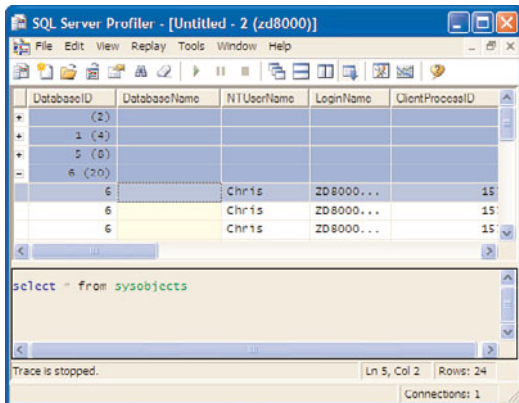

FIGURE 6.7 Grouping on a single column.

If you select multiple columns for grouping, the output in the trace window is ordered based on the columns in the grouping. The events are not rolled up like a single column, but the trace output grid automatically places the incoming events in the proper order in the output display.

TIP

The organization of columns in a trace can happen after a trace has been defined and executed. If you save the trace to a file or table, you can open it later and specify whatever ordering or grouping you want to reorganize the output. This flexibility gives you almost endless possibilities for analyzing the trace data.

Filters

Filters restrict the event data returned in your trace output. You can filter the events captured by the SQL Profiler via the Column Filters button on the Events Selection tab. An example of the Edit Filter window is shown in Figure 6.8. All the available columns for the

trace are shown on the left side of the Edit Filter window. Those columns that have filters on them have a filter icon displayed next to the column in the column list.

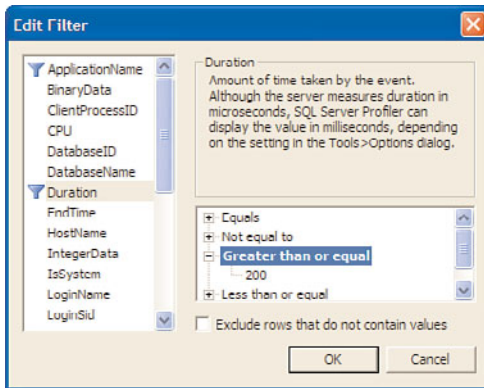

FIGURE 6.8 Editing filter properties.

The filtering options in SQL Server 2008 are similar to those available in SQL Server 2005. Which options are available depends on the type of column you are filtering on. The different filtering options are as follows:

- ▶ **Like/Not Like**—This option enables you to include or exclude events based on a wildcard. You should use the % character as your wildcard character. When you have completed a filter definition you can press Enter to create an entry space for another filter definition. For example, with the `ApplicationName` filter, you can specify `Like Microsoft%`, and you get only those events related to applications that match the wildcard, such as `Microsoft SQL Server Management Studio`. This filtering option is available for text data columns and data columns that contain name information, such as `NTUserName` and `ApplicationName`.
- ▶ **Equals/Not Equal To/Greater Than or Equal/Less Than or Equal**—Filters with this option have all four of these conditions available. For the `Equals` and `Not Equal To` conditions, you can specify a single value or a series of values. For a series of values, you hit enter after each value is entered and a new entry space is created for you to enter the next value. For the other conditional types, a single value is supplied. For example, you can filter on `DatabaseID` and input numeric values under the `Equals To` node of the filtering tree. This filtering option is available for numeric data columns such as `Duration`, `IndexId`, and `ObjectId`.
- ▶ **Greater Than/Less Than**—This type of filtering option is available only on time-based data columns. This includes `StartTime` and `EndTime` filters. These filters expect date formats of the form `YYYY-MM-DD` or `YYYY-MM-DD HH:MM:SS`.

Each data column can use one of these three filtering options. When you click the data column available for filtering, you see the filtering options for that column displayed in the right pane of the Edit Filter window. You enter the values on which you want to filter

in the data entry area on the filter tree. This input area is shown when you select a specific filtering option. For multiple filter values, you press the Enter key after you enter each value. This causes a new data entry area to appear below the value you were on.

CAUTION

Filters applied to columns that are not available or selected for an event do not prevent the event data from being returned. For example, if you place a filter on the `ObjectName` column and choose the `SQL:StmtStarting` event as part of your trace, the event data is not filtered because `ObjectName` is not a valid column for that event. This behavior may seem relatively intuitive, but it is something to consider when you are receiving output from a trace that you believe should have been filtered out.

Also, be careful when specifying multiple filter values and consider the Boolean logic applied to them. When you specify multiple values for the `Like` filter, the values are evaluated with an OR condition. For example, if you create a filter on `ObjectName` and have a `Like` filter with values of `A%`, `B%`, and `C%`, the filter returns object names that start with A or B or C. When you use the `Not Like` filter, the AND condition is used on multiple values. For example, `Not Like` filter values for `ObjectName` of `A%` and `C%` result in objects with names that do not start with A and object names that do not start with C.

Executing Traces and Working with Trace Output

After you define the events and columns you want to capture in a trace, you can execute the Profiler trace. To do so, you click the Run button on the Trace Properties window, and the Profiler GUI starts capturing the events you have selected. The GUI contains a grid that is centrally located on the Profiler window, and newly captured events are scrolled on the screen as they are received. Figure 6.9 shows a simple example of the Profiler screen with output from an actively running trace.

The Profiler GUI provides many different options for dealing with an actively running trace. You can turn off scrolling on the trace, pause the trace, stop the trace, and view the properties of an actively running trace. You can find strings within the trace output, and you can even move the columns around in the display so that they are displayed in a different order. These options provide a great deal of flexibility and allow you to focus on the output that is most important to you.

Saving and Exporting Traces

In many cases, you want to save or export the trace output generated by a Profiler trace. The output can be analyzed, replayed, imported, or manipulated at a later time after it has been saved. Trace output can be saved as the trace is running or saved after it has been generated to the Profiler GUI. The Trace Properties window provides options for saving trace output while the trace is running. The options are defined using the Save to File and Save to Table options on the General tab of the Trace Properties window. You can save to a

file, a table, or both a table and a file. Figure 6.10 shows an example of a trace that will save to both a file and table while it is executing.

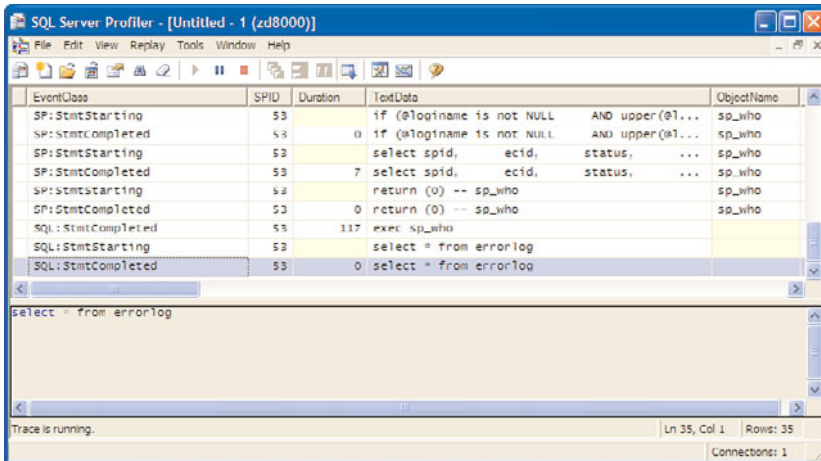

FIGURE 6.9 The Profiler GUI with an active trace.

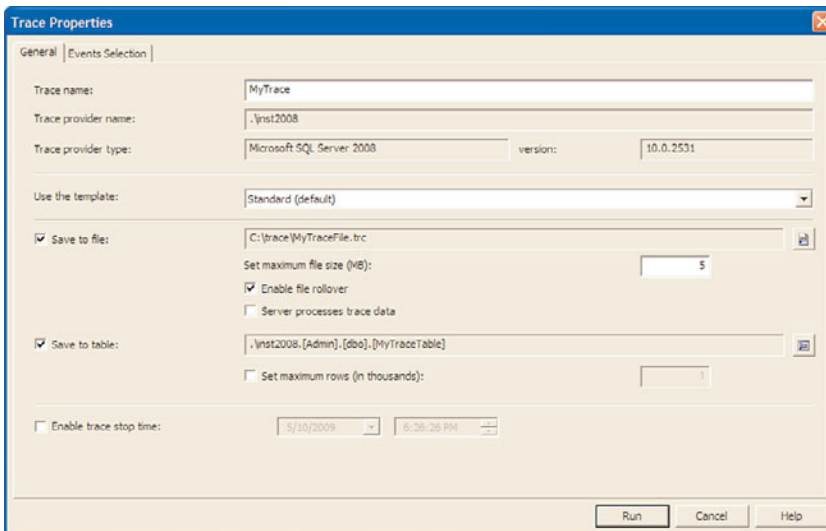

FIGURE 6.10 Saving trace output while a trace is running.

Saving Trace Output to a File

When you save a running trace to a file, you have several options for controlling the output. One option you should always consider is the Set Maximum File Size (MB) option. This option prevents a trace output file from exceeding the specified size. Controlling the

size helps make the file more manageable and, more importantly, it can save you from having a trace file gobble up all the disk space on the drive you are writing to. Remember that the amount of trace data written to a file on a busy production system can be extensive. You can also use this file size option in conjunction with the Enable File Rollover option. When the Enable File Rollover option is used, the trace does not stop when the file size maximum is met. Instead, a new trace file is created, and the output is generated to that file until it reaches the file size maximum.

Saving Trace Output to a Table

The Save to Table option writes the trace output directly to a SQL Server table as the trace is running. Having the data in a SQL table provides a great deal of flexibility for analyzing the data. You can use the full power of Transact-SQL against the table, including sorting, grouping, and more complex search conditions that are not available through the SQL Profiler filters.

You need to consider both the disk space requirements and impact on performance when the Save to Table option is used. The Profiler provides an option, Set Maximum Rows (in Thousands), to limit the amount of output generated from the trace. The performance impact depends on the volume of data being written to the table. Generally, you should avoid writing the trace output to a table when using high-volume SQL servers. The best option for high-volume servers is to first write the trace output to a file and then import the file to a trace table at a later time.

Saving the Profiler GUI Output

Another option for saving trace output occurs after trace output has been generated to the Profiler GUI and the trace has been stopped. Similar to the save options for an executing trace, the GUI output can be saved to a file or table. You access the options to save the GUI output by selecting File, Save As. The Trace File and Trace Table options are used to save to a file or table consecutively. With SQL Server 2008, you can also save the output to an XML file. The Trace XML File and Trace XML File for Replay options generate XML output that can be edited or used as input for replay with the SQL Server Profiler.

NOTE

Two distinct save operations are available in the SQL Profiler. You can save trace events to a file or table as just described, or you can save a trace definition in a template file. The Save As Trace Table and Save As Trace File options are for saving trace events to a file. The Save As Trace Template option saves the trace definition. Saving a trace template saves you the trouble of having to go through all the properties each time to set up the events, data columns, and filters for your favorite traces.

An alternative to saving all the event data associated with a particular trace is to select specific event rows from the SQL Profiler windows. You can capture all the trace information associated with a trace row by selecting a row in the trace output window of Profiler

and choosing Edit, Copy. Or, you can just copy the event text (typically a SQL statement) by selecting the row, highlighting the text in the lower pane, and using the Copy option. You can then paste this data into SSMS or the tool of your choice for further execution and more detailed analysis. This capability can be particularly useful during performance tuning. After you identify the long-running statement or procedure, you can copy the SQL, paste it into SSMS, and display the query plan to determine why the query was running so long.

Importing Trace Files

A trace saved to a file or table can be read back into SQL Profiler at a later time for more detailed analysis or to replay the trace on the same SQL Server or another SQL Server instance. You can import data from a trace file or trace table by choosing File, Open and then selecting either a trace file or trace table. If you choose to open a trace file, you are presented with a dialog to locate the trace file on the local machine. If you choose to import a trace table, you are first presented with a connection dialog to specify the SQL Server name, the login ID, and the password to connect to it. When you are successfully connected, you are presented with a dialog to specify the database and name of the trace table you want to import from. After you specify the trace file or trace table to import into Profiler, the entire contents of the file or table are read in and displayed in a Profiler window.

You may find that large trace files or trace tables are difficult to analyze, and you may just want to analyze events associated with a specific application or table, or specific types of queries. To limit the amount of information displayed in the Profiler window, you can filter out the data displayed via the Properties dialog. You can choose which events and data columns you want to display and also specify conditions in the Filters tab to limit the rows displayed from the trace file or trace table. These options do not affect the information stored in the trace file or trace table—only what information is displayed in the Profiler window.

Importing a Trace File into a Trace Table

Although you can load a trace file directly into Profiler for analysis, very large files can be difficult to analyze. Profiler loads an entire file. For large files, this process can take quite awhile, and the responsiveness of Profiler might not be the best. Multiple trace output files for a given trace can also be cumbersome and difficult to manage when those files are large.

You can use the trace filters to limit which rows are displayed but not which rows are imported into Profiler. You often end up with a bunch of rows displayed with no data in the columns you want to analyze. In addition, while the filters allow you to limit which rows are displayed, they don't really provide a means of running more complex reports on the data, such as generating counts of events or displaying the average query duration.

Fortunately, SQL Server 2008 provides a way for you to selectively import a trace file into a trace table. When importing a trace file into a trace table, you can filter the data before it goes into the table as well as combine multiple files into a single trace table. When the

data is in a trace table, you can load the trace table into Profiler or write your own queries and reports against the trace table for more detailed analysis than is possible in Profiler.

Microsoft SQL Server also includes some built-in user-defined functions for working with Profiler traces. The `fn_trace_gettable` function is used to import trace file data into a trace table. Following is the syntax for this function:

```
fn_trace_gettable( [ @filename = ] filename , [ @numfiles = ] number_files )
```

This function returns the contents of the specified file as a table result set. You can use the result set from this function just as you would any table. By default, the function returns all possible Profiler columns, even if no data was captured for the column in the trace. To limit the columns returned, you specify the list of columns in the query. If you want to limit the rows retrieved from the trace file, you specify your search conditions in the `WHERE` clause. If your Profiler trace used rollover files to split the trace across multiple files, you can specify the number of files you want it to read in. If the default value of `default` is used, all rollover files for the trace are loaded. Listing 6.1 provides an example of creating and populating a trace table from a trace file, using `SELECT INTO`, and then adding rows by using an `INSERT` statement. Note that this example limits the columns and rows returned by specifying a column list and search conditions in the `WHERE` clause.

LISTING 6.1 Creating and Inserting Trace Data into a Trace Table from a Trace File

```

/*****
** NOTE - you will need to edit the path/filename on your system if
**       you use this code to load your own trace files
*****/

select EventClass,
       EventSubClass,
       TextData = convert(varchar(8000), TextData),
       BinaryData,
       ApplicationName,
       Duration,
       StartTime,
       EndTime,
       Reads,
       Writes,
       CPU,
       ObjectID,
       IndexID,
       NestLevel
into TraceTable
FROM ::fn_trace_gettable('c:\temp\sampletrace_20090510_0622.trc', default)
where TextData is not null
      or EventClass in (16, -- Attention
                       25, -- Lock:Deadlock

```

```

27, — Lock:Timeout
33, — Exception
58, — Auto Update Stats
59, — Lock:Deadlock Chain
79, — Missing Column Statistics
80, — Missing Join Predicate
92, — Data File Auto Grow
93, — Log File Auto Grow
94, — Data File Auto Shrink
95) — Log File Auto Shrink

```

```

Insert into TraceTable (EventClass, EventSubClass,
    TextData, BinaryData,
    ApplicationName, Duration, StartTime, EndTime, Reads, Writes,
    CPU, ObjectID, IndexID, nestlevel)
select EventClass, EventSubClass,
    TextData = convert(varchar(7900), TextData), BinaryData,
    ApplicationName, Duration, StartTime, EndTime, Reads, Writes,
    CPU, ObjectID, IndexID, nestlevel
FROM ::fn_trace_gettable('c:\temp\sampletrace_ 20090510_0205.trc', -1)
where TextData is not null
    or EventClass in (16, — Attention
        25, — Lock:Deadlock
        27, — Lock:Timeout
        33, — Exception
        58, — Auto Update Stats
        59, — Lock:Deadlock Chain
        79, — Missing Column Statistics
        80, — Missing Join Predicate
        92, — Data File Auto Grow
        93, — Log File Auto Grow
        94, — Data File Auto Shrink
        95) — Log File Auto Shrink

```

go

After the trace file is imported into a trace table, you can open the trace table in Profiler or run your own queries against the trace table from a query editor window in SSMS. For example, the following query returns the number of lock timeouts encountered for each table during the period the trace was running:

```

select object_name(ObjectId), count(*)
    from TraceTable
    where EventClass = 27 — Lock:Timeout Event
    group by object_name(ObjectId)

```

go

Analyzing Trace Output with the Database Engine Tuning Advisor

In addition to being able to manually analyze traces in Profiler, you can also use the Database Engine Tuning Advisor to analyze the queries captured in a trace and recommend changes to your indexing scheme. The Database Engine Tuning Advisor is a replacement for the Index Tuning Wizard that was available in SQL Server 2000. You can invoke it from the Tools menu in SQL Profiler. The Database Engine Tuning Advisor can read in a trace that was previously saved to a table or a file. This feature allows you to capture a workload, tune the indexing scheme, and re-run the trace to determine whether the index changes improved performance as expected.

Because the Database Engine Tuning Advisor analyzes SQL statements, you need to make sure that the trace includes one or more of the following events:

```
SP:StmtCompleted
SP:StmtStarting
SQL:BatchCompleted
SQL:BatchStarting
SQL:StmtCompleted
SQL:StmtStarting
```

One of each class (one SP: and one SQL:) is sufficient to capture dynamic SQL statements and statements embedded in stored procedures. You should also make sure that the trace includes the text data column, which contains the actual queries.

The Database Engine Tuning Advisor analyzes the trace and gives you recommendations, along with an estimated improvement-in-execution time. You can choose to create indexes now or at a later time, or you can save the CREATE INDEX commands to a script file.

Replaying Trace Data

To replay a trace, you must have a trace saved to a file or a table. The trace must be captured with certain trace events to enable playback. The required events are captured by default if you use the Profiler template TSQL_Replay. You can define a trace to be saved when you create or modify the trace definition. You can also save the current contents of the trace window to a file or table by using the Save As Trace File or Save As Trace Table options in the File menu.

To replay a saved trace, you choose File and then Open to open a trace file or trace table. After you select the type of trace to replay, a grid with the trace columns selected in the original trace is displayed. At this point, you can either start the replay of the trace step-by-step or complete execution of the entire trace. The options for replaying the trace are found under the Replay menu. When you start the replay of the trace, the Connect to

Server dialog is displayed, enabling you to choose the server that you want to replay the traces against. When you are connected to a server, a Replay Configuration dialog like the one shown in Figure 6.11 is displayed.

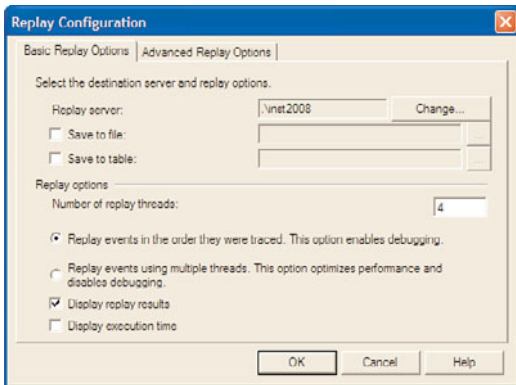

FIGURE 6.11 Basic replay options.

The first replay option, which is enabled by default, replays the trace in the same order in which it was captured and allows for debugging. The second option takes advantage of multiple threads; it optimizes performance but disables debugging. A third option involves specifying whether to display the replay results. You would normally want to see the results, but for large trace executions, you might want to forgo displaying the results and send them to an output file instead.

If you choose the option that allows for debugging, you can execute the trace in a manner similar to many programming tools. You can set breakpoints, step through statements one at a time, or position the cursor on a statement within the trace and execute the statements from the beginning of the trace to the cursor position.

NOTE

Automating testing scripts is another important use of the SQL Profiler Save and Replay options. For instance, a trace of a heavy production load can be saved and rerun against a new release of the database to ensure that the new release has similar or improved performance characteristics and returns the same data results. The saved traces can help make regression testing much easier.

You also have the option of specifying advanced replay options in SQL Server 2008. These options are found on the Advanced Replay Options tab of the Replay Configuration dialog (see Figure 6.12).

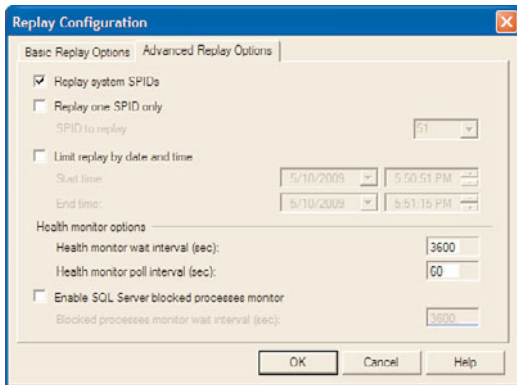

FIGURE 6.12 Advanced replay options.

The first two options on the Advanced Replay Options tab relate to the system process IDs (SPIDs) targeted for replay. If the Replay System SPIDs option is selected, the trace events for every SPID in the trace file will be replayed. If you want to target activity for a specific SPID, you should choose the Replay One SPID Only option and select the SPID from the drop-down menu. You can also limit the events that will be replayed based on the timing of the events. If you want to replay a specific time-based section of the trace, you can use the Limit Replay by Date and Time option. Only those trace events that fall between the data range you specify will be replayed.

The last set of advanced options is geared toward maintaining the health of the server on which you are replaying the trace. The Health Monitor Wait Interval (sec) option determines the amount of time a thread can run during replay before being terminated. This helps avoid an excessive drain on the server's resources. The Health Monitor Poll Interval (sec) option determines how often the health monitor will poll for threads that should be terminated. The last advanced option on the screen relates to blocked processes. When it is enabled, the monitor polls for blocked processes according to the interval specified.

Defining Server-Side Traces

Much of the SQL Server Profiler functionality can also be initiated through a set of system stored procedures. Through these procedures, you can define a server-side trace that can be run automatically or on a scheduled basis, such as via a scheduled job, instead of through the Profiler GUI. Server-side traces are also useful if you are tracing information over an extended period of time or are planning on capturing a large amount of trace information. The overhead of running a server-side trace is less than that of running a client-side trace with Profiler.

To start a server-side trace, you need to define the trace by using the trace-related system procedures. These procedures can be called from within a SQL Server stored procedure or batch. You define a server-side trace by using the following four procedures:

- ▶ **sp_trace_create**—This procedure is used to create the trace definition. It sets up the trace and defines the file to store the captured events. `sp_trace_create` returns a trace ID number that you need to reference from the other three procedures to further define and manage the trace.
- ▶ **sp_trace_setevent**—You need to call this procedure once for each data column of every event that you want to capture.
- ▶ **sp_trace_setfilter**—You call this procedure once for each filter you want to define on an event data column.
- ▶ **sp_trace_setstatus**—After the trace is defined, you call this procedure to start, stop, or remove the trace. You must stop and remove a trace definition before you can open and view the trace file.

You will find that manually creating procedure scripts for tracing can be rather tedious. Much of the tedium is due to the fact that many numeric parameters drive the trace execution. For example, the `sp_trace_setevent` procedure accepts an `eventid` and a `columnid` that determine what event data will be captured. Fortunately, SQL Server 2008 provides a set of catalog views that contain these numeric values and what they represent. The `sys.trace_categories` catalog view contains the event categories. The `sys.trace_events` catalog view contains the trace events, and `sys.trace_columns` contains the trace columns. The following `SELECT` statement utilizes two of these system views to return the available events and their related categories:

```
select e.trace_event_id, e.name 'Event Name', c.name 'Category Name'
  from sys.trace_events e
  join sys.trace_categories c on e.category_id = c.category_id
 order by e.trace_event_id
```

The results of this `SELECT` statement are shown in Table 6.2.

You have to call the `sp_trace_setevent` procedure once for each data column you want captured for each event in the trace. Based on the number of events and number of columns, you can see that this can result in a lot of executions of the `sp_trace_setevent` procedure for a larger trace definition.

To set up filters, you must pass the column ID, the filter value, and numeric values for the logical operator and column operator to the `sp_trace_setfilter` procedure. The logical operator can be either 0 or 1. A value of 0 indicates that the specified filter on the column should be ANDed with any other filters on the column, whereas a value of 1 indicates that the OR operator should be applied. Table 6.4 describes the values allowed for the column operators.

TABLE 6.4 Column Operator Values for `sp_trace_setfilter`

Value	Comparison Operator
0	= (equal)
1	<> (not equal)
2	> (greater than)
3	< (less than)
4	>= (greater than or equal)
5	<= (less than or equal)
6	LIKE
7	NOT LIKE

Fortunately, there is an easier way of generating a trace definition script. You can set up your traces by using the SQL Profiler GUI and script the trace definition to a file. After you define the trace and specify the events, data columns, and filters you want to use, you select File, Export, Script Trace Definition. The SQL commands (including calls to the aforementioned system stored procedures) to define the trace, start the trace, and write the trace to a file are generated into one script file. You have the option to generate a script that works with SQL Server 2000, 2005 or 2008. Listing 6.2 shows an example of a trace definition exported from the Profiler. It contains the trace definitions for the TSQL trace template. You must replace the text `InsertFileNameHere` with an appropriate filename, prefixed with its pathname, before running this script.

LISTING 6.2 A SQL Script for Creating and Starting a Server-Side Trace

```

/*****
/* Created by: SQL Server 2008 Profiler          */
/* Date: 05/10/2009 07:20:54 PM                */
*****/

-- Create a Queue
declare @rc int
declare @TraceID int
declare @maxfilesize bigint

```

```

set @maxfilesize = 5

-- Please replace the text InsertFileNameHere, with an appropriate
-- filename prefixed by a path, e.g., c:\MyFolder\MyTrace. The .trc extension
-- will be appended to the filename automatically. If you are writing from
-- remote server to local drive, please use UNC path and make sure server has
-- write access to your network share

exec @rc = sp_trace_create @TraceID output, 0, N'InsertFileNameHere', @maxfilesize,
NULL
if (@rc != 0) goto error

-- Client side File and Table cannot be scripted

-- Set the events
declare @on bit
set @on = 1
exec sp_trace_setevent @TraceID, 10, 2, @on
exec sp_trace_setevent @TraceID, 10, 12, @on
exec sp_trace_setevent @TraceID, 10, 13, @on
exec sp_trace_setevent @TraceID, 12, 1, @on
exec sp_trace_setevent @TraceID, 12, 12, @on
exec sp_trace_setevent @TraceID, 12, 13, @on

-- Set the Filters
declare @intfilter int
declare @bigintfilter bigint

-- Set the trace status to start
exec sp_trace_setstatus @TraceID, 1

-- display trace id for future references
select TraceID=@TraceID
goto finish

error:
select ErrorCode=@rc
finish:

go

```

TIP

If you want to always capture certain trace events when SQL Server is running, such as auditing events, you can create a stored procedure that uses the `sp_trace` stored procedures to create a trace and specify the events to be captured. You can use the code in Listing 6.2 as a basis to create the stored procedure. Then you can mark the procedure as a startup procedure by using the `sp_procoption` procedure to set the `autostart` option. The trace automatically starts when SQL Server is started, and it continues running in the background.

Just be aware that although using server-side traces is less intrusive than using the SQL Profiler client, some overhead is necessary to run a trace. You should try to limit the number of events and number of columns captured to minimize the overhead as much as possible.

Monitoring Running Traces

SQL Server 2008 provides some additional built-in user-defined functions to get information about currently running traces. Like the `fn_trace_gettable` function discussed previously, these functions return the information as a tabular result. The available functions are as follows:

- ▶ **`fn_trace_getinfo(trace_id)`**—This function is passed a `traceid`, and it returns information about the specified trace. If passed the value of `default`, it returns information about all existing traces. An example of the output from this function is shown in Listing 6.3.
- ▶ **`fn_trace_geteventinfo(trace_id)`**—This function returns a list of the events and data columns being captured for the specified trace. Only the event and column ID values are returned. You can use the information provided in Tables 6.2 and 6.3 to map the IDs to the more meaningful event names and column names.
- ▶ **`fn_trace_getfilterinfo(trace_id)`**—This function returns information about the filters being applied to the specified trace. Again, the column ID and logical and comparison operator values are returned as integer IDs that you need to decipher. See Table 6.4 for a listing of the column operator values.

LISTING 6.3 An Example of Using the Built-in User-Defined Functions for Monitoring Traces

```
SELECT * FROM ::fn_trace_getinfo(default)
```

traceid	property	value
1	1	2
1	2	C:\Program Files\Microsoft SQL Server\MSSQL.1\MSSQL\LOG\log_376.trc

```

1          3          20
1          4          NULL
1          5          1
2          1          0
2          2          c:\trace\mytrace.trc.trc
2          3          5
2          4          NULL
2          5          1

```

```
select * from ::fn_Trace_getfilterinfo(2)
```

columnid	logical_operator	comparison_operator	value
3	0	0	6
10	0	7	Profiler
10	0	7	SQLAgent

NOTE

You may be wondering why there is always a traceid with a value of 1 running when you run the `fn_trace_getinfo` procedure. This is the default trace that SQL Server automatically initiates when it starts. The default trace is enabled by default. You can identify which trace is the default by selecting from the `sys.traces` catalog view and examining the `is_default` column. The default trace captures a number of different types of events, including object creates and drops, errors, memory and disk changes, security changes, and more. You can disable this default trace, but it is generally lightweight and should be left enabled.

The output from the functions that return trace information is relatively cryptic because many of the values returned are numeric. For example, the property values returned by `fn_trace_getinfo` are specified as integer IDs. Table 6.5 describes each of these property IDs.

TABLE 6.5 Description of Trace Property ID Values

Property ID	Description
1	Trace options specified in <code>sp_trace_create</code>
2	Trace filename
3	Maximum size of trace file, in MB
4	Date and time the trace will be stopped
5	Current trace status

Stopping Server-Side Traces

It is important to keep track of the traces you have running and to ensure that “heavy” traces are stopped. Heavy traces are typically traces that capture a lot of events and are run on a busy SQL Server. These traces can affect the overall performance of your SQL Server machine and write a large amount of information to the trace output file. If you specified a stop time when you started the trace, it automatically stops and closes when the stop time is reached. For example, in the SQL script in Listing 6.2, if you wanted the trace to run for 15 minutes instead of indefinitely, you would set the value for the `stoptime` variable at the beginning of the script, using a command similar to the following:

```
set @stoptime = dateadd(minute, 15, getdate())
```

To otherwise stop a running server-side trace, you use the `sp_trace_setstatus` stored procedure and pass it the trace ID and a status of 0. Stopping a trace only stops gathering trace information and does not delete the trace definition from SQL Server. Essentially, it pauses the trace. You can restart the trace by passing `sp_trace_setstatus` a status value of 1.

After you stop a trace, you can close the trace and delete its definition from SQL Server by passing `sp_trace_setstatus` the ID of the trace you want to stop and a status value of 2. After you close the trace, you must redefine it before you can restart it.

If you don't know the ID of the trace you want to stop, you can use the `fn_trace_getinfo` function or the `sys.traces` catalog view to return a list of all running traces and select the appropriate trace ID. The following example shows how to stop and close a trace with a trace ID of 2:

```
-- Set the trace status to stop
exec sp_trace_setstatus 2, 0
go

-- Close and Delete the trace
exec sp_trace_setstatus 2, 2
go
```

If you want to stop and close multiple traces, you must call `sp_trace_setstatus` twice for each trace. Listing 6.4 provides an example of a system stored procedure that you can

create in SQL Server to stop a specific trace or automatically stop all currently running traces.

LISTING 6.4 A Sample System Stored Procedure to Stop Profiler Traces

```

use master
go
if object_id ('sp_stop_profiler_trace') is not null
    drop proc sp_stop_profiler_trace
go

create proc sp_stop_profiler_trace @TraceID int = null
as

if @TraceID is not null
begin
    -- Set the trace status to stop
    exec sp_trace_setstatus @TraceID, 0

    -- Delete the trace
    exec sp_trace_setstatus @TraceID, 2
end
else
begin
    -- the following cursor does not include the default trace
    declare c1 cursor for
    SELECT distinct traceid FROM :: fn_trace_getinfo (DEFAULT)
        WHERE traceId not in (select ID from sys.traces where is_default = 1)
    open c1
    fetch c1 into @TraceID
    while @@fetch_status = 0
    begin
        -- Set the trace status to stop
        exec sp_trace_setstatus @TraceID, 0

        -- Delete the trace
        exec sp_trace_setstatus @TraceID, 2
        fetch c1 into @TraceID
    end
    close c1
    deallocate c1
end
end

```

Profiler Usage Scenarios

This chapter has already covered many of the technical aspects of SQL Profiler, but what about some practical applications? Beyond the obvious uses of identifying what SQL statements an application is submitting, the following sections look at a few scenarios in which the SQL Profiler can be useful. These scenarios are presented to give you some ideas about how SQL Profiler can be used. You'll see that the monitoring and analysis capabilities of SQL Profiler are limited only by your creativity and ingenuity.

Analyzing Slow Stored Procedures or Queries

After you identify that a particular stored procedure is running slowly, what should you do? You might want to look at the estimated execution plan for the stored procedure, looking for table scans and sections of the plan that have a high cost percentage. But what if the execution plan has no obvious problems? This is the time you should consider using the SQL Profiler.

You can set up a trace on the stored procedure that captures the execution of each statement within it, along with its duration, in milliseconds. Here's how:

1. Create a new trace, using the `TSQL_Duration` template.
2. Add the `SP:StmtCompleted` event from the stored procedure event class to the trace.
3. Add a filter on the `Duration` column with the duration not equal to 0. You can also set the filter to a larger number to exclude more of the short-running statements.

If you plan to run the procedure from SSMS, you might want to add a filter on the `SPID` column as well. Set it equal to the process ID for your session; the `SPID` is displayed at the bottom of the SSMS window next to your username, in parentheses. This traces only those commands that are executed from your SSMS query editor window.

When you run the trace and execute the stored procedure, you see only those statements in the procedure that have nonzero duration. The statements are listed in ascending duration order. You need to look to the bottom of the Profiler output window to find your longer-running statements. You can isolate these statements, copy them to SSMS, and perform a separate analysis on them to determine your problem.

You can also add showplan events to your Profiler trace to capture the execution plan as the trace is running. SQL Server now has showplan events that capture the showplan results in XML format. Traces with this type of XML output can have a significant impact on server performance while they are running but make the identification of poorly performing statements much easier. When you are tracing stored procedure executions, it is a good idea to add a filter on the specific stored procedure you are targeting to help minimize the impact on performance.

After you run a trace with an XML showplan event, you can choose to extract the showplan events to a separate file. To do so, in the SQL Server Profiler you select File, Export,

Extract SQL Server Events, Extract Showplan Events. At this point, you can save the showplan events in a single file or to a separate file for each event. The file(s) is saved with a SQLPlan file extension. This file can then be opened in SSMS, and the graphical query execution plan is displayed.

Deadlocks

Deadlocks are a common occurrence in database management systems (DBMSs). In simple terms, deadlocks occur when a process (for example, SPID 10) has a lock on a resource that another process (for example, SPID 20) wants. In addition, the second process (SPID 20) wants the resource that the first process has locked. This cyclic dependency causes the DBMS to kill one of the processes to resolve the deadlock situation.

Resolving deadlocks and identifying the deadlock participants can be difficult. In SQL Server 2008 and past versions, trace flag 1204 can be set to capture the processes involved in the deadlock. The output is text based but provides valuable information about the types of locks and the statements that were executing at the time of the deadlock. In addition to this approach, SQL Server 2008 offers the capability to capture detailed deadlock information via the SQL Server Profiler. This type of tracing can be accomplished as follows:

1. Create a new trace, using a Blank template; this leaves the selection of all the events, data columns, and filters to you.
2. Add the Locks:Deadlock graph event to the trace from the Locks category. An additional tab named Event Extraction Settings appears on the Trace Properties window.
3. Click the Save Deadlock XML Events Separately check box. This causes the deadlock information to be written to a separate file. You could also export the results after the trace has been run by using the File, Export option.

When you run this trace, it captures any deadlock event that occurs and writes it to the XML file specified. To test this, you can open two query editor windows and execute the following statements, in the order listed, and in the query window specified:

```
-- In Query Window # 1
--Step1
USE ADVENTUREWORKS2008
GO
BEGIN TRAN
    UPDATE HumanResources.Employee SET ModifiedDate = GETDATE()

-- In Query Window # 2
--Step2
USE ADVENTUREWORKS2008
GO
BEGIN TRAN
    UPDATE HumanResources.Department SET ModifiedDate = GETDATE()
    SELECT * FROM HumanResources.Employee

-- In Query Window # 1
```

```
--Step3
SELECT * FROM HumanResources.Department
```

When the deadlock occurs, the results pane for one of the query windows contains a message similar to the following:

```
Msg 1205, Level 13, State 51, Line 3
Transaction (Process ID 55) was deadlocked on lock resources with another
process and has been chosen as the deadlock victim. Rerun the transaction.
```

When the row with the Deadlock graph event is selected in the Profiler output grid, a graph like the one shown in Figure 6.13 is displayed.

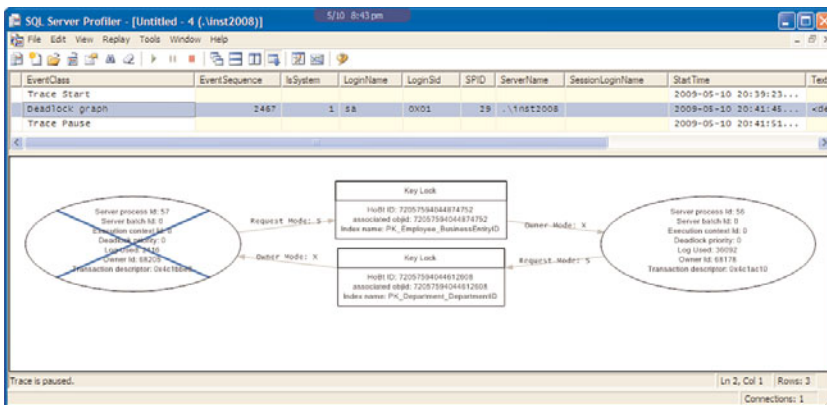

FIGURE 6.13 Output from the **Deadlock graph** event.

The Deadlock graph event contains a wealth of information about the deadlock occurrence. The oval nodes represent the processes involved in the deadlock. The oval with an X mark across it is the deadlock victim that had its process killed. The other oval represents the process that was allowed to complete when the deadlock was resolved. The boxes in the middle of the graph display lock information about the specific objects involved in the deadlock.

The graph is interactive and displays relevant information about the processes that were running when the deadlock occurred. For example, when you mouse over the oval nodes, pop-up text appears, displaying the SQL statement that was executing at the time of the deadlock. This is the same type of information that is displayed when the aforementioned trace flag is used, but the graph tends to be easier to decipher.

Identifying Ad Hoc Queries

One problem that can plague a production system is the execution of ad hoc queries against the production database. If you want to identify ad hoc queries, the application, and the users who are running them, SQL Profiler is your tool. You can create a trace as follows:

1. Create a new trace, using the `SQLProfilerStandard` template.
2. Add a new `ApplicationName` filter with `Like Microsoft%`.

When this trace is run, you can identify database access that is happening via SSMS or Microsoft Access. The user, the duration, and the actual SQL statement are captured. An alternative would be to change the `ApplicationName` filter to trace application access for all application names that are not like the name of your production applications, such as `Not Like MyOrderEntryApp%`.

Identifying Performance Bottlenecks

Another common problem with database applications is identifying performance bottlenecks. For example, say that an application is running slow, but you're not sure why. You tested all the SQL statements and stored procedures used by the application, and they were relatively fast. Yet you find that some of the application screens are slow. Is it the database server? Is it the client machine? Is it the network? These are all good questions, but what is the answer? SQL Profiler can help you find out.

You can start with the same trace definition used in the preceding section. For this scenario, you need to specify an `ApplicationName` filter with the name of the application you want to trace. You might also want to apply a filter to a specific `NTUserName` to further refine your trace and avoid gathering trace information for users other than the one that you have isolated.

After you start your trace, you use the slow-running application's screens. You need to look at the trace output and take note of the duration of the statements as they execute on the database server. Are they relatively fast? How much time was spent on the execution of the SQL statements and stored procedures relative to the response time of the application screen? If the total database duration is 1,000 milliseconds (1 second), and the screen takes 10 seconds to refresh, you need to examine other factors, such as the network or the application code.

With SQL Server 2008, you also combine Windows System Monitor (Perfmon) output with trace output to identify performance bottlenecks. This feature helps unite system-level metrics (for example, CPU utilization, memory usage) with SQL Server performance metrics. The result is a very impressive display that is synchronized based on time so that a correlation can be made between system-level spikes and the related SQL Server statements.

To try out this powerful new feature, you open the Perfmon application and add a new performance counter log. For simplicity, you can just add one counter, such as `% Processor Time`. Then you choose the option to manually start the log and click OK. Now, you want to apply some kind of load to the SQL Server system. The following script does index maintenance on two tables in the `AdventureWorks2008` database and can be used to apply a sample load:

```
USE [AdventureWorks2008]
GO
ALTER INDEX [PK_SalesOrderDetail_SalesOrderID_SalesOrderDetailID]
ON [Sales].[SalesOrderDetail]
```

```

REORGANIZE WITH ( LOB_COMPACTION = ON )
GO
PRINT 'FIRST INDEX IS REBUILT'
WAITFOR DELAY '00:00:05'
USE [AdventureWorks2008]
GO
ALTER INDEX [PK_Person_BusinessEntityID]
ON [Person].[Person] REBUILD WITH
( PAD_INDEX = OFF, STATISTICS_NORECOMPUTE = OFF,
  ALLOW_ROW_LOCKS = ON, ALLOW_PAGE_LOCKS = ON,
  SORT_IN_TEMPDB = OFF )
GO
PRINT 'SECOND INDEX IS REORGANIZED'

```

Next, you open the script in SSMS, but you don't run it yet. You open SQL Profiler and create a trace by using the Standard Profiler template. This template captures basic SQL Server activity and also includes the StartTime and EndTime columns that are necessary to correlate with the Perfmon counters. Now you are ready to start the performance log and the SQL Server Profiler trace. When they are running, you can run the sample load script. When the script has completed, you stop the performance log and Profiler trace. You save the Profiler trace to a file and then open the file in the Profiler application.

The correlation of the Perfmon log to the trace output file is accomplished from within the Profiler application. To do this, you select File, Import Performance Data. Then you select the performance log file that was just created; these files are located by default in the c:\perflogs folder. After you import the performance data, a new performance graph and associated grid with the performance counters is displayed in the Profiler, as shown in Figure 6.14

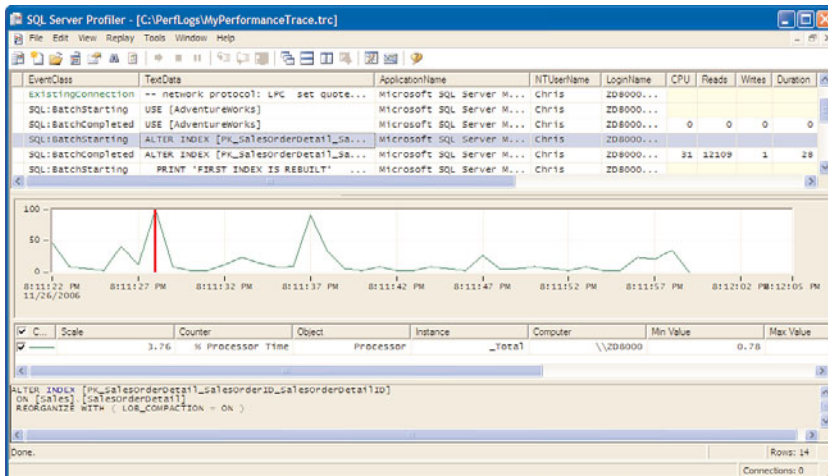

FIGURE 6.14 System Monitor counters correlated within a Profiler trace.

Now the fun begins! If you click one of the statements captured in the Profiler grid, a vertical red line appears in the Perfmon graph that reflects the time at which the statement was run. Conversely, if you click a location in the graph, the corresponding SQL statement that was run at that time is highlighted in the grid. If you see a spike in CPU in the Perfmon graph, you can click the spike in the graph and find the statement that may have caused the spike. This can help you quickly and efficiently identify bottlenecks and the processes contributing to it.

Monitoring Auto-Update Statistics

As discussed in Chapter 35, “Understanding Query Optimization,” SQL Server updates index statistics automatically as data is changed in a table. In some environments, excessive auto-updating of statistics can affect system performance while the statistics are being updated. SQL Profiler can be used to monitor auto-updating of statistics as well as automatic statistics creation.

To monitor auto-updating of statistics, you create a trace and include the `AutoStats` event from the `Performance` event category. Then you select the `TextData`, `Integer Data`, `Success`, and `Object ID` columns. When the `AutoStats` event is captured, the `Integer Data` column contains the number of statistics updated for a given table, the `Object ID` is the ID of the table, and the `TextData` column contains names of the columns together with either an `Updated:` or `Created:` prefix. The `Success` column contains potential failure indication.

If you see an excessive number of `AutoStats` events on a table or index, and the duration is high, it could be affecting system performance. You might want to consider disabling auto-update for statistics on that table and schedule statistics to be updated periodically during nonpeak periods. You may also want to utilize the `AUTO_UPDATE_STATISTICS_ASYNC` database setting, which allows queries that utilize affected statistics to compile without having to wait for the update of statistics to complete.

Monitoring Application Progress

The 10 user-configurable events can be used in a variety of ways, including for tracking the progress of an application or procedure. For instance, perhaps you have a complex procedure that is subject to lengthy execution. You can add debugging logic in this procedure to allow for real-time benchmarking via SQL Profiler.

The key to this type of profiling is the use of the `sp_trace_generateevent` stored procedure, which enables you to launch the `User configurable` event. The procedure needs to reference one of the `User configurable` event IDs (82 to 91) that correspond to the `User configurable` event 0 to 9. If you execute the procedure with `eventid = 82`, then `User configurable` event 0 catches these events.

Listing 6.5 contains a sample stored procedure that (in debug mode) triggers the trace events that SQL Profiler can capture.

LISTING 6.5 A Stored Procedure That Raises **User configurable** Events for SQL Profiler

```

CREATE PROCEDURE SampleApplicationProc (@debug bit = 0)
as
declare @userinfoParm nvarchar(128)
select @userinfoParm = getdate()

--if in debug mode, then launch event for Profiler
--    indicating Start of Application Proc
if @debug =1
begin
    SET @userinfoParm = 'Proc Start: ' + convert(varchar(30),getdate(),120)
    EXEC sp_trace_generateevent @eventid = 83, @userinfo = @userinfoParm
end

--Real world would have complex proc code executing here
--The WAITFOR statement was added to simulate processing time
WAITFOR DELAY '00:00:05'

--if debug mode, then launch event indicating next significant stage
if @debug =1
begin
    SET @userinfoParm = 'Proc Stage One Complete: '
                        + convert(varchar(20),getdate(),120)
    EXEC sp_trace_generateevent @eventid = 83, @userinfo = @userinfoParm
end

--Real world would have more complex proc code executing here
--The WAITFOR statement was added to simulate processing time
WAITFOR DELAY '00:00:05' --5 second delay

--if debug mode, then launch event indicating next significant stage
if @debug =1
begin
    SET @userinfoParm = 'Proc Stage Two Complete: '
                        + convert(varchar(30),getdate(),120)
    EXEC sp_trace_generateevent @eventid = 83, @userinfo = @userinfoParm
end

--You get the idea

GO

```

Now you need to set up a new trace that includes the `UserConfigurable:1` event. To do so, you choose the `TextData` data column to capture the `User configurable` output and

any other data columns that make sense for your specific trace. After this task is complete, you can launch the sample stored procedure from Listing 6.5 and get progress information via SQL Profiler as the procedure executes. You can accumulate execution statistics over time with this kind of trace and summarize the results. The execution command for the procedure follows:

```
EXEC SampleApplicationProc @debug = 1
```

The resulting SQL Profiler results are shown in Figure 6.15.

EventClass	TextData	SPID	StartTime
Trace Start			2009-05-10 21:25:09...
UserConfigurable:1	Proc start: 2009-05-10 21:26:36	57	2009-05-10 21:26:36...
UserConfigurable:1	Proc Stage One Complete: 2009-05-10...	57	2009-05-10 21:26:41...
UserConfigurable:1	Proc Stage Two Complete: 2009-05-10...	57	2009-05-10 21:26:46...
Trace Pause			2009-05-10 21:27:00...

FIGURE 6.15 **User configurable** trace results.

There are many other applications for `User configurable` events. How you use them depends on your specific need. As is the case with many Profiler scenarios, there are seemingly endless possibilities.

Summary

Whether you are a developer or database administrator, you should not ignore the power of the SQL Profiler. It is often one of the most underused applications in the SQL Server toolkit, yet it is one of the most versatile. Its auditing capabilities and ability to unravel complex server processes define its value.

This chapter wraps up the introduction to the tools and utilities available with SQL Server. Now you should be equipped to start administering and working with SQL Server.

The chapters in the next section focus on the overall administration of SQL, using some of the tools that you have been exposed to thus far. Chapter 7, “SQL Server System and Database Administration,” gives you some insight into the inner workings of SQL Server and what it takes to effectively administer a SQL Server instance.

CHAPTER 7

SQL Server System and Database Administration

This chapter outlines the role of a SQL Server system administrator and explores some of the methods that an administrator can use to query important system data. As with any other job, understanding the roles and responsibilities of the job is critical to doing the job well. The responsibilities of an administrator vary depending on the job, but there are some core responsibilities covered in this chapter.

You also need the right tools and right information to do the job well and do it efficiently. The system data covered in this chapter provides some of the key information. The methods discussed to access this information are among the tools you will need. System data discloses information that can be invaluable when assessing your SQL Server environment and is an essential part of administering a SQL Server database.

What's New in SQL Server System and Database Administration

The means for accessing system information has changed very little from SQL Server 2005 to SQL Server 2008. The new systems views that were introduced in SQL Server 2005 are still the preferred means for getting at that all-important system information. These views, which include catalog, compatibility, and dynamic views, are discussed in detail later in this chapter.

What is new in SQL Server 2008 is an expanded set of system views. These new views are geared toward some of the new functionality offered with SQL Server 2008. For example, new catalog and dynamic management views that

IN THIS CHAPTER

- ▶ What's New in SQL Server System and Database Administration
- ▶ System Administrator Responsibilities
- ▶ System Databases
- ▶ System Tables
- ▶ System Views
- ▶ System Stored Procedures

return information about Change Tracking and the Resource Governor have been added to cover these new features.

System Administrator Responsibilities

A system administrator is responsible for the integrity and availability of the data in a database. This is a simple concept, but it is a huge responsibility. Some large corporations place a valuation on their data as high as \$1 million per 100MB. The investment in dollars is not the only issue; many companies that lose mission-critical data simply never recover.

Job descriptions for system administrators vary widely. In small shops, the administrator might lay out the physical design, install SQL Server, implement the logical design, tune the installation, and then manage ongoing tasks, such as backups. At larger sites, tasks might be broken out into separate job functions. Managing users and backing up data are common examples. However, a lead administrator should still be in place to define policy and coordinate efforts.

Whether performed by an individual or as a team, the core administration tasks are as follows:

- ▶ Install and configure SQL Server.
- ▶ Plan and create databases.
- ▶ Manage data storage.
- ▶ Control security.
- ▶ Tune the database.
- ▶ Perform backup and recovery.

Another task sometimes handled by administrators is managing stored procedures. Because stored procedures for user applications often contain complex Transact-SQL (T-SQL) code, they tend to fall into the realm of the application developer. However, because stored procedures are stored as objects in the database, they are also the responsibility of the administrator. If an application calls custom stored procedures, the system administrator must be aware of this and coordinate with the application developers.

The system administration job can be stressful, frustrating, and demanding, but it is a highly rewarding, interesting, and respected position. As a system administrator, you are expected to know all, see all, and predict all, but you should be well compensated for your efforts.

System Databases

SQL Server uses system databases to support different parts of the database management system (DBMS). Each database plays a specific role and stores information that SQL Server needs to do its job. The system databases are much like the user databases created in SQL Server. They store data in tables and contain the views, stored procedures, and other

database objects that you also see in user databases. They also have associated database files (that is, .mdf and .ldf files) that are physically located on the SQL Server machine. Table 7.1 lists system databases and their related database filenames.

TABLE 7.1 System Databases and Their Associated Database Files

Database	.mdf Filename	.ldf Filename
master	master.mdf	mastlog.ldf
resource	mssqlsystemresource.mdf	mssqlsystemresource.ldf
model	model.mdf	modellog.ldf
msdb	msdbdata.mdf	msdblog.ldf
distribution	distmdl.ldf	distmdl.mdf
tempdb	tempdb.mdf	templog.ldf

TIP

You can use the `sys.master_files` catalog view to list the physical locations of the system database files as well as the user database files. This catalog view contains a myriad of information, including the logical name, current state, and size of each database file.

The folder where each of these database files is located depends on the SQL Server installation. By default, the installation process places these files in a folder named `<drive>:\Program Files\Microsoft SQL Server\MSSQL.1\MSSQL\Data\`. You can move these files after the installation by using special procedures that are documented in the SQL Server Books Online topic “Moving System Databases.”

The following sections describe the function of each system database.

The master Database

The master database contains server-wide information about the SQL Server system. This server-wide information includes logins, linked server information, configuration information for the server, and information about user databases created in the SQL Server instance. The actual locations of the database files and key properties that relate to each user database are stored in the master database.

SQL Server cannot start without a master database. This is not surprising, given the type of information that it contains. Without the master database, SQL Server does not know

the location of the databases that it services and does not know how the server is configured to run.

The resource Database

The resource database contains all the system objects deployed with SQL Server 2008. These system objects include the system stored procedures and system views that logically appear in each database but are physically stored in the resource database. Microsoft moved all the system objects to the resource database to simplify the upgrade process. When a new release of the software is made available, upgrading the system objects is accomplished by simply copying the single resource database file to the local server. Similarly, rolling back an upgrade only requires overwriting the current version of the resource database with the older version.

You do not see the resource database in the list of system databases shown in SQL Server Management Studio (SSMS). You also cannot add user objects to the resource database. For the most part, you should not be aware of the existence of the resource database. It has database files named `mssqlsystemresources.mdf` and `mssqlsystemresources.ldf` that are located in the `Binn` folder, but you cannot access the database directly. In addition, you do not see the database listed when selecting databases using system views or with system procedures, such as `sp_helpdb`.

The model Database

The `model` database is a template on which all user-created databases are based. All databases must contain a base set of objects known as the *database catalog*. When a new database is created, the `model` is copied to create the requisite objects. Conveniently, objects can be added to the `model` database. For example, if you want a certain table created in all your databases, you can create the table in the `model` database, and it is then propagated to all subsequently created databases.

The msdb Database

The `msdb` database is used to store information for the SQL Server Agent, the Service Broker, Database Mail, log shipping, and more. When you create and schedule a SQL Server Agent job, the job's parameters and execution history are stored in `msdb`. Backups and maintenance plan information are stored in `msdb` as well. If log shipping is implemented, critical information about the servers and tables involved in this process is stored in `msdb`.

The distribution Database

The distribution database, utilized during replication, stores metadata and history information for all types of replication. It is also used to store transactions when transactional replication is utilized. By default, replication is not set up, and you do not see the distribution database listed in SSMS. However, the actual data files for the distribution database are installed by default.

Refer to Chapter 19, “Replication,” for a more detailed discussion of the intricacies of replication.

The tempdb Database

The tempdb database stores temporary data and data objects. The temporary data objects include temporary tables, temporary stored procedures, and any other objects you want to create temporarily. The longevity of data objects in the temporary database depends on the type of object created. Ultimately, all temporary database objects are removed when the SQL Server service is restarted. The tempdb database is re-created, and all objects and data added since the last restart of SQL Server are lost.

tempdb can also be used for some of SQL Server’s internal operations. Large sort operations are performed in tempdb before the result set is returned to the client. Certain index operations can be performed in tempdb to offload some of the space requirements or to spread I/O. SQL Server also uses tempdb to store row versions that are generated from database modifications in databases that use row versioning or snapshot isolation transactions. Refer to Chapter 37 “Locking and Performance,” for a more detailed discussion of transaction isolation levels and row versioning.

Maintaining System Databases

You should give system databases the same attention that you give your user databases. These databases should be backed up on a regular basis and secured in the event that one of them needs to be restored. All the system databases, with the exception of tempdb and resource, can be backed up. These same databases can also be restored to bring them back to a previous state.

NOTE

Although you cannot back up the resource database using SQL Server’s BACKUP and RESTORE commands, you can make a backup copy of it by performing a file-based or disk-based backup of the mssqlsystemresource.mdf file (SQL Server must not be running at the time). Likewise, you can manually restore a backup copy of the mssqlsystemresource.mdf file only when SQL Server is not running. You must be careful not to overwrite the current resource database with a version for a different release level of SQL Server.

It’s important that you monitor the size of your system databases. The amount of data that accumulates in these databases can be significant. This is particularly true for the tempdb, msdb, and distribution databases. Large sort or index operations can increase the size of your tempdb database in a short period of time. The msdb and distribution databases contain a great deal of historical information. Consider, for example, a server with hundreds of databases that have log backups occurring every 15 minutes. The information captured for each individual backup is not significant, but the total number of databases

and frequency of the backups cause many rows to be stored in the `msdb` database. Cleanup tasks and similar activities that remove older historical data can help keep the database size manageable.

System Tables

System tables contain data about objects in the SQL Server databases (that is, metadata) as well as information that SQL Server components use to do their job. Many of the system tables are now hidden (in the resource database) and are no longer available for direct access by end users. In SQL Server 2008, compatibility views, which are discussed later in this chapter, have the same names as the system tables available in SQL Server 2000. For example, if you had a query in SQL Server 2000 that selected from `syscolumns`, this query continues to work in SQL Server 2008, but the results come from a view instead of a system table.

The system tables that you can view are now found in some of the system databases, such as `msdb` or `master`. You can use the Object Explorer in SSMS to view the system tables in these databases. Figure 7.1 shows the system tables listed for the `master` database in the Object Explorer.

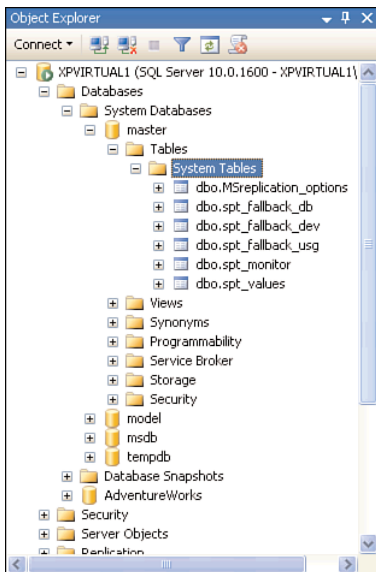

FIGURE 7.1 System tables listed in Object Explorer.

The most significant number of viewable system tables is found in the `msdb` system database. The system tables there support backup and restore, log shipping, maintenance plans, Notification Services, the SQL Server Agent, and more. You can retrieve a tremendous amount of information from these system tables if you know what you are looking

for. The following query selects from the system tables in msdb to report on recent restores for the AdventureWorks2008R2 database:

```
select destination_database_name 'database', h.restore_date, restore_type,
       cast((backup_size/1024)/1024 as numeric(8,0)) 'backup_size MB',
       f.physical_device_name
from msdb..restorehistory h (NOLOCK)
     LEFT JOIN msdb..backupset b (NOLOCK)
         ON h.backup_set_id = b.backup_set_id
     LEFT JOIN msdb..backupmediafamily f (NOLOCK)
         ON b.media_set_id = f.media_set_id
where h.restore_date > getdate() - 5
     and UPPER(h.destination_database_name) = 'AdventureWorks2008R2'
order by UPPER(h.destination_database_name), h.restore_date desc
```

One of the challenges with using system tables is determining the relationships between them. Some vendors offer diagrams of these tables, and you can also determine the relationships by reviewing the foreign keys on these tables and by referring to SQL Server 2008 Books Online, which describes the use for each column in the system table.

CAUTION

Microsoft does not recommend querying system tables directly. It does not guarantee the consistency of system tables across versions and warns that queries that may have worked against system tables in past versions may no longer work. Catalog views or information schema views should be used instead, especially in production code.

Queries against system tables are best used for ad hoc queries. The values in system tables should never be updated, and an object's structure should not be altered, either. Making changes to the data or structure could cause problems and cause SQL Server or one of its components to fail.

System Views

System views are virtual tables that expose metadata that relates to many different aspects of SQL Server. Several different types of views target different data needs. SQL Server 2008 offers an extended number of system views and view types that should meet most, if not all, your metadata needs.

The available system views can be shown in the Object Explorer in SSMS. Figure 7.2 shows the Object Explorer with the System Views node highlighted. There are far too many views to cover in detail in this chapter, but we cover each type of view and provide an example of each to give you some insight into their value. Each system view is covered in

detail in SQL Server Books Online, which includes descriptions of each column in the view.

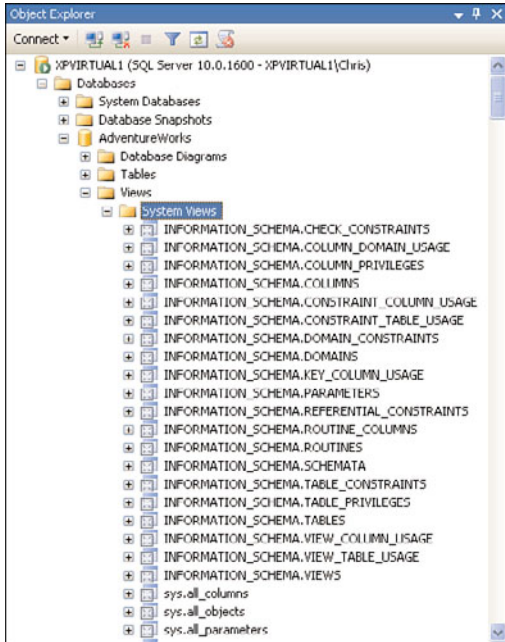

FIGURE 7.2 System views listed in Object Explorer.

Compatibility Views

Compatibility views were retained in SQL Server 2008 for backward compatibility. Many of the system tables available in SQL Server 2000 and prior versions of SQL Server are now implemented as compatibility views. These views have the same name as the system tables from prior versions and return the same metadata available in SQL Server 2000. They do not contain information that was added after SQL Server 2000.

You can find most of the compatibility views in the Object Explorer by looking for system views that have names starting with `sys.sys`. For example, `sys.syscolumns`, `sys.syscomments`, and `sys.sysobjects` are all compatibility views. The first part of the name indicates the schema that the object belongs to (in this case, `sys`). All system objects are part of this `sys` schema or the `INFORMATION_SCHEMA` schema. The second part of the name is the view name, which corresponds to the name of a system table in SQL Server 2000.

TIP

To see a list of compatibility views, use the index lookup in SQL Server 2008 Books Online and look for `sys.sys`. The index is placed at the beginning of a list of compatibility views, starting with `sys.sysaltfiles`. Objects in the list that are compatibility views have the text `compatibility view` following the object name, so you can easily identify them and get help.

You also can use the new IntelliSense feature available with SQL Server 2008 to obtain information about the compatibility views and other system views. Simply open a query window in SSMS and start typing a `SELECT` statement. When you start typing the name of the view that you want to select from (for example, `sys.`) the IntelliSense drop-down appears listing the views that start with the letters `sys`. You can also determine the columns available from the view by referencing the view or alias for the view in the column selection list. When you enter the period following the view or alias, the IntelliSense drop-down shows you the available columns.

You should transition from the use of compatibility views to the use of other system views, such as catalog views. The scripts that were created in SQL Server 2000 and reference SQL Server 2000 system tables should continue to function in SQL Server 2008, but this capability is strictly for backward compatibility. Table 7.2 provides a list of SQL Server 2000 system tables and alternative SQL Server 2008 system views you can use instead.

TABLE 7.2 SQL Server 2008 Alternatives for SQL Server 2000 System Tables

SQL Server 2000 System Table	SQL Server 2008 System View	View Type
<code>sysaltfiles</code>	<code>sys.master_files</code>	Catalog view

sysusers	sys.database_principals	Catalog view

Catalog Views

Using catalog views is the preferred method for returning information used by the Microsoft SQL Server database engine. There is a catalog view to return information about almost every aspect of SQL Server. The number of catalog views is far too large to list here, but you can gain some insight into the range of information available by looking at the following list, which shows the categories of information covered by catalog views:

- ▶ Change Tracking
- ▶ Common language runtime (CLR) assembly
- ▶ Data spaces and full text
- ▶ Database mirroring
- ▶ Data spaces
- ▶ Endpoint
- ▶ Extended properties
- ▶ Linked servers
- ▶ Messages (for errors)
- ▶ Objects
- ▶ Partition function
- ▶ Resource Governor
- ▶ Scalar types
- ▶ Schemas

- ▶ Security
- ▶ Server-wide configuration
- ▶ Service Broker
- ▶ SQL Server Extended Events
- ▶ XML schemas (XML type system)

Some of the catalog views return information that is new to SQL Server 2008. Examples include the Change Tracking and Resource Governor catalog views. Other catalog views provide information that may have been available in prior versions through system tables, system procedures, and so on, but the new catalog views expand on the information returned and include elements that are new to SQL Server 2008.

To demonstrate the use of a catalog view, let's compare a simple SQL Server 2000 `SELECT` statement that returns object information to a `SELECT` statement in SQL Server 2008 that returns similar information. The following example shows a `SELECT` statement written in SQL Server 2000 to return any stored procedure created after a given date:

```
select o.crdate, o.name
  from sysobjects o
 where type = 'p'
    and crdate > '1/1/08'
 order by crdate, name
```

Now, compare this `SELECT` statement to one that uses a SQL Server 2008 catalog view. The `sys.objects` catalog view is a new alternative to the SQL Server 2000 `sysobjects` system table. The following `SELECT` uses the `sys.objects` catalog view to return the same type of information as the preceding example:

```
select o.create_date, o.modify_date, name
  from sys.objects o
 where type = 'p'
    and (create_date > '1/1/08'
        or o.modify_date >= '1/1/08')
 order by 1, 2, 3
```

As you can see, the `modify_date` column has been added to the `SELECT` statement. This column did not exist with the `sysobjects` system table. The addition of this column allows you to identify objects that were created as well as objects that were modified or altered.

Let's look at an example of using a catalog view to return the same kind of information returned in SQL Server 2000 with a system procedure. The handy `sp_helpfile` system procedure returns information about database files associated with a given database. This SQL Server 2000 procedure is still available in SQL Server 2008. An alternative to this procedure is the new `sys.master_files` catalog view. This view returns all the information that `sp_helpfile` returns and more. The following example shows a `SELECT` statement

using the `sys.master_files` catalog view to return the database files for the AdventureWorks2008R2 database:

```
select *
  from sys.master_files
 where db_name(database_id) = 'AdventureWorks2008R2'
```

You have the distinct advantage of being able to select the database files for all the databases on your server by using this catalog view. You can also tailor your `SELECT` statement to isolate database files based on the size of the database or the location of the physical database files. For example, to return all database files that are found somewhere on your C drive, you could use the following `SELECT`:

```
select db_name(database_id), physical_name
  from sys.master_files
 where physical_name like 'c:\%'
```

There are plenty of catalog views that provide information about SQL Server. When you are looking to return information about SQL Server components, you should look to the catalog views first. These views provide a great deal of flexibility and allow you to isolate the specific information you need.

Information Schema Views

Information schema views provide another system table-independent option for accessing SQL Server metadata. This type of view was available in prior versions of SQL Server. Using information schema views is a viable alternative for accessing SQL Server metadata from a production application. The information schema views enable an application that uses them to function properly even though the underlying system tables may have changed. Changes to the underlying system tables are most prevalent when a new version of SQL Server is released (such as SQL Server 2008), but changes can also occur as part of service packs to an existing version.

The information schema views also have the advantage of being SQL-92 compatible. Compliance with the SQL-92 standard means that SQL statements written against these views work with other DBMSs that also adhere to the SQL-92 standard. The SQL-92 standard supports a three-part naming convention, which SQL Server has implemented as `database.schema.object`.

In SQL Server 2008, all the information schema views are in the same schema, named `INFORMATION_SCHEMA`. The following information schema views or objects are available:

- ▶ `CHECK_CONSTRAINTS`
- ▶ `COLUMN_DOMAIN_USAGE`
- ▶ `COLUMN_PRIVILEGES`
- ▶ `COLUMNS`
- ▶ `CONSTRAINT_COLUMN_USAGE`

- ▶ CONSTRAINT_TABLE_USAGE
- ▶ DOMAIN_CONSTRAINTS
- ▶ DOMAINS
- ▶ KEY_COLUMN_USAGE
- ▶ PARAMETERS
- ▶ REFERENTIAL_CONSTRAINTS
- ▶ ROUTINES
- ▶ ROUTINE_COLUMNS
- ▶ SCHEMATA
- ▶ TABLE_CONSTRAINTS
- ▶ TABLE_PRIVILEGES
- ▶ TABLES
- ▶ VIEW_COLUMN_USAGE
- ▶ VIEW_TABLE_USAGE
- ▶ VIEWS

When you refer to information schema views in a SQL statement, you must use a qualified name that includes the schema name. For example, the following statement returns all the tables and columns in a given database, using the `tables` and `columns` information schema views:

```
select t.TABLE_NAME, c.COLUMN_NAME
from INFORMATION_SCHEMA.TABLES t
  join INFORMATION_SCHEMA.COLUMNS c on t.TABLE_NAME = c.TABLE_NAME
order by t.TABLE_NAME, ORDINAL_POSITION
```

TIP

You can expand the Views node in a given database in the Object Explorer and open the System Views node to see a list of the available information schema views. The information schema views are listed at the top of the System Views node. If you expand the Column node under each information schema view, you see the available columns to select from the view. You can then drag the column into a query window for use in a SELECT statement. You can also use IntelliSense in a query window determine the columns.

Fortunately, the names of the information schema views are fairly intuitive and reflect the kind of information they contain. The relationships between the information schema views can be derived from the column names shared between the tables.

Dynamic Management Views

Dynamic management views (DMVs), which were introduced in SQL Server 2005, provide a simple means for assessing the state of a server. These views provide a lightweight means for gathering diagnostic information without the heavy burden associated with the tools available in SQL Server 2000. The SQL Server 2000 diagnostic tools, such as heavy Profiler traces, PerfMon, dbcc executions, and pssdiag, are still available, but oftentimes, the information returned from the DMVs is enough to determine what may be ailing a SQL Server machine.

An extensive number of DMVs are available in SQL Server 2008. Some DMVs are scoped at the server level, and others are scoped at the database level. They are all found in the sys schema and have names that start with dm_. Table 7.3 lists the different types of DMVs. The DMVs in this table are categorized based on function as well as the starting characters in the DMV names. The naming convention gives you an easy means for identifying the type of each DMV.

TABLE 7.3 Types of DMVs

Category	Name Prefix	Information Captured
Auditing	dm_audit	New Auditing information
Service Broker	dm_broker	Server Broker statistics, including activated tasks and connections
Change Data	dm_cdc	New Change Data Capture information
CLR	dm_clr	CLR information, including the CLR loaded assemblies
Cryptographic	dm_cryp	Security related data
TDE	dm_database	Transparent Data Encryption
Database	dm_db	Databases and database objects
Execution	dm_exec	Execution of user code
Full-Text	dm_fts	Full-Text Search information
I/O	dm_io	Input and output on network disks
Operating system	dm_os	Low-level operating system information, including memory and locking information
Provider	dm_provider	Extensible Key Management (EKM)
Query Notification	dm_qn	Active Query Notification subscriptions
Replication	dm_rep1	Replication information, including the articles, publications, and transaction involved in replication

TABLE 7.3 Types of DMVs

Category	Name Prefix	Information Captured
Server	dm_server	Server Audit status
Transaction	dm_tran	Transactions and isolation-level information
Object	dm_sql	Object References
Extended Events	dm_xe	New event handling infrastructure

TIP

You can expand the Views node in a given database in the Object Explorer and open the System Views node to see a list of the available DMVs. The DMVs are all listed together and start with dm_. If you expand the Column node under each DMV, you see the available columns to select from the view. You can then drag the column into a query window to be included in a SELECT statement.

To illustrate the value of the DMVs, let's look at a performance scenario and compare the SQL Server 2000 approach to a SQL Server 2008 approach using DMVs. A common performance-related question is "What stored procedures are executing most frequently on my server?" With SQL Server 2000, the most likely way to find out is to run a Profiler trace. You must have a Profiler trace that has already been running to capture the stored procedure executions, or you must create a new trace and run it for a period of time to answer the performance question. The trace takes time to create and can affect server performance while it is running.

With SQL Server 2008, you can use one of the DMVs in the execution category to answer the same performance question. The following example uses the sys.dm_exec_query_stats DMV along with a dynamic management function named dm_exec_sql_text. It returns the object IDs of the five most frequently executed stored procedures, along with the actual text associated with the procedure:

```
select top 5 q.execution_count, q.total_worker_time,
  s.dbid, s.objectid, s.text
from sys.dm_exec_query_stats q
CROSS APPLY sys.dm_exec_sql_text (q.sql_handle) s
ORDER BY q.execution_count desc
```

The advantage of using a DMV is that it can return past information without having to explicitly create a trace or implement some other performance tool. SQL Server automatically caches the information so that you can query it at any time. The collection of the data starts when the SQL Server instance is started, so you can get a good cross-section of information. Keep in mind that your results can change as the server continues to collect information over time.

Many of the performance scenarios such as those that relate to memory, CPU utilization, blocking, and recompilation can be investigated using DMVs. You should consider using

DMVs to address performance problems before using other methods in SQL Server 2008. In many cases, you may be able to avoid costly traces and glean enough information from the DMV to solve your problem.

NOTE

Dynamic management functions return the same type of information as DMVs. The dynamic management functions also have names that start with `dm_` and reside in the `sys` schema. You can find the dynamic management functions listed in the Object Explorer within the master database. If you select Function, System Functions, Table-Valued Functions, you see the dynamic management functions listed at the top.

DMVs are also a great source of information that does not relate directly to performance. For example, you can use the `dm_os_sys_info` DMV to gather important server information, such as the number of CPUs, the amount of memory, and so on. The following example demonstrates the use of the `dm_os_sys_info` DMV to return CPU and memory information:

```
select cpu_count, hyperthread_ratio, physical_memory_in_bytes
from sys.dm_os_sys_info
```

```
/* Results from prior select
```

```
cpu_count    hyperthread_ratio  physical_memory_in_bytes
-----
2            2                  2146357248
*/
```

The `cpu_count` column returns the number of logical CPUs, `hyperthread_ratio` returns the ratio between physical CPUs and logical CPUs, and the last column selected returns the physical memory on the SQL Server machine.

System Stored Procedures

System stored procedures have been a favorite of SQL Server DBAs since the inception of SQL Server. They provide a rich set of information that covers many different aspects of SQL Server. They can return some of the same types of information as system views, but they generally return a fixed set of information that cannot be modified as you can when using a `SELECT` statement against the system views. That is not to say that they are not valuable; they are valuable, and they are particularly useful for people who have been using SQL Server for a long time. System stored procedures such as `sp_who`, `sp_lock`, and `sp_help` are tools for a database professional that are as basic as a hammer is to a carpenter.

System stored procedures have names that start with `sp_`, and they are found in the `sys` schema. They are global in scope, which allows you to execute them from any database,

without qualifying the stored procedure name. They also run in the context of the database where you are working. In other words, if you execute `sp_helpfile` in the AdventureWorks2008R2 database, the database files for the AdventureWorks2008R2 database are returned. This same type of behavior exists for any stored procedure that is created in the master database with a name that starts with `sp_`. For example, if you create a procedure named `sp_helpme` in the master database and execute that procedure in the AdventureWorks2008R2 database, SQL Server ultimately looks for and finds the procedure in the master database.

NOTE

It is often useful to create your own system stored procedures to make it easier to execute complex queries against the system views (or to provide information not provided by the built-in system procedures). For more information and tips on creating your own system stored procedures, refer to Chapter 28, “Creating and Managing Stored Procedures.”

System stored procedures are listed in the Object Explorer, in the Programmability node within Stored Procedures and then System Stored Procedures. There are far too many system stored procedures to list or discuss them all here. A quick check of the master database lists more than 1,000 procedures. SQL Server Books Online provides detailed help on these procedures, which it groups into 18 different categories.

Useful System Stored Procedures

You are likely to use only a handful of system stored procedures on a regular basis. What procedures you use depends on the type of work you do with SQL Server and your capacity to remember their names. Table 7.4 contains a sample set of system stored procedures that you may find useful.

TABLE 7.4 Useful System Stored Procedures

System Stored Procedure	Description
<code>sp_configure</code>	Displays or changes server-wide configuration settings.
<code>sp_createstats</code>	Creates statistics that are used by the Query Optimizer for all tables in a database.
<code>sp_help</code>	Provides details about the object that is passed to it. If a table name is passed to this procedure, it returns information on the columns, constraints, indexes, and more.
<code>sp_helpdb</code>	If no parameters are supplied, returns relevant database information (including the space used) for all the databases on an instance of SQL Server.

TABLE 7.4 Useful System Stored Procedures

System Stored Procedure	Description
sp_helpfile	Lists the database files associated with the database you are connected to.
sp_lock	Displays current locking information for the entire SQL Server instance.
sp_spaceused	Provides the number of rows and disk space used by the table, indexed view, or queue passed to it.
sp_who	Lists current processes that are connected to an instance of SQL Server.

Many of the administrative functions performed by SSMS can also be accomplished with system stored procedures. Examples include procedures that start with `sp_add` and `sp_delete`, which can be used to add and delete database objects. In addition, more than 90 system stored procedures start with `sp_help`, which return help information on database objects.

TIP

You can use the `sys.all_objects` catalog view to search for available system stored procedures. This catalog view lists objects that are schema scoped as well as system objects. For example, the query `SELECT * FROM sys.all_objects WHERE name LIKE 'sp_help%'` returns all the system stored procedures that start with `sp_help`. You can turn to Books Online for detailed help on any of the system stored procedures. Just enter `sp_` in the index search, and you see a list of them all.

Becoming familiar with some of the system stored procedures is well worth your while. Using them is a very fast and effective means for gathering information from SQL Server. They do not require the formation of a `SELECT` statement, and using them is often the easiest way to get information via a query window.

Summary

Administering SQL Server can be a complex and time-consuming job. Understanding the SQL Server internals and some of the easy ways to obtain information about a SQL Server instance can make this job a lot easier. Taking the time to learn what makes SQL Server tick expands your knowledge of this comprehensive DBMS and helps you make better decisions when working with it.

Now that you know a bit about managing SQL Server, you may need to install an instance of SQL Server to administer. Take a look at Chapter 8, “Installing SQL Server 2008,” which guides you through the installation process.

This page intentionally left blank

CHAPTER 8

Installing SQL Server 2008

Installing SQL Server is the first and one of the easiest tasks you'll accomplish as an administrator. And even though it may take as little as 15 minutes to get SQL Server 2008 up and running by clicking through the install screens and accepting the defaults (Next, Next, Next...), it is crucial to first understand the meaning of each install option and its ramifications for your environment.

What's New in Installing SQL Server 2008

The installation process has been completely revamped for SQL Server 2008, introducing enhancements to simplify the installation compared to SQL Server 2005. The new installation features for SQL Server 2008 include the following:

- ▶ A new SQL Server 2008 Installation Center landing page, which includes a number of options for planning, installing, and maintaining a SQL Server implementation, as well as links to SQL Server documentation for planning and reviewing before starting the install.
- ▶ New maintenance tasks available in the installation process, allowing DBAs to either repair a corrupt SQL Server 2008 installation or conduct a feature upgrade. The Feature Upgrade Wizard allows DBAs to upgrade or change their installed edition of SQL Server 2008 (for example, upgrading from Standard Edition to Enterprise Edition without having to perform a complete reinstall).

IN THIS CHAPTER

- ▶ What's New in Installing SQL Server 2008
- ▶ Installation Requirements
- ▶ Installation Walkthrough
- ▶ Installing SQL Server Using a Configuration File
- ▶ Installing Service Packs and Cumulative Updates
- ▶ Slipstream Installations

- ▶ A discovery report that provides details on all SQL Server components, features, and settings associated with an installation.
- ▶ The potential to automate SQL Server installations by using an existing configuration file.
- ▶ An Advanced Cluster Preparation tool, which streamlines and prepares a SQL Server 2008 failover cluster installation.

With the release of Service Pack 1, SQL Server 2008 also now supports Slipstream installation. Slipstreaming is a method of integrating a SQL Server 2008 update (such as a service pack or cumulative update) with the original installation media so that the original media and update are installed at the same time. This capability can be a huge timesaver over having to manually apply service packs or cumulative updates after performing a full installation.

Installation Requirements

Before you install SQL Server 2008 on your server, it's a good idea (even if you own the latest-and-greatest system) to review the hardware and software requirements. The next two sections gather all the fine print into a few conveniently organized tables.

NOTE

The SQL Server 2008 installer helps determine whether your system meets the minimum requirements by running the new System Configuration Checker (SCC) early in the install. SCC conveniently provides a savable (via a button click) textual report on its results (and displays them onscreen). SCC is covered in detail later in this chapter.

Hardware Requirements

To install SQL Server 2008, you must ensure your system possesses a few basic components:

- ▶ A pointing device
- ▶ A display device with resolution of at least 1024×768 (required by SQL Server Management Studio [SMSS])
- ▶ A DVD-ROM or CD-ROM drive (for installation from disc)

Table 8.1 lists server environment hardware requirements, by SQL Server edition, with reference to processor type and/or word length. This table lists the base minimum hardware requirements. In most installations, you want to have at least 2GB of memory and a 2GHz or faster processor. In addition, installation using a redundant array of disks (RAID) on production systems is highly recommended.

Of course, faster editions of processors, increased RAM, and more disk space don't negatively impact any installation either. One final (and perhaps obvious) note: The more SQL Server components you install, the more disk space you need. Analysis Services, for example, requires an additional 90MB of disk space for the install.

The hard disk space requirements for SQL Server are dependent on which SQL Server components are installed. Table 8.2 breaks down the disk space requirements by feature.

TABLE 8.1 SQL Server 2008 Minimum Hardware Requirements, by Edition

SQL Server Editions	Memory (RAM)	Processors (CPU)
Enterprise, Datacenter, Standard, Workgroup, Web, and Developer (32-bit)	1GB	1GHz Pentium III
Enterprise, Datacenter, Standard, Workgroup, Web, and Developer (64-bit)	1GB	1.4GHz AMD Opteron, AMD Athlon 64, Intel Xeon with Intel EM64T support, or Intel Pentium IV with EM64T support
Enterprise, Standard, and Developer (Itanium)	1GB	1GHz Itanium
Express (64-bit)	256MB	1.4GHz AMD Opteron, AMD Athlon 64, Intel Xeon with Intel EM64T support, or Intel Pentium IV with EM64T support
Express (32-bit)	256MB	1GHz Pentium III
Express with Tools and Express with Advanced Services (32-bit)	512MB	1GHz Pentium III

NOTE

Licensing for multicore processors is the same as for single-core processors: only a single license is required for each multicore processor. Another way of saying this is licensing is per CPU socket, not per processor core.

TABLE 8.2 SQL Server 2008 Disk Space Requirements, by Feature

SQL Server Feature	Disk Space Requirement
Database Engine and data files, Replication, and Full-Text Search	280MB
Analysis Services and data files	90MB
Reporting Services and Report Manager	120MB
Integration Services	120MB
Client Components	850MB
SQL Server Books Online	240MB

Software Requirements

The following software prerequisites must be installed on any server running any SQL Server edition:

- ▶ Microsoft Internet Explorer 6.0 Service Pack 1 (SP1) or later (required because it is a dependency of SMSS, Books Online, Business Intelligence Development Studio [for Analysis Services], and the Report Designer)
- ▶ Windows Installer 4.5 or later (sometimes distributed by Microsoft Windows Update services; also will be installed by the SQL Server Installation Center)
- ▶ .NET Framework 3.5 SP1, SQL Server Native Client and SQL Server Setup support files (if not installed already, these are also installed by SQL Server Installation Center)

Table 8.3 lists the software and operating system requirements for SQL Server 2008, by edition.

TABLE 8.3 SQL Server 2008 R2 Software Requirements, by Edition

SQL Server Editions	Supported Operating Systems
Enterprise and Datacenter (32-bit)	Windows Server 2003 Standard, Enterprise, and Datacenter Editions with SP2 or later Windows Server 2008 Web, Standard, Enterprise, and Datacenter Editions with SP2 or later Windows Server 2008 R2 Web, Standard, Enterprise, and Datacenter Editions
Enterprise and Datacenter (64-bit)	Windows Server 2003 Standard, Enterprise, and Datacenter x64 Editions with SP2 or later Windows Server 2008 Standard, Web, Enterprise, and Datacenter x64 Editions with SP2 or later Windows Server 2008 R2 Standard, Web, Enterprise, and Datacenter x64 Editions
Enterprise (Itanium)	Windows Server 2003 Enterprise and Datacenter 64-bit Itanium Editions SP2 or later Windows Server 2008 64-bit Itanium with SP2 or later Windows Server 2008 R2 64-bit Itanium

TABLE 8.3 SQL Server 2008 R2 Software Requirements, by Edition

SQL Server Editions	Supported Operating Systems
Standard and Developer (32-bit)	<p>Windows XP SP3 or later</p> <p>Windows Vista SP2 Ultimate, Enterprise, Business, and Home Basic/Premium Editions</p> <p>Windows 7 Ultimate, Enterprise, Professional, and Home Basic/Premium x64 Editions</p> <p>Windows Server 2003 Enterprise, Standard, and Datacenter Editions with SP2 or later</p> <p>Windows Server 2008 R2 Web Standard, Enterprise, and Datacenter Editions</p> <p>Windows Server 2008 Web, Standard, Enterprise, and Datacenter Editions</p>
Standard and Developer (64-bit)	<p>Windows Server 2003 Standard, Enterprise, and Datacenter x64 Editions with SP2 or later</p> <p>Windows XP Professional x64 Edition</p> <p>Windows Vista Ultimate, Enterprise, Business, and Home Basic/Premium x64 Editions</p> <p>Windows 7 Ultimate, Enterprise, Professional, and Home Basic/Premium x64 Editions</p> <p>Windows Server 2008 Web, Standard, Datacenter, and Enterprise x64 Editions</p> <p>Windows Server 2008 R2 Web, Standard, Datacenter, and Enterprise x64 Editions</p>
Developer (Itanium)	<p>Windows Server 2003 Enterprise and Datacenter Editions for Itanium-based systems with SP2 or later</p> <p>Windows Server 2008 64-bit Itanium Enterprise and Datacenter Edition SP2 or later</p> <p>Windows Server 2008 R2 64-bit Itanium Enterprise Edition</p>
Workgroup (32-bit)	<p>Windows XP SP3 and later</p> <p>Windows Server 2003 Standard, Enterprise, and Datacenter Editions with SP2 or later</p> <p>Windows Vista SP2 Ultimate, Enterprise, Business, and Home Basic/Premium Editions</p> <p>Windows 7 Ultimate, Enterprise, Professional, and Home Basic/Premium Editions</p> <p>Windows Server 2008 SP2 Web, Standard, Enterprise, and Datacenter Editions</p> <p>Windows Server 2008 R2 Web, Standard, Enterprise, and Datacenter Editions</p>

TABLE 8.3 SQL Server 2008 R2 Software Requirements, by Edition

SQL Server Editions	Supported Operating Systems
Workgroup (64-bit)	<p>Windows XP x64 Professional</p> <p>Windows Server 2003 Standard, Enterprise, and Datacenter x64 Editions with SP2 or later</p> <p>Windows Vista Ultimate, Home Premium, Home Basic, Enterprise, and Business x64 Editions</p> <p>Windows 7 Ultimate, Enterprise, Professional, and Home Basic/Premium x64 Editions</p> <p>Windows Server 2008 SP2 Web, Standard, Enterprise, and Datacenter x64 Editions</p> <p>Windows Server 2008 R2 Web, Standard, Enterprise, and Datacenter x64 Editions</p>
Web (32-bit)	<p>Windows Server 2003 Standard, Enterprise, and Datacenter Editions with SP2 or later</p> <p>Windows Server 2008 SP2 Web, Standard, Enterprise, and Datacenter Editions</p> <p>Windows Server 2008 R2 Web, Standard, Enterprise, and Datacenter Editions</p>
Web (64-bit)	<p>Windows Server 2003 Standard, Enterprise, and Datacenter x64 Editions with SP2 or later</p> <p>Windows Server 2008 SP2 Web, Standard, Enterprise, and Datacenter x64 Editions</p> <p>Windows Server 2008 R2 Web, Standard, Enterprise, and Datacenter x64 Editions</p>
Express (32-bit)	<p>Windows XP (Home, Tablet, Professional, and Media Editions) SP2 or later</p> <p>Windows Server 2003 (Web, Standard, Enterprise, and Datacenter Editions with SP2 or later)</p> <p>Windows Vista SP2 Ultimate, Home Premium, Home Basic, Enterprise, and Business Editions</p> <p>Windows 7 Ultimate, Enterprise, Professional, and Home Basic/Premium Editions</p> <p>Windows Server 2008 SP2 Web, Standard, Enterprise, and Datacenter Editions</p> <p>Windows Server 2008 R2 Web, Standard, Enterprise, and Datacenter Editions</p>

TABLE 8.3 SQL Server 2008 R2 Software Requirements, by Edition

SQL Server Editions	Supported Operating Systems
Express (64-bit)	Windows Server 2003 Standard, Enterprise, and Datacenter x64 Editions with SP2 or later Windows Vista Ultimate, Home Premium, Home Basic, Enterprise, and Business x64 Editions Windows 7 Ultimate, Enterprise, Professional, and Home Basic/Premium x64 Editions Windows Server 2008 SP2 Web, Standard, Enterprise, and Datacenter x64 Editions Windows Server 2008 R2 Web, Standard, Enterprise, and Datacenter x64 Editions

Network Protocol Support

The following network protocols are supported for all editions (where applicable):

- ▶ Shared memory (but not for failover clusters)
- ▶ Named pipes
- ▶ TCP/IP (required for SQL Server endpoint communications)
- ▶ Virtual Interface Adapter (VIA)

Running Multiple Simultaneous Editions

You can install multiple editions of SQL Server 2008 on the same machine and run them simultaneously. This capability comes in handy when you need to test code or other feature functionality on one edition versus another, such as when your development and deployment environments differ. In fact, you can even install and run SQL Server 2008 Enterprise Evaluation Edition on XP SP2 (not supported for the non-Evaluation Enterprise Edition) if you need to test an Enterprise Edition feature on a non-Windows Server system.

NOTE

You can quickly ascertain the SQL Server edition you're running by executing this T-SQL query:

```
select serverproperty('edition')
```

Installation Walkthrough

The following sections walk you through a typical installation scenario step by step. We bring up important points of information along the way, providing a real-world perspective on the process. No past experience with SQL Server is required to understand these sections.

NOTE

SQL Server 2008 is actually version 10 of the product, just as SQL Server 2005 is version 9, and SQL Server 2000 was version 8, which succeeded SQL Server 7. SQL Server 2008 R2 is considered version 10.5. Although versioning by year seems straightforward, it may obfuscate the reasoning behind the naming convention used for many installed items, such as shared folder names (for example, Microsoft SQL Server\100), SQL Server instance folder names (for example, \MSSQL10_50.MSSQLSERVER), and so on. In addition, SQL Server 2000 servers appear as version 8 when registered in SSMS (and elsewhere). You can still administer many aspects of SQL Server 2000 instances via the 2008 and 2008 R2 management tools.

Install Screens, Step by Step

The first step in installing SQL Server 2008 or 2008 R2 is, of course, to launch the SQL Server Installation Center. You do this by inserting the install DVD in the drive and double-clicking `setup.exe` in the root folder (if AutoPlay is enabled, setup runs automatically). If you're installing from a decompressed `.iso` file or network share, locate the root folder and double-click the `setup.exe` file in the root folder.

If Windows Installer 4.5 or Microsoft .NET Framework 3.5 Service Pack 1 are not installed, the SQL Server Setup program first needs to install them before you can continue. If this is the case, you see a dialog like the one shown in Figure 8.1

FIGURE 8.1 SQL Server 2008 prerequisites warning dialog.

NOTE

If the prerequisites for the Installer need to be installed, you likely need to restart the computer for the updates to take effect. After restarting, rerun `setup.exe` to continue the installation.

When the prerequisites are installed, the Installation Wizard runs the SQL Server Installation Center, as shown in Figure 8.2.

FIGURE 8.2 SQL Server 2008 Installation Center window.

NOTE

The same installation program is used whether you want to perform a full SQL Server installation or to install just the client tools. You have the option to choose which components to install on the Feature Selection screen, which is displayed after you install the Setup Support Files.

The first thing you'll notice is that there is a great deal of content immediately available from the SQL Server Installation Center Planning window, including documentation on hardware and software requirements, release notes, security and upgrade documentation,

and the System Configuration Checker. You typically first want to run the System Configuration Checker to confirm that your system meets the minimum hardware and software requirements for installing SQL Server 2008. Click on the link for the System Configuration Checker to bring up the screen shown in Figure 8.3. This is essentially the Setup Support Rules screen that also runs during the actual installation. It's better to find out now if there will be any issues with the installation before you get into the actual installation.

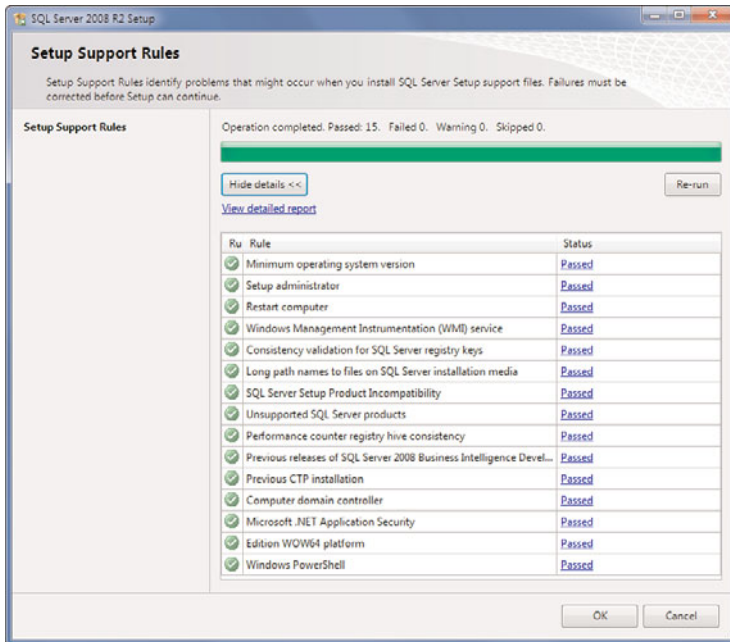

FIGURE 8.3 System Configuration Checker window

When the SCC scan is complete, overall status of the check is detailed at the top of the main window. You can click the Show Details button to view a detailed report of the checks performed. This report notes any issues found. If any checks fail, or a warning is raised, click the hyperlink in the Status column for more detailed report with specifics and suggestions for resolution. Click the View Detailed Report link to see the SCC results in an HTML report format, which is also saved to a file (see Figure 8.4).

After you verify that the system configuration is sufficient to support the SQL Server 2008 installation, click OK to go back to the SQL Server Installation Center. Then click on the Installation option in the menu on the left of the SQL Server Installation Center. This brings up the installation options. To install a new instance of SQL Server, select the New Installation or Add Features to an Existing Installation option, as shown in Figure 8.5.

Microsoft SQL Server 2008 R2 Setup - System Configuration Check Report

Computer Name(s): LATTITUDE830-W7
 Report Date/Time: 11/11/2009 6:22 PM
 Saved to Directory: d:\Program Files\Microsoft SQL Server\100\Setup_Bootstrap\Log\20091111_182218\SystemConfiguratio\SystemConfigurationCheck_Report.htm

Rule Name	Rule Description	Result	Message/Corrective Action
Global Rules: SQL Server 2008 R2 Setup configuration checks for rules group 'GlobalRules'			
AcPermissionsFacet	Checks if the SQL Server registry keys are consistent.	Passed	SQL Server registry keys are consistent and can support SQL Server installation or upgrade.
MediaPathLength	Checks whether the SQL Server installation media is too long.	Passed	The SQL Server installation media is not too long.
OsVersionCheck	Checks whether the computer meets minimum operating system version requirements.	Passed	The operating system version meets the minimum requirements for this product.
RebootRequiredCheck	Checks if a pending computer restart is required. A pending restart can cause Setup to fail.	Passed	The computer does not require a restart.
SetupCompatibilityCheck	Checks whether the current version of SQL Server is compatible with a later installed version.	Passed	Setup has not detected any incompatibilities.
ThreadHasAdminPrivilegeCheck	Checks whether the account running SQL Server Setup has administrator rights on the computer.	Passed	The account running SQL Server Setup has administrator rights on the computer.
WmiServiceStateCheck	Checks whether the WMI service is started and running on the computer.	Passed	The Windows Management Instrumentation (WMI) service is running.
Standalone Rules: These rules do not belong to any rule group			
Bids2008InstalledCheck	Checks if any of SQL Server 2008 Business Intelligence Development Studio installation exists.	Passed	SQL Server 2008 Business Intelligence Development Studio is not installed.
BlockInstall5x5	Checks whether there is an existing SQL Server 2008 CTP installation.	Passed	There are no previous CTP installations of SQL Server 2008.

FIGURE 8.4 System Configuration Checker HTML report.

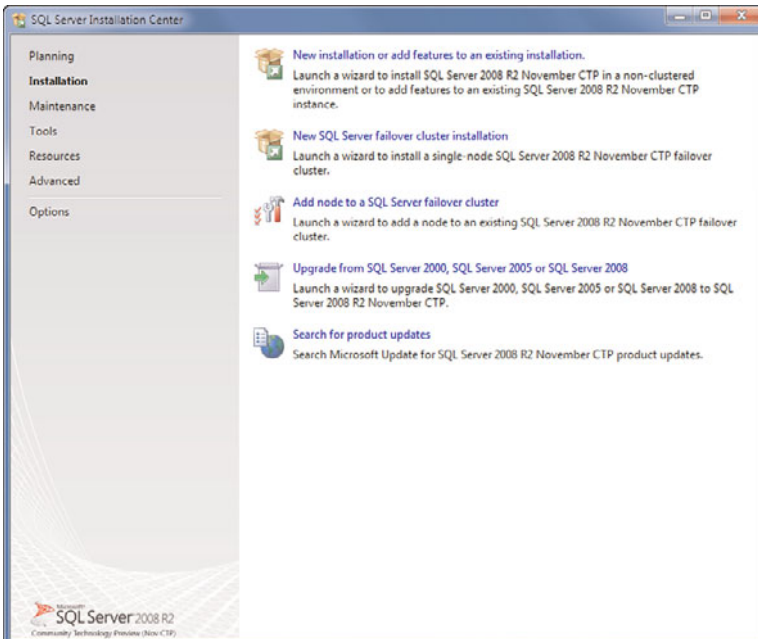

FIGURE 8.5 SQL Server Installation menu.

NOTE

The following installation steps and screenshots are based on the installation of SQL Server 2008 R2. For SQL Server 2008 installations, the order of the install screens and options may be slightly different, but the screen contents and options are similar.

The first step of the installation is to run the Setup Support Rules to identify any potential issues that might occur when the installer installs the SQL Server Setup support files and lists any items that may need to be corrected before Setup can continue. These checks include the following:

- ▶ Operating system version
- ▶ Whether there are any reboots pending from other installers
- ▶ Whether the logged-in user is a system administrator (a must)
- ▶ Whether there is support for long pathnames where the installation media resides
- ▶ The consistency of any SQL Server Registry keys

After the Setup Support Rules run for the Setup Support Files, you can click on the Show Details button to display a window like that shown in Figure 8.6.

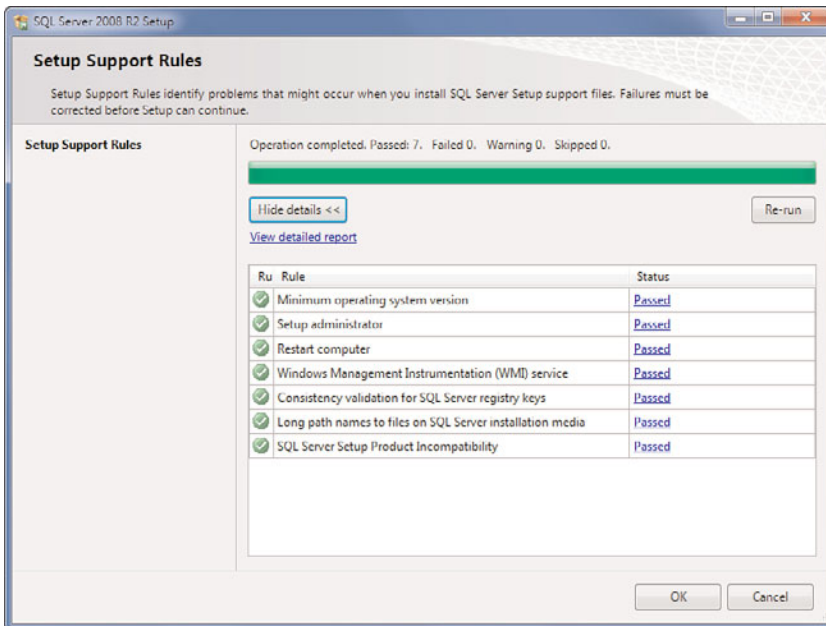

FIGURE 8.6 Setup Support Rules for Setup Support Files Detail.

If any tests fail, you can click on the View Detailed Report link to see a more detailed report file. You can also click on the hyperlink in the Status column of the failed rule to

view specifics on the failed rule. If there are no failed Setup Support Rules to hinder installation, click OK to continue to the installation of the Setup Support Files (see Figure 8.7). The Setup Support Files are components that need to be installed so that the actual SQL Server product installation can proceed. Click Install to initiate the installation of the Setup Support Files.

FIGURE 8.7 Setup Support Files installation screen.

After the installation of the Setup Support Files has completed successfully, the Installer reruns the Setup Support Rules, this time running additional checks to verify that the system will support the installation of SQL Server and its features. Again, if any of the tests fail or a warning is generated, you typically need to address this situation before continuing to ensure a successful SQL Server installation. For example, Figure 8.8 shows a warning regarding Windows Firewall. Clicking on the Warning hyperlink in the Status column brings up a dialog with more information about the warning. In this case, the warning indicates that if Windows Firewall is enabled, the network ports for SQL Server need to be opened to allow remote clients to access SQL Server on this machine.

If no tests have failed and all warnings have been reviewed or resolved, click Next to bring up the Product Key page to enter any necessary product keys if you are installing a version of SQL Server 2008 that is not free (see Figure 8.9).

After entering the product key (if needed), click Next to review the License Terms for SQL Server 2008 R2 (see Figure 8.10). Note that you need to accept the license agreement that follows; otherwise, you can't proceed. Click the check box indicating your acceptance of the license terms and click Next to bring up the Setup Role page, as shown in Figure 8.11.

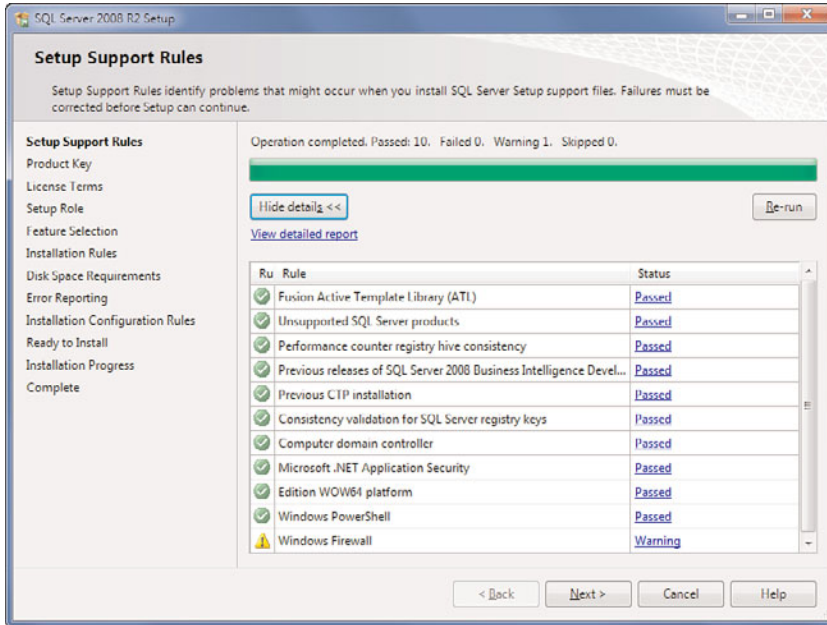

FIGURE 8.8 Setup Support Rules for SQL Server installation detail.

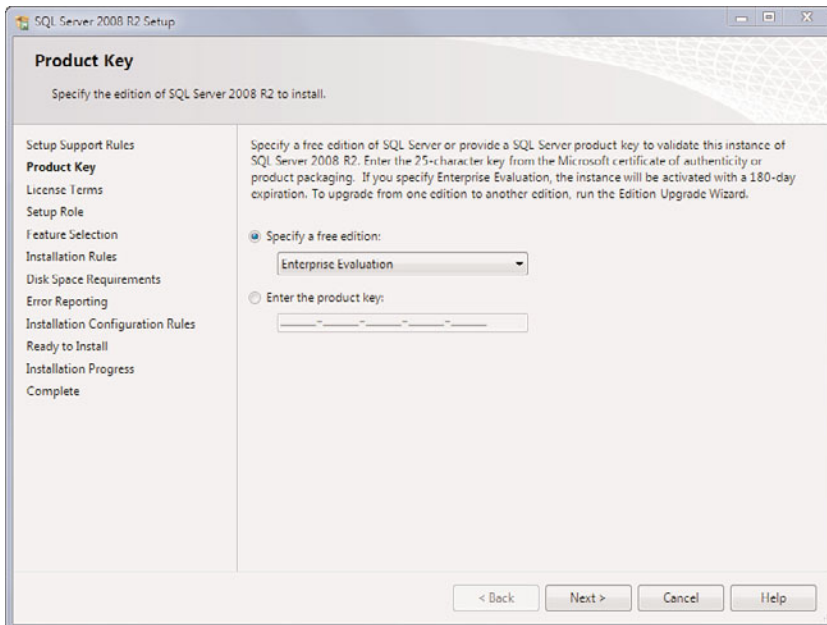

FIGURE 8.9 Product Key entry page.

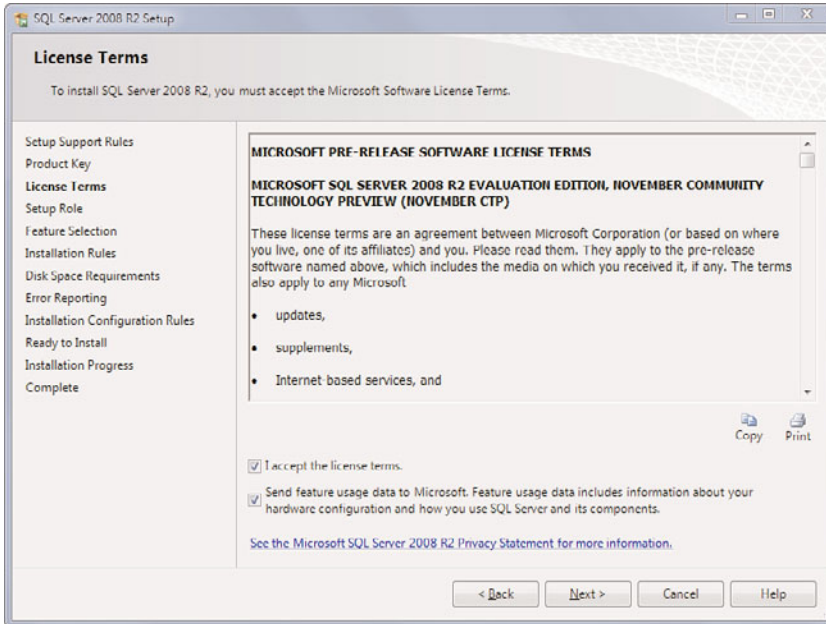

FIGURE 8.10 License Terms page.

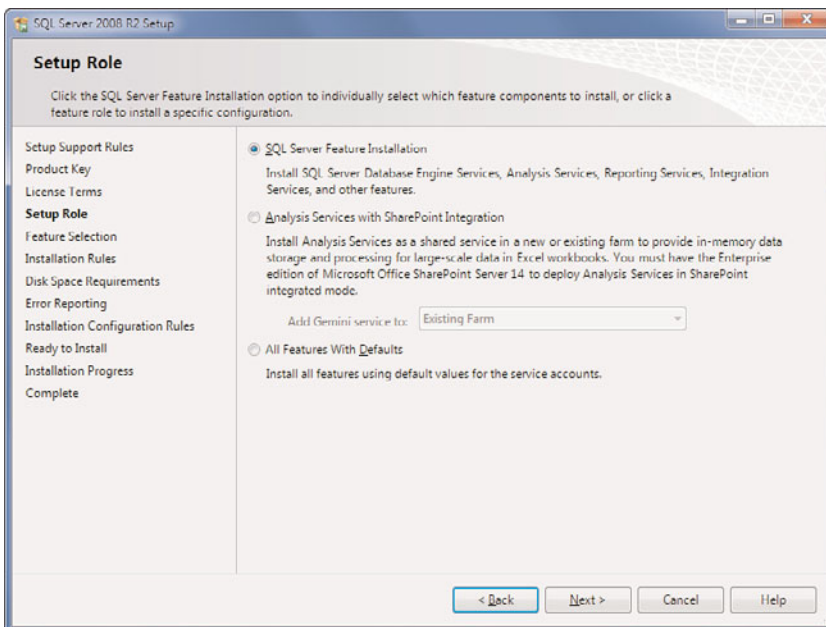

FIGURE 8.11 Setup Role page.

The Setup Role page is new with SQL Server 2008 R2. This page was not available in SQL Server 2008. The Setup Role page lets you specify whether to use the Feature Selection page to select individual features to be installed or to install using a setup role. A *setup role* is a fixed selection of all the features and shared components required to implement a predefined SQL Server configuration. For example, in Figure 8.11, you are presented with three options. The SQL Server Feature Installation option lets you select individual features and shared components to be installed, such as Database Engine Services, Analysis Services (native mode), Reporting Services, and Service Broker. The Analysis Services with SharePoint Integration option allows you to install Analysis Services server components in a Microsoft Office SharePoint Server farm. This option enables large-scale query and data processing for published Excel workbooks that contain embedded PowerPivot data. The All Features with Defaults option skips the Feature Selection screen and installs all SQL Server 2008 R2 features available for the current release. All services are installed with the default system accounts, and the current user running the install is provisioned as a member of the SQL Server sysadmin role.

In most cases, you choose the SQL Server Feature Installation option. After selecting this option, click Next to display the Feature Selection window (see Figure 8.12). Here, you can select which SQL Server features you want to install. For example, if you want to install only the SQL Server Client Tools, this is the place you specify that choice.

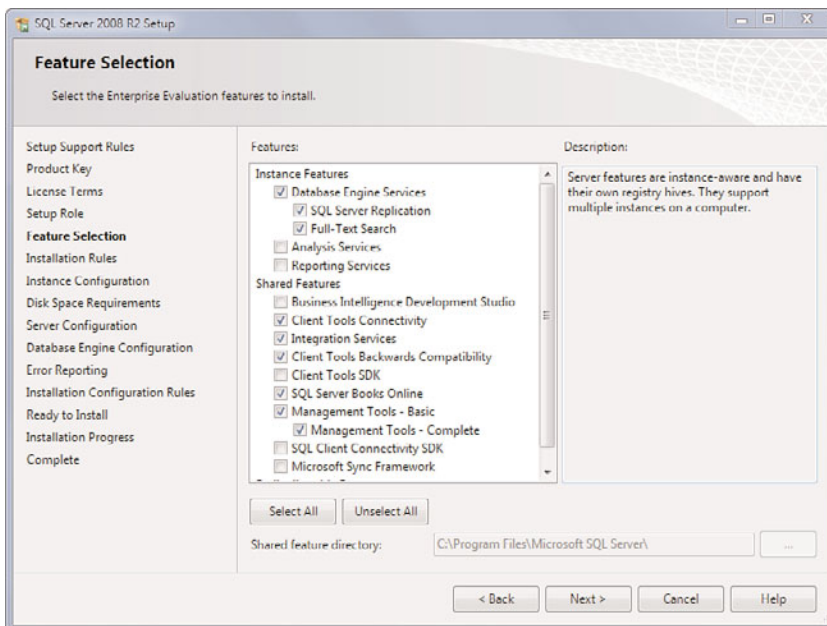

FIGURE 8.12 The Feature Selection page.

Following are the most commonly available features (detailed in subsequent chapters of this book):

- ▶ **Database Engine Services**—Includes the core Database Engine services, optional replication (see Chapter 19, “Replication”), and Full-Text Search (see Chapter 50, “SQL Server Full-Text Search”) services.
- ▶ **Analysis Services**—Includes the engine used to create business intelligence solutions that rely on OLAP and data mining (see Chapter 51, “SQL Server 2008 Analysis Services”).
- ▶ **Reporting Services**—Includes the engine and tools used to generate and deploy data-centric reports (see Chapter 53, “SQL Server 2008 Reporting Services”).
- ▶ **Shared Features**—Includes optional features shared among multiple SQL Server instances on the same system, such as Business Intelligence Development Studio, Client Tools Connectivity components, Integration Services, SQL Server Books Online, SQL Server Management Tools, and the Microsoft Sync Framework.

If you are uncertain about the need for a specific feature, when you click on it in this window, a description of the feature and what will be installed is displayed in the Description pane on the right.

The Feature Selection page is also the place where you can change the installation location for the shared features (if this is the first time any of the shared features are being installed on the system). The default location is `C:\Program Files\Microsoft SQL Server`. In most production installations, you'll most likely want the shared features to remain in the `Program Files` folder.

After you finish making your selections, click **Next** to move on to the Installation Rules page (see Figure 8.13).

NOTE

In versions of SQL Server 2008 prior to R2, the installation rules were not run until later in the installation process.

The Installation Rules page runs a check to determine whether there are any issues that will block the installation of the selected features. From this page, you can address any issues and rerun the rules until they all pass or only warning messages are displayed. Like the Setup Support Rules page, this page enables you to get detailed information on the rule checks performed by clicking on the **Show Details** button. You can get more information on a specific rule by clicking the hyperlink in the **Status** column. A detailed HTML report can be generated as well by clicking on the **View Detailed Report** hyperlink.

When no errors are displayed on the Installation Rules page, click **Next** to proceed to the Instance Configuration page.

You can choose to install SQL Server as the default instance (if a default instance has not already been installed) or as a named instance. SQL Server supports multiple instances of SQL Server on a single server or workstation, but only one instance can be the default instance. The default instance can be an installation of SQL Server 2000, SQL Server 2005, or SQL Server 2008. All other instances must be named instances. The named instances

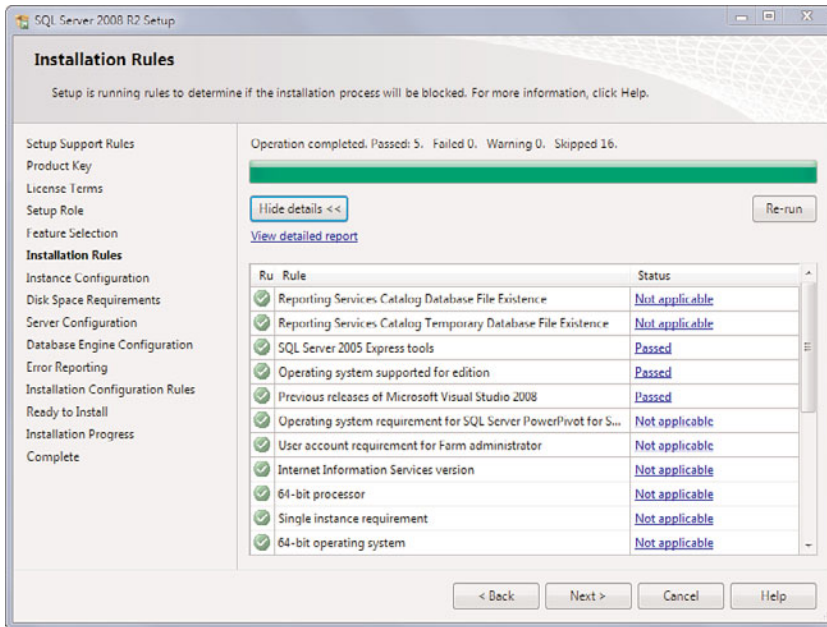

FIGURE 8.13 The Installation Rules page.

can be different versions and/or editions of SQL Server. You can run multiple instances of SQL Server concurrently on the same machine with each instance running independently of other instances. You can also install SQL Server as a named instance without installing a default instance first. If any instances are already installed, they are listed in the Installed Instances list. (For example, Figure 8.14 shows that an instance of the Shared Components from SQL Server 2005 is already installed.)

Another option you can specify on this screen is the Instance Root Directory. This determines where the data files for the system databases for the SQL Server instance will be installed. The installation path for SQL Server 2008 defaults to the system drive of the machine to which you are installing, followed by the root default folder: *[system drive letter]:Program Files\Microsoft SQL Server*. From here, two main subfolders branch out:

- ▶ **100**—This is the version-specific parent folder (SQL Server 2008 is version 10.0, hence 100) for shared features such as Integration Services (under DTS), client tools (under Tools), shared tools (under Shared), and COM components (under COM).
- ▶ **MSSQL10_50.InstanceName**—This is the parent folder for Database Engine components (under MSSQL/Binn) and data files (under MSSQL/Data). *InstanceName* is determined by the value specified during the installation process.
- ▶ **MSAS10_50.InstanceName**—This is the parent folder for Analysis Services components.

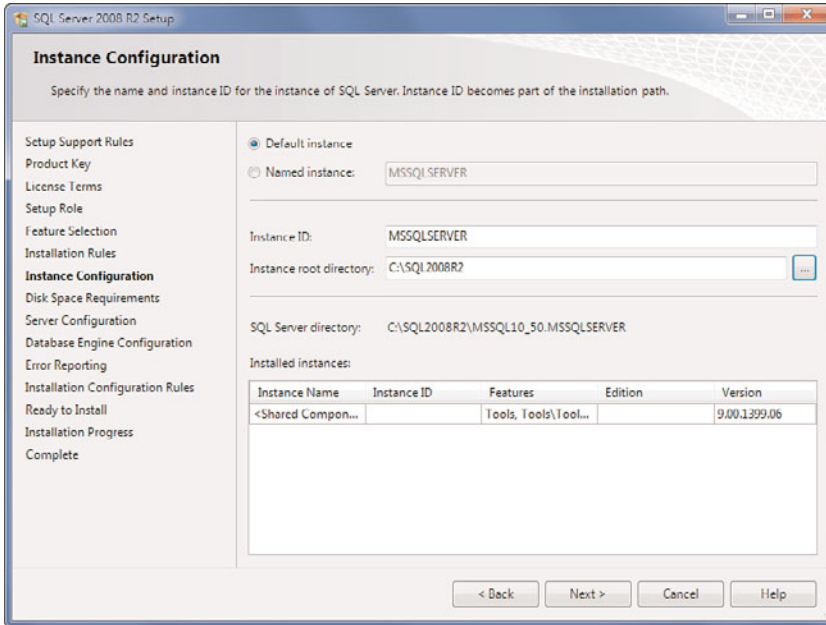

FIGURE 8.14 Instance Configuration page.

- **MSRS10_50.InstanceName**—This is the parent folder for Reporting Services components.

After you finish configuring the instance, click Next to bring up the Disk Space Requirements page. This information screen shows only the disk space requirements for the features you've chosen to install and the available space in the drives you selected to install to. If you want to change the install locations, click on the Back button to return to the screen where the installation directory you want to change is specified. When you are satisfied with your selections, click Next to move onto the Server Configuration page (see Figure 8.15).

On the Server Configuration page, you can specify the specific user accounts and passwords to use for the selected SQL Server services you chose to install. To simplify matters, you can click the Use the Same Account for All SQL Server Services button to specify a single local or domain account dedicated for SQL Server 2008 R2 use and assign it to all services. However, for improved security, it is recommended that you create multiple accounts, one for each service. This helps reinforce the least-privileged user account approach, which states that a user should have only the privileges required to get the job done—and no more. Having multiple accounts also makes it clearer for network administrators to determine which SQL Server services (as opposed to the multitude of other running services) are requesting access to a resource. If you don't specify a user account, the services are set up to run under the Local System account, which is an account with local admin privileges that does not have access to any network resources. The Installer provides warnings if you specify an account with insufficient privileges or credentials.

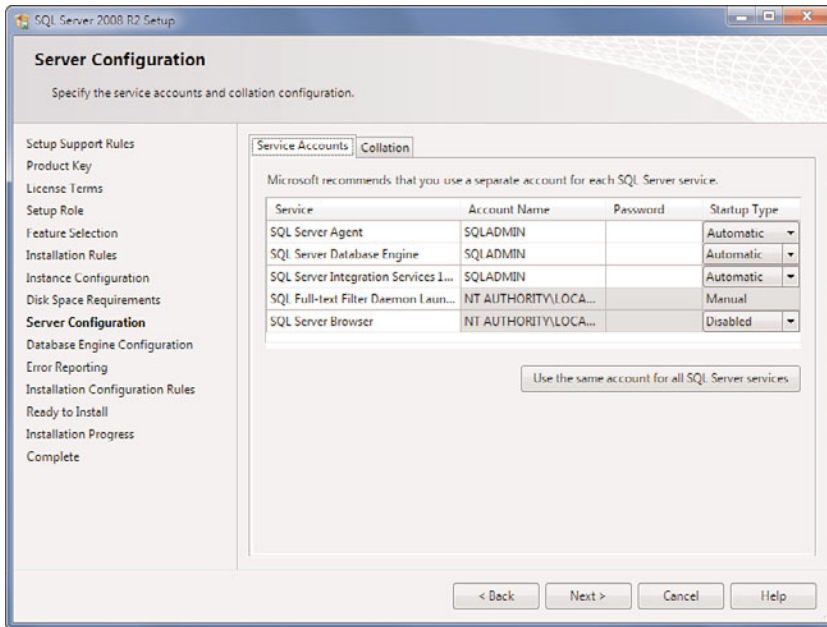

FIGURE 8.15 Server Configuration page.

Also on the Service Accounts tab, you can select the server startup options for the SQL Server services being installed by selecting the startup type in the drop-down selection list to the right of the service. It is highly recommended to autostart the SQL Server service so it's available when the system is started. (If necessary, you can change the startup options for the SQL Server services later, using the SQL Server Configuration Manager.)

NOTE

The SQL Server Browser service is installed only once, no matter how many instances you install.

NOTE

If you are not sure what accounts to set up for the various services, don't worry too much at this point. You can always change the service accounts later using the SQL Server Configuration Manager.

The Server Configuration page also allows you to override the default SQL Server collation settings. You do so by first clicking on the Collation tab (see Figure 8.16). Collations are important because they are used to determine case sensitivity of textual data for comparisons, sort order in indexes, and so on.

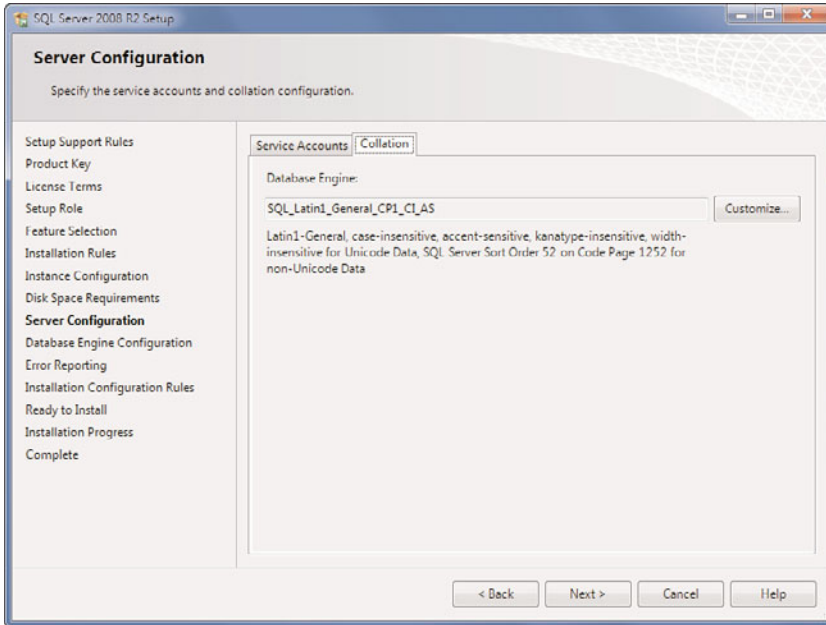

FIGURE 8.16 Server Configuration Collation setting.

If you're running Windows in the United States, the collation selection defaults to `SQL_Latin1_General_CP1_CI_AS` for the Database Engine. The default settings should be changed only if the collation setting for this installation of SQL Server needs to match the collation settings used by another instance of SQL Server, or if it needs to match the Windows system locale of another computer. If you need to change the collation settings, click on the **Customize** button. This brings up the Database Engine Collation Customization dialog, where you can select from standardized SQL Collations or customize your own by specifying a Windows collation setting and the desired sort options.

After making your selections on the Server Configuration page, click **Next** to move onto the Database Engine Configuration page. On this page, you can specify the authentication mode to use for SQL Server. This is done on the Account Provisioning tab (see Figure 8.17). The default setting is for Windows Authentication only. However, Mixed Mode authentication is required if you plan to have any clients authenticating to SQL Server 2008 R2 but will not be authenticating to a Windows domain. If you do select Mixed Mode authentication, you also have to enter a password to use for the built-in in SQL Server administration account (`sa`). A strong `sa` password is recommended. The Account Provisioning page also provides the opportunity to specify local or domain accounts to be mapped to the `sysadmin` role in SQL Server (you must provide at least one). These accounts have unrestricted access to SQL Server for performing SQL Server administration and maintenance tasks. For more information on user accounts, passwords, and server roles, see Chapter 11, "Security and User Administration."

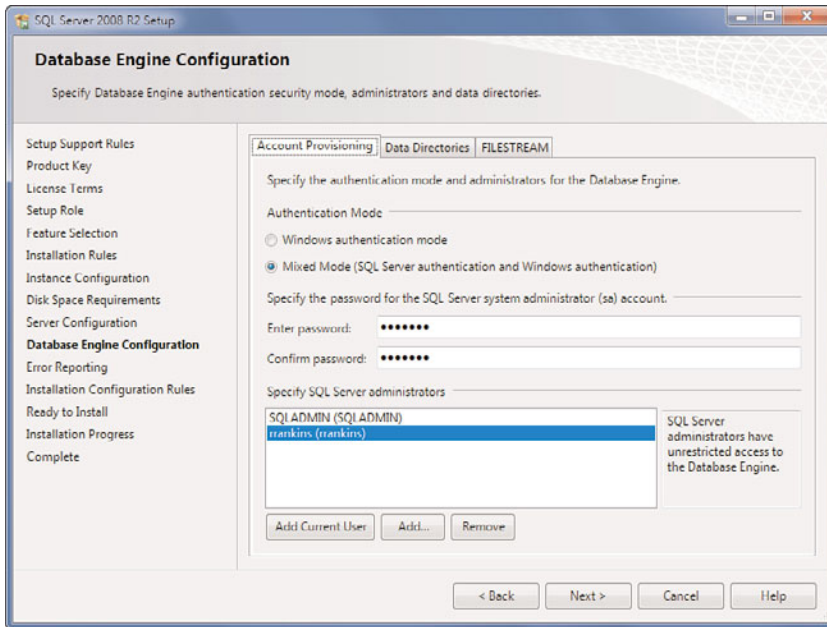

FIGURE 8.17 The Account Provisioning tab.

On the Data Directories tab (see Figure 8.18), you can configure the data root directory and default directories where the user and tempdb data and log files will be created, as well as the default location for the Backup directory. Note that the System Database Directory cannot be changed here; you need to return to the Instance Configuration page and modify the Instance Root directory. In a production installation, for performance reasons, you should set up multiple drives or drive arrays to store the data and log files. Typically, you do not want the system data files stored on the C: drive, especially buried in the Program Files folder. You likely want to locate the data files on a high-performance drive setup specifically for database files and away from the system swap file and other applications. For recoverability purposes, you also should keep your backup files on a separate drive from your data files. (For more information on database devices and performance, see Chapter 38, “Database Design and Performance.”) As a general rule, you also should place the log files on separate disks from the data files, and placing tempdb on its own disk further helps improve performance

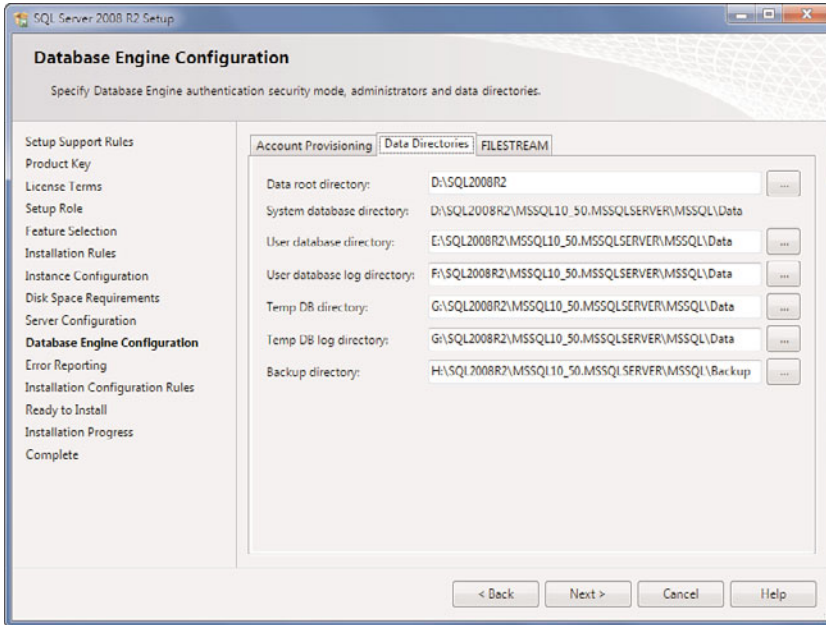

FIGURE 8.18 The Data Directories tab.

NOTE

If you are planning on installing multiple SQL Server instances on the same server, consider using separate subdirectories for each instance's data and log files. This way, you avoid potential conflicts between data and log filenames for databases with the same names created in more than on SQL Server instance. As you notice, by default, the SQL Server Installer creates subdirectories under the specified root directory name using the SQL Server version number and instance name (for example, MSSQL10_50.MSSQLSERVER) and then an additional subdirectory for the services type (MSSQL for SQL Server, MSAS for Analysis Services, and MSRS for Reporting Services).

The final tab on the Database Engine Configuration tab is FILESTREAM (see Figure 8.19). The FILESTREAM data type is a column property available in SQL Server 2008. FILESTREAM storage is implemented as a `varbinary(max)` column, but the actual data is stored as BLOBs in the file system. Because of security considerations, FILESTREAM, by default, is disabled. If you want to use the FILESTREAM option, click the Enable FILESTREAM for Transact-SQL Access check box to enable FILESTREAM capabilities. This control must be checked before the other control options will be available. The Enable FILESTREAM for File I/O Streaming Access check box enables Win32 streaming access for FILESTREAM. If this option is selected, you can specify the name of the Windows share in which the FILESTREAM data

will be stored. The Allow Remote Clients to Have Streaming Access to FILESTREAM Data check box determines whether to allow remote clients to access this FILESTREAM data on this server. For more information on defining and using FILESTREAM data in SQL Server 2008, see Chapters 24, “Creating and Managing Tables,” and 42, “What’s New for Transact-SQL in SQL Server 2008.” If you are unsure whether you need or want to use FILESTREAM data, you can leave this option disabled during the install. You can enable FILESTREAM data at any time via the SQL Server Configuration Manager.

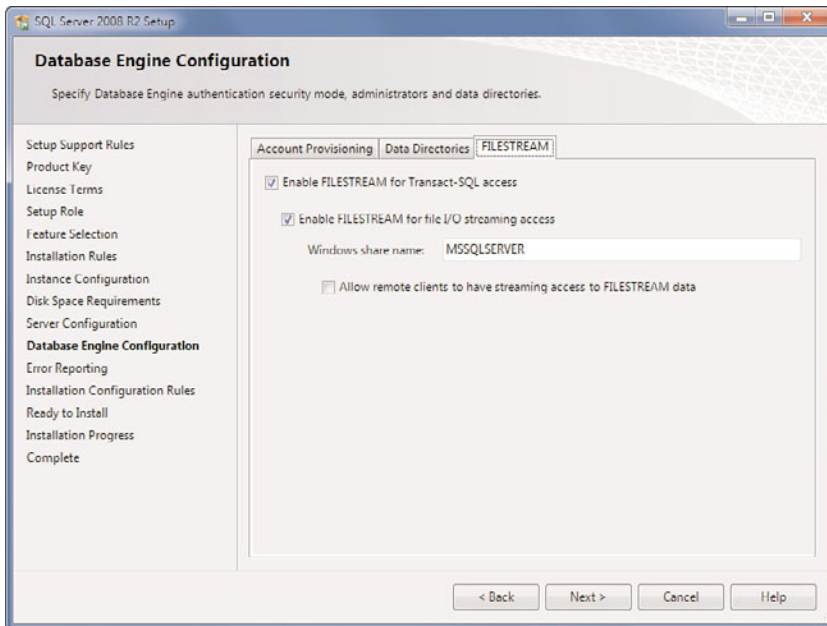

FIGURE 8.19 The FILESTREAM tab.

Some of the remaining configuration screens depend on which features you selected in the Feature Selection page. For example, if you chose to install Analysis Services or Reporting Services, you have configuration pages to specify the installation options for these features. For more information on configuring Analysis Services and Reporting Services, see Chapters 51, “SQL Server 2008 Analysis Services,” and 53, “SQL Server 2008 Reporting Services.” As with the FILESTREAM option, you do not have to install Analysis Services or Reporting Services during the initial install. You can always run the SQL Server Installation Center later to add these features to an existing SQL Server instance.

After you finish making your selections, click Next to move on to the Error Reporting page. On the Error Reporting page, you have the option to indicate whether you want to have error reports sent to Microsoft automatically for any of the SQL Server services that run without user interaction. This option, if enabled, helps Microsoft improve future releases of SQL Server features by sending error reports to Microsoft automatically. This

process is colloquially known as “phoning home,” and you may be inclined to keep this option unchecked. Note that doing so reduces Microsoft’s capability to gather important information that can be helpful for identifying possible bugs and developing fixes in future service pack releases. Specify whether you want to participate and click Next to continue to the Installation Configuration Rules page, as shown in Figure 8.20.

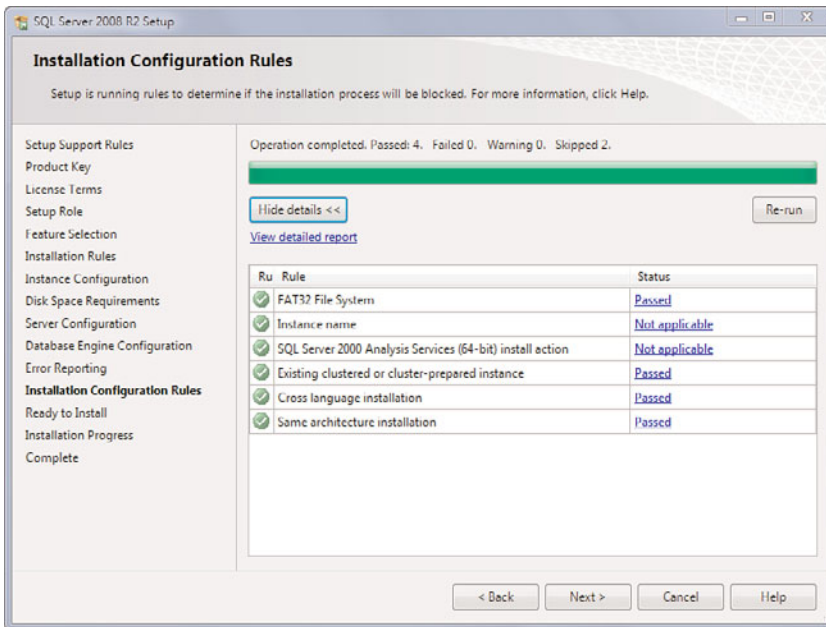

FIGURE 8.20 The Installation Configuration Rules page.

NOTE

In SQL Server 2008, the Error Reporting page was referred to as the Error and Usage Reporting page. In addition to the option to have error reports sent to Microsoft automatically, it also provided the option to participate in the Customer Experience Improvement program.

The Installation Configuration Rules page runs a final set of checks to determine if there are any issues that will prevent a successful installation of SQL Server 2008. If no errors are reported, click Next to continue to the Ready to Install page (see Figure 8.21). This page displays a summary of the installation options chosen as well as the file locations specified. Review this information to ensure the features and file locations match what you

specified during the previous screens. This page also displays the location of the Configuration file path where you can find the `ConfigurationFile.ini` file generated by the installer. This `.ini` file can be used for unattended installations, which are discussed later in this chapter. The `ConfigurationFile.ini` file is located in the same place where you can find the installation log files, which you can review if any problems occur during the installation.

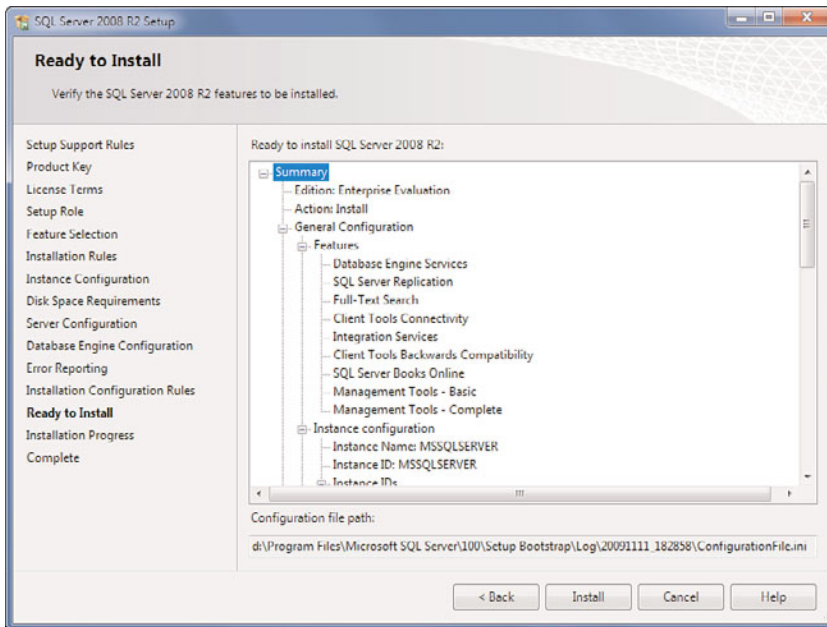

FIGURE 8.21 The Ready to Install Page.

If everything looks satisfactory on the Ready to Install Page, click the Install button to proceed with the SQL Server installation. This displays the Installation Progress screen, which shows a progress bar and messages to allow you to track the progress of the installation. When the setup process is complete, the Installer displays the Complete page, which contains a hyperlink to the Installer log file and supplemental information about the installation.

One of the notes that may be displayed in the Supplemental Information section of the Complete page refers to the installation of the SQL Server sample databases. If you've worked with previous versions of SQL Server, you may remember that there was an option to install the sample databases during the SQL Server installation. With SQL Server 2008, the sample databases are not part of the SQL Server Installation Center, nor are they available on the install media. To install the sample databases and sample code for non-Express editions of SQL Server 2008, you need to go to the Microsoft CodePlex website to download the installer for the sample databases. There is a link to the SQL Server samples on the CodePlex website on the Resources page of the SQL Server Installation Center.

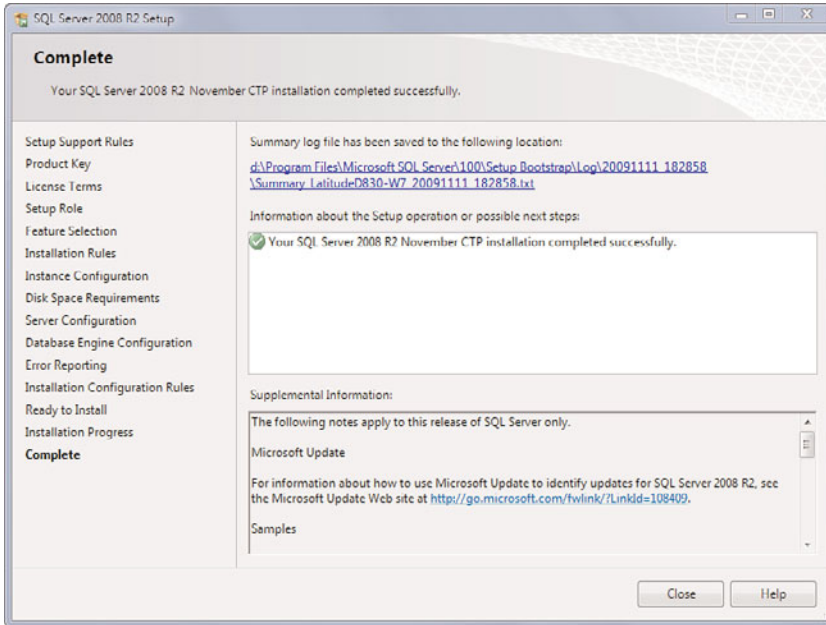

FIGURE 8.22 The Complete page.

The Supplemental Information section also provides a link to the latest readme file for the release of SQL Server installed and a note regarding how SQL Server updates are now available via Microsoft Update. Before leaving the Installation Center, you might want to click the Search for Product Update link on the Installation page to see whether there are any critical hotfixes or service packs already available for your SQL Server installation.

Other Options Available in the SQL Server Installation Center

Before leaving the SQL Server Installation Center, let's explore a few other utilities available from the main menu. The Maintenance menu provides tools to upgrade an installed SQL Server 2008 Edition (for example, from Standard Edition to Enterprise Edition), repair a corrupt installation, or remove a node from a SQL Server 2008 cluster. The Tools menu provides links to the System Configuration Checker, the Installed features discovery report that generates information regarding all SQL Server products and features installed on the local machine, and a utility to upgrade existing SQL Server 2005 Integration Services packages to the SQL Server 2008 Integration Services package format.

Finally, on the Advanced menu, there are options to prepare and complete a SQL Server failover cluster and to install an instance of SQL Server 2008 from an existing configuration file. Installing using an existing configuration file allows you to repeat an installation without having to go through all the individual steps and enter/select all the options you normally have to go through with the installation wizard.

Installing SQL Server Using a Configuration File

If you need to install SQL Server 2008 to multiple machines, you'll likely want to do so without having to manually select the same options over and over. Running the installer using a configuration file provides this much-needed timesaving feature. With the SQL Server 2008 installer, you have the option of running the installer with a configuration file in a couple of ways: using the Installer Wizard with options prefilled by the configuration file or using a fully automated and unattended installation from the command line. If you use the GUI with the options prefilled by the configuration file, you have the opportunity to review and change options along the way as necessary.

The `ConfigurationFile.ini` file is a text file composed of parameters in name/value pairs along with descriptive comments. Many of the parameter names correspond to the screens and screen options you would see when using the Installer Wizard. Here are some examples:

- ▶ **INSTANCENAME**—Specifies a named instance name for the value or specifies the special value `MSSQLSERVER` to install the default instance.
- ▶ **FEATURES**—Specifies which features to install, uninstall, or upgrade. The list of top-level features include SQL, AS, RS, IS, and Tools. The SQL feature installs the Database Engine, Replication, and Full-Text. The Tools feature installs Management Tools, Books Online, Business Intelligence Development Studio, and other shared components.
- ▶ **INSTALLSHAREDIR**—Specifies the root installation directory for native shared components.
- ▶ **INSTANCEDIR**—Specifies the installation directory for instance-specific components.
- ▶ **INSTALLSQLDATADIR**—Specifies the Database Engine root data directory.
- ▶ **SQLBACKUPDIR**—Specifies the default directory for the Database Engine backup files.
- ▶ **SQLUSERDBDIR**—Specifies the default directory for the Database Engine user databases.
- ▶ **SQLUSERDBLOGDIR**—Specifies the default directory for the Database Engine user database logs.
- ▶ **SQLTEMPDBDIR**—Specifies the directory for Database Engine tempdb files.
- ▶ **SQLCOLLATION** or **ASCOLLATION**—Specifies values to set the collation for SQL Server or Analysis Services.
- ▶ **SQLSVCACCOUNT**—Specifies the user account for the SQL Server service: `domain\user` or system account.
- ▶ **TCPENABLED**—Specifies whether the TCP/IP protocol is enabled (1) or disabled (0).
- ▶ **NPENABLED**—Specifies whether the Named Pipes protocol is enabled (1) or disabled (0).

- **SECURITYMODE**—Specifies authentication mode for SQL Server. You can use the special value "SQL" here to override the default of Windows-only authentication.

The following example shows the contents of a configuration file for SQL Server 2008 R2:

```
;SQLSERVER2008 Configuration File
[SQLSERVER2008]

; Specify the Instance ID for the SQL Server features you have specified. SQL
  Server directory structure, registry structure, and service names will reflect
  the instance ID of the SQL Server instance.
INSTANCEID="MSSQLSERVER"

; Specifies a Setup work flow, like INSTALL, UNINSTALL, or UPGRADE. This is a
  required parameter.
ACTION="Install"

; Specifies features to install, uninstall, or upgrade. The list of top-level
  features include SQL, AS, RS, IS, and Tools. The SQL feature will install the
  database engine, replication, and full-text. The Tools feature will install
  Management Tools, Books online, Business Intelligence Development Studio, and
  other shared components.
FEATURES=SQLENGINE,REPLICATION,FULLTEXT,CONN,IS,BC,BOL,SSMS,ADV_SSMS

; Displays the command line parameters usage
HELP="False"

; Specifies that the detailed Setup log should be piped to the console.
INDICATEPROGRESS="False"

; Setup will not display any user interface.
QUIET="False"

; Setup will display progress only without any user interaction.
QUIETSIMPLE="False"

; Specifies that Setup should install into WOW64. This command line argument is
  not supported on an IA64 or a 32-bit system.
X86="False"

; Detailed help for command line argument ENU has not been defined yet.
ENU="True"

; Parameter that controls the user interface behavior. Valid values are Normal for
  the full UI, and AutoAdvance for a simplified UI.
UIMODE="Normal"
```

```

; Specify if errors can be reported to Microsoft to improve future SQL Server
releases. Specify 1 or True to enable and 0 or False to disable this feature.
ERRORREPORTING="True"

; Specify the root installation directory for native shared components.
INSTALLSHAREDDIR="C:\Program Files\Microsoft SQL Server"

; Specify the installation directory.
INSTANCEDIR="C:\SQL2008R2"

; Specify that SQL Server feature usage data can be collected and sent to
Microsoft. Specify 1 or True to enable and 0 or False to disable this feature.
SQMREPORTING="True"

; Specify a default or named instance. MSSQLSERVER is the default instance for
non-Express editions and SQLEXPRESS for Express editions. This parameter is
required when installing the SQL Server Database Engine (SQL), Analysis Services
(AS), or Reporting Services (RS).
INSTANCENAME="MSSQLSERVER"

; Agent account name
AGTSVCACCOUNT="SQLADMIN"

; Auto-start service after installation.
AGTSVCSTARTUPTYPE="Automatic"

; Startup type for Integration Services.
ISSVCSTARTUPTYPE="Automatic"

; Account for Integration Services: Domain\User or system account.
ISSVCACCOUNT="SQLADMIN"

; Startup type for the SQL Server service.
SQLSVCSTARTUPTYPE="Automatic"

; Level to enable FILESTREAM feature at (0, 1, 2 or 3).
FILESTREAMLEVEL="1"

; Specifies a Windows collation or an SQL collation to use for the Database Engine.
SQLCOLLATION="SQL_Latin1_General_CP1_CI_AS"

; Account for SQL Server service: Domain\User or system account.
SQLSVCACCOUNT="SQLADMIN"

```

```
; Windows account(s) to provision as SQL Server system administrators.
```

```
SQLSYSADMINACCOUNTS="SQLADMIN"
```

```
; The default is Windows Authentication. Use "SQL" for Mixed Mode Authentication.
```

```
SECURITYMODE="SQL"
```

```
; The Database Engine root data directory.
```

```
INSTALLSQLDATADIR="C:\SQL2008R2"
```

```
; Default directory for the Database Engine backup files.
```

```
SQLBACKUPDIR="C:\SQL2008R2\MSSQL10_50.MSSQLSERVER\MSSQL\Backup"
```

```
; Default directory for the Database Engine user databases.
```

```
SQLUSERDBDIR="C:\SQL2008R2\MSSQL10_50.MSSQLSERVER\MSSQL\Data"
```

```
; Default directory for the Database Engine user database logs.
```

```
SQLUSERDBLOGDIR="C:\SQL2008R2\MSSQL10_50.MSSQLSERVER\MSSQL\Data"
```

```
; Directory for Database Engine TempDB files.
```

```
SQLTEMPDBDIR="C:\SQL2008R2\MSSQL10_50.MSSQLSERVER\MSSQL\Data"
```

```
; Provision current user as a Database Engine system administrator for  
SQL Server 2008 R2 Express.
```

```
ADDCURRENTUSERASSQLADMIN="False"
```

```
; Specify 0 to disable or 1 to enable the TCP/IP protocol.
```

```
TCPENABLED="0"
```

```
; Specify 0 to disable or 1 to enable the Named Pipes protocol.
```

```
NPENABLED="0"
```

```
; Startup type for Browser Service.
```

```
BROWSERSVCSTARTUPTYPE="Disabled"
```

```
; Add description of input argument FTSSVCACCOUNT
```

```
FTSSVCACCOUNT="NT AUTHORITY\LOCAL SERVICE"
```

Depending on which options you chose during an install, other options may be listed in the Configuration.ini file, some of which are designed solely for clustered installs, Analysis Services, Reporting Services, Integration Services, or Tools.

To create a configuration file (sorry, no configuration file template is available on the installation media), run the installation program and follow the wizard all the way through to the Ready to Install page where the location of the Configuration.ini file generated is specified (see Figure 8.21). If you do not want to continue with an actual

installation at this point, simply click the Cancel button to cancel the setup. At this point, you can copy the `Configuration.ini` file to another location so you can make edits to it.

NOTE

The Installer writes out all the appropriate parameters for the options and values specified, with the exception of sensitive information such as passwords. For an unattended install, these values can be provided at the command prompt when you run `setup.exe`. In addition, the new SQL Server 2008 R2 `/IAcceptSQLServerLicenseTerms` parameter is also not written out to the configuration file and requires either you modify the configuration file or supply a value at the command prompt.

The `setup.exe` command-line program can be found at the root level of the installation media. To use a configuration file to install a standalone SQL Server instance, run the installation through the command-line `setup.exe` program and supply the `ConfigurationFile.ini` using the `ConfigurationFile` parameter, as in the following example:

```
Setup.exe /ConfigurationFile=CustomConfigurationFile.INI
```

If you want to override any of the values in the configuration file or provide values not specified in the configuration file, you can provide additional command-line parameters to `setup.exe`. For example, to avoid having to enter the service account passwords during the installation, you can enter them on the command line using the password parameters to `config.exe`:

```
Setup.exe /SQLSVCPASSWORD="mypassword" /AGTSVCPASSWORD="mypassword"  
/ASSVCPASSWORD="mypassword" /ISSVCPASSWORD="mypassword"  
/RSSVCPASSWORD="mypassword" /ConfigurationFile=CustomConfigurationFile.INI
```

NOTE

The password parameters are required to run a fully unattended installation. Also, if the `SECURITYMODE` setting is set to SQL in the configuration file or via the command-line parameter, you need to provide the `/SAPWD` parameter to provide a password for the sa account.

Most of the other available `setup.exe` command-line parameters are the same as the parameter names used in the configuration file as listed previously. For full details of the available `setup.exe` parameters, refer to SQL Server Books Online.

Running an Automated or Manual Install

When installing SQL Server from the command prompt, you can also specify what level of the installer interface you want to run, either silent, basic, or full interaction. SQL Server supports full quiet mode by using the `/Q` parameter or Quiet Simple mode by using the `/QS` parameter. The `/Q` switch is intended for running unattended installations. With this switch provided, Setup runs in quiet mode without any user interface. The `/QS` switch only shows progress via the GUI; it does not accept any input and displays no error messages if encountered.

Regardless of the installation method chosen, you are required to confirm acceptance of the software license terms as an individual or on behalf of an entity, unless your use of the software is governed by a separate agreement such as a Microsoft volume licensing agreement or a third-party agreement with an ISV or OEM. For full unattended installations (using the `/Q` or `/QS` parameters) with SQL Server 2008 R2, you must include the `/IACCEPTSQLSERVERLICENSETERMS` parameter to avoid the display of the License Terms page. Following is a sample command line for running an unattended installation of SQL Server 2008:

```
C:\Documents and Settings\rrankins\My Documents\Downloads\SQL2008\R2
Nov CTP>setup.exe /configurationfile=customconfigurationfile.ini
/Q /IACCEPTSQLSERVERLICENSETERMS /SQLSVCPASSWORD="riddler"
/AGTSVCPASSWORD="riddler" /SAPWD="riddler"
```

SQL Server 2008 R2 introduces a new option to the `setup.exe` that allows you to run a somewhat more attended mode of the installation that gives you a bit more control over the install than the `/Q` and `/QS` parameters, while streamlining the install somewhat. You can now specify the `/UIMODE` parameter instead of the `/Q` or `/QS` switches. The `/UIMODE` parameter specifies whether to present the full set of Installer Wizard pages for review and confirmation while running the setup or to present a minimum number of pages during setup. `/UIMODE=Normal`, the default option, presents all setup dialog boxes for the selected features, allowing you to review the values or manually enter values not provided in the configuration file (such as service account passwords). You can specify the `/UIMODE=AutoAdvance` option to skip nonessential dialogs and auto advances through a number of pages, including the Ready to Install page.

NOTE

Although SQL Server 2008 Configuration.ini files are compatible with the SQL Server 2008 R2 setup.exe program, some of the options generated in a SQL Server 2008 R2 Configuration.ini file are not compatible with the pre-R2 installer, such as the `ENU`, `UIMODE`, `FARMADMINPORT`, and `IACCEPTSQLSERVERLICENSETERMS` parameters.

Installing Service Packs and Cumulative Updates

If you are installing SQL Server 2008 instead of SQL Server 2008 R2, it is recommended that you install SQL Server 2008 Service Pack 1. SQL Server 2008 SP1 doesn't provide any significant new features for SQL Server 2008 but does provide a number of fixes to the GA release version of SQL Server 2008 (Microsoft Knowledge Base article 968369 lists all the fixes).

Service Pack 1 does provide a few new features primarily to ease the deployment of service packs and cumulative updates. The first of these is Slipstream installations. *Slipstreaming* is an installation method that integrates the base installation files for SQL Server with its service packs and cumulative updates and enables you to install them in a single step. You can slipstream SQL Server 2008 SP1 and subsequent cumulative updates with the original installation media so that original media and the updates are installed at the same time. The next section in this chapter describes how to set up a Slipstream installation.

SQL Server 2008 SP1 also provides the capability to uninstall SQL Server 2008 cumulative updates or service packs via the Programs and Features Control Panel (or the Add/Remove Programs Control Panel in Windows XP or Windows Server 2003).

Before installing SP1, you should make sure to back up all user-created databases, as well as the system databases `master`, `model`, `msdb`, and any replicated databases. If you have installed Analysis Services, back up the entire OLAP directory (as discussed earlier in this chapter, in the "Installation Paths" section) and all its subdirectories.

You also should make sure to close all open connections to the instance to which you are applying SP1 (including any connections via the management tools; setup should prompt you to close them) and make sure the various SQL Server services are started in the Services Control Panel. Also, be sure `master` and `msdb` each have 500KB free (or that they are autogrow enabled).

When you're ready, log on to the machine as an admin and start the downloaded SP1 executable. After extracting the contents to a temporary folder on the C: drive, the SP1 setup launches, displaying the Welcome screen shown in Figure 8.23. As you can see from this window, the SP1 Welcome screen runs the SP1 setup support rules to verify that the SP1 install can be run.

Click Next to display the License Agreement screen. Click the check box to select the license agreement and then click Next again to advance to the Select Features screen to display and select the installed features to be updated (see Figure 8.24). The ensuing Feature Selection window lists (again) the features to be updated, organized in tree fashion, by SQL Server instance name. You can uncheck the features or instances you do not want to upgrade to SP1, except for shared features, which are required to be updated.

Click Next to move onto the Check Files in Use screen (see Figure 8.25). This screen identifies any open or running files that the SP1 setup program needs access to during the install. If any files are listed, you have the option to shut down the services or applications associated with the files and run the check again to see whether the all items are cleared from the list. Note that it is not critical for the Files in Use list to be empty, but if

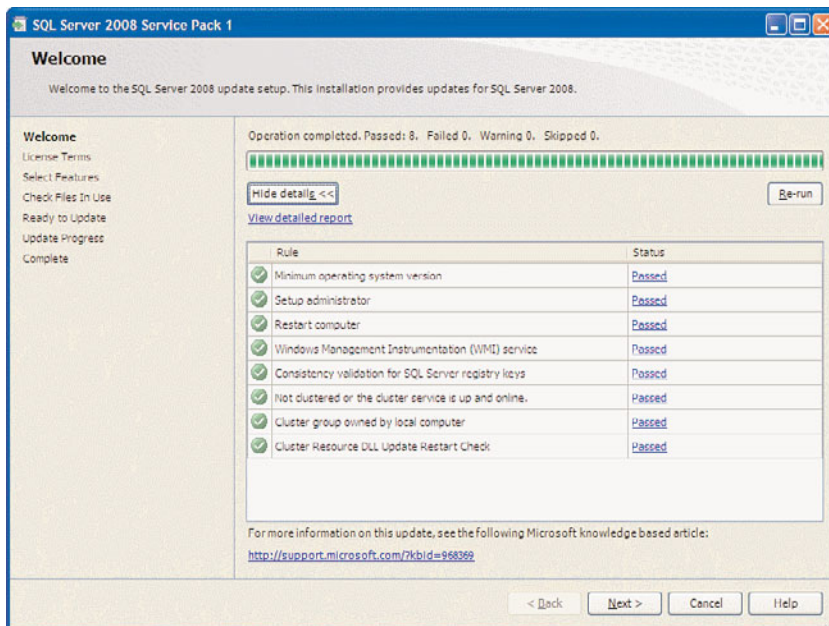

FIGURE 8.23 SQL Server 2008 SP1 Welcome screen.

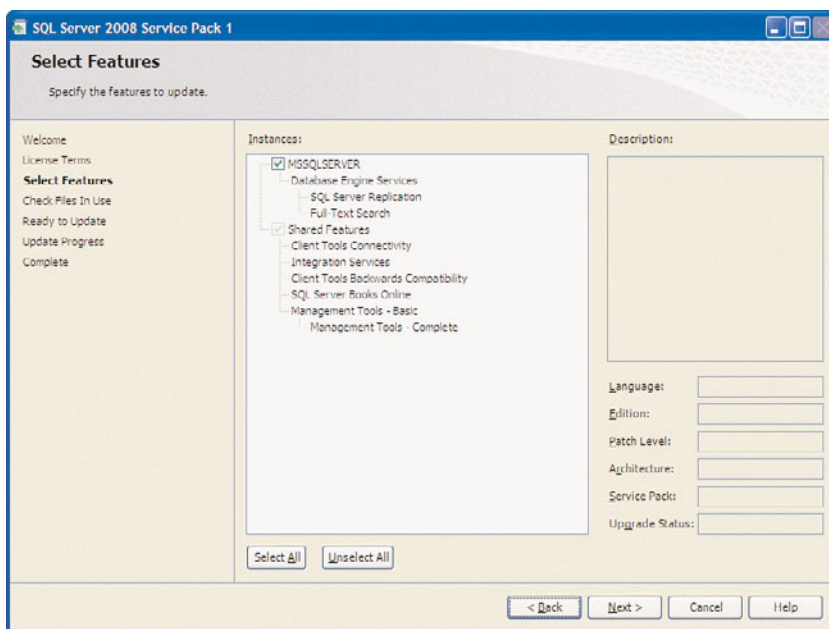

FIGURE 8.24 SQL Server 2008 SP1 Feature Selection screen.

any files are listed, you need to reboot the system after running the SP1 setup to complete the installation.

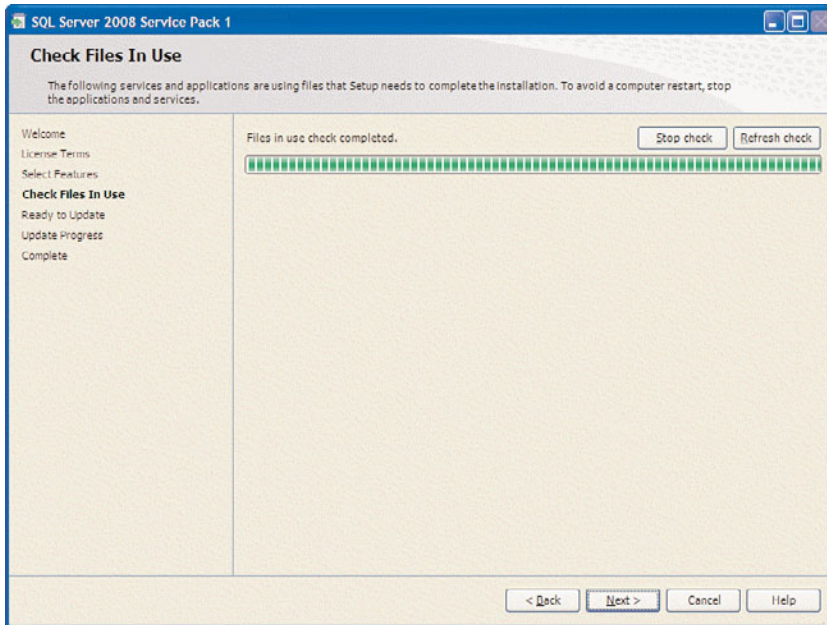

FIGURE 8.25 SQL Server 2008 SP1 Check Files in Use screen.

Click Next again to proceed to the Ready to Update screen (see Figure 8.26), which displays a summary of the instances and features that will be updated to SP1. Click Update to start the installation and display the Update Progress screen. When the SP1 installation is complete, click Next to proceed to the Complete screen. The Complete screen displays the location of the SP1 summary log file (see Figure 8.27). The default location of the SP1 summary log file is `C:\Program Files\Microsoft SQL Server\100\Setup Bootstrap\LOG`.

Installing SP1 from the Command Line

Like the SQL Server 2008 main install, SP1 can also be installed from the command line with no user interaction. This capability is useful if you need to install SP1 to a number of servers and want to avoid having to go through all the SP1 Install Wizard screens each time. To run SP1 from the command line, you must first extract the setup files from the SP1 download file, which is an executable archive file. You can do this by running the `SQLServer2008SP1-KB968369-x64-ENU.exe` file with the `/x` option from the command line. This launches the extractor, which prompts you for a location to extract the files to. Alternatively, you can specify a directory on a local drive to have it extract the setup files to automatically:

```
SQLServer2008SP1-KB968369-x64-ENU.exe /x:C:\SP1
```

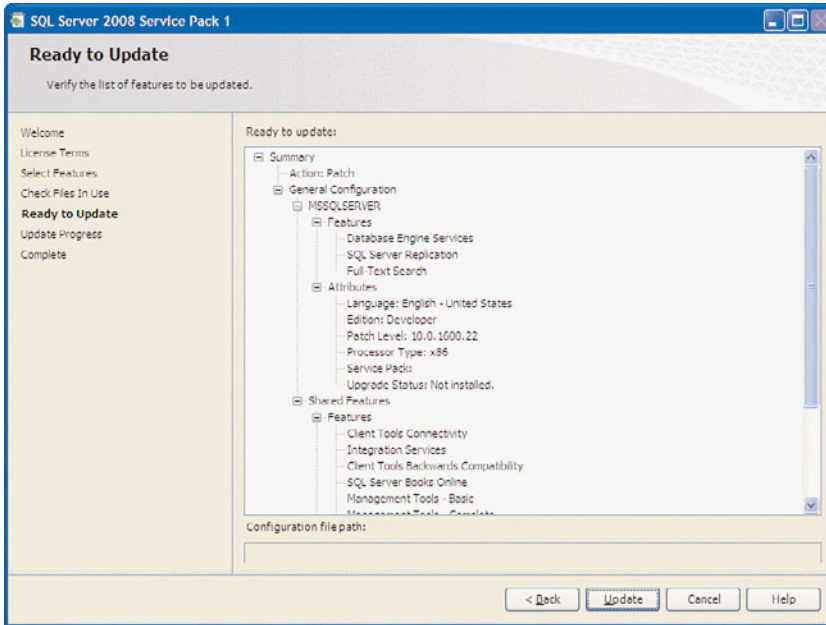

FIGURE 8.26 SQL Server 2008 SP1 Ready to Update screen.

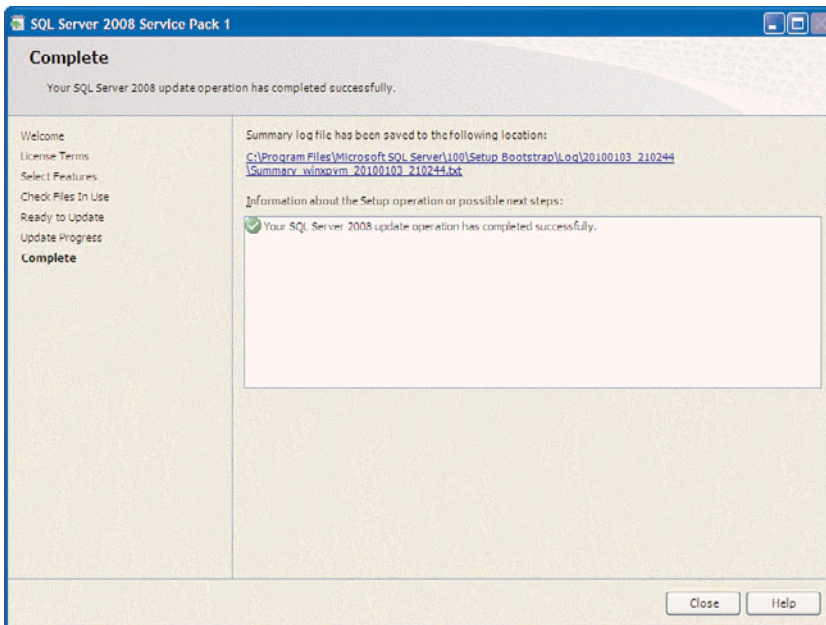

FIGURE 8.27 SQL Server 2008 SP1 Installation Complete screen.

After extracting the SP1 setup files to a folder, you can run the `setup.exe` program from the command line. The SP1 setup program supports options similar to the SQL Server 2008 installer command-line options (although significantly fewer options are available):

- ▶ **/HELP**—Displays these command-line parameters.
- ▶ **/ALLINSTANCES**—Specifies that all instances are to be included in the setup operation.
- ▶ **/CLUSTERPASSIVE**—Specifies that the setup utility should not automatically start and stop the SQL Server services if running in a non-Microsoft cluster environment.
- ▶ **/INDICATEPROGRESS**—Specifies that the detailed Setup log messages should be displayed to the console.
- ▶ **/INSTANCENAME**—Specifies the default or named instance to be updated
- ▶ **/QUIET**—Runs the install in full unattended mode. Setup does not display any user interface.
- ▶ **/QUIETSIMPLE**—Runs the install in Quiet Simple mode. Setup displays the wizard screens but without any user interaction.
- ▶ **/X86**—Specifies that Setup should install a 32-bit edition into WOW64 on an x64-based system.

For example, to install SP1 with no user interaction for all instances on a server, you would run the following command:

```
setup.exe /quiet /allinstances
```

Slipstream Installations

With the release of SQL Server 2008 SP1, Microsoft provides the capability to create Slipstream installations of SQL Server 2008. Slipstreaming is a method of integrating a SQL Server 2008 update with the original installation media so that the original media and update are installed at the same time. This capability can be a huge timesaver over having to manually run a service pack and possible cumulative update installations after running a full SQL Server install, especially if you have to repeat the installation in multiple environments.

Slipstreaming is supported in the following scenarios:

- ▶ Installing the original media and a service pack
- ▶ Installing the original media, a service pack, and a cumulative update to the service pack

NOTE

Slipstreaming a cumulative update for SQL Server 2008 with the original media but without a service pack is not supported because slipstreaming wasn't supported until SQL Server 2008 SP1 was released. Also, a Slipstream installation cannot be performed to update a SQL Server 2008 instance to SQL Server 2008 R2.

If you are doing a single install of SQL Server 2008 and at the same time want to apply SP1 and possibly a cumulative update as well, you can run the Slipstream installation by performing the following steps:

1. If they are not installed already on the target machine, install the required prerequisites for the SQL Server 2008 Installer (.NET Framework 3.5 SP1 and Windows Installer 4.5). You can install them manually from the SQL Server install disk (the installers are located in the *Drive_Letter:\platform\redist\Windows Installer* folder). Alternatively, after you extract the service pack files, run the `sqlsupport.msi` file from within the folder where the service pack files have been extracted. For example, if you extracted the Service pack to the `C:\sql2k8xp1` folder on an X86 platform, this file would be found in the `C:\SQL2K8SP1\x86\setup\1033` folder.

NOTE

To confirm whether the setup support files are installed, search for the Microsoft SQL Server 2008 Setup Support Files entry in the Programs and Features Control Panel (or the Add or Remove Programs Control Panel in operating systems prior to Windows Vista or Windows Server 2008).

NOTE

On the IA-64 platform, the .NET Framework 3.5 is not supported. The .NET Framework 2.0 SP2 is required instead. The .NET Framework 2.0 SP2 is located in the *Drive_Letter:\ia64\redist\2.0\NetFx20SP2_ia64.exe* folder on the source media.

2. If not done already, download the Service Pack (PCU) package that matches your system architecture and, if desired, the cumulative update (CU) package you want to install.
3. For each package you want to include in the Slipstream installation, extract the contents to a folder on the local drive by running a command similar to the following at the command prompt from within the folder where you downloaded the package(s):

```
Name_of_the_PCU_or_CU_package.exe /x:Root_of_path_to_extract_to<PCU | CU>
```

4. Now things get a bit tricky. Because Slipstream support is introduced with SP1, the `setup.exe` program that shipped with the original SQL Server 2008 installation media doesn't support the `/PCUSource` or `/CUSource` options that allow you to specify the locations of the service pack and cumulative updates to be slipstreamed. Instead, you need to run the SQL Server 2008 Setup program for Service Pack 1 and specify the action as `INSTALL`, and the file paths for the original media, as well as service pack and cumulative update files. These are specified using the `/ACTION`, `/MEDIASource`, `/PCUSource`, and `/CUSource` parameters. The following example shows how to run a slipstream install of SQL Server 2008 from the install CD in the D: drive with SP1 extracted to the C:\SQLServer2008SP1 folder:

```
C:\SQLServer2008SP1>setup.exe /PCUSource=C:\SQLServer2008SP1 /ACTION=INSTALL
/MEDIASOURCE=D:\
```

This command runs the SQL Server installation in the normal GUI mode, requiring you to specify and confirm all settings. If you want, you can also choose to run the install in a limited interface or automated mode, as described previously in this chapter in the section describing how to use a configuration file. However, the first time you run a Slipstream installation, you should at least use an interface that allows you to view the Ready to Install page before running the installation so that you can verify whether the desired Slipstream installation is being performed. If the setup utility is running a Slipstream installation, it is indicated in the Action field, as shown in Figure 8.28.

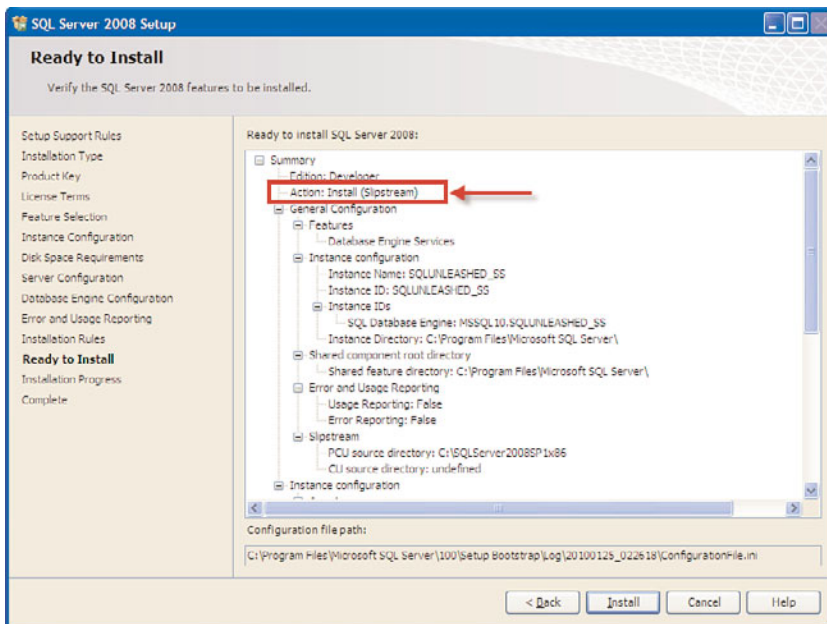

FIGURE 8.28 Verifying a Slipstream installation on the Ready to Install page.

Summary

This chapter provides a fairly detailed overview of the SQL Server 2008 install process from start to finish. The chapter shows how the new Installer Wizard makes it easy to install as many instances as you like, with whatever feature sets and in whatever configuration you choose.

The chapter also shows how the installer reports progress, failure, and success on an individual task basis rather than with one seemingly endless progress bar, making it a lot easier to rectify problems without calling Microsoft or scouring the newsgroups to figure out what went wrong.

Chapter 9, “Upgrading to SQL Server 2008,” takes a similar approach to examining the process of upgrading from SQL Server 2000 or SQL Server 2005 to SQL Server 2008 or SQL Server 2008 R2.

This page intentionally left blank

CHAPTER 9

Upgrading to SQL Server 2008

SQL Server 2008 offers a number of new features and improvements that make upgrading desirable. You can upgrade instances of SQL Server 2000 and SQL Server 2005 to SQL Server 2008 or SQL Server 2008 R2, as well as upgrade SQL Server 2008 to SQL Server 2008 R2. Whether you're a gung-ho developer or the most conservative of administrators, there's an upgrade path to suit your comfort level. This chapter provides best practices and recommendations for upgrading to SQL Server 2008 with minimal issues.

What's New in Upgrading SQL Server

SQL Server 2008 provides a new installer program for performing installations and upgrades. The new features of the SQL Server 2008 Installer include

- ▶ A new SQL Server 2008 Installation Center landing page, which includes a number of options for planning, installing, and maintaining a SQL Server implementation; links to SQL Server documentation for planning and reviewing before starting the upgrade; and a link to install the Upgrade Advisor.
- ▶ The Feature Upgrade Wizard, which allows DBAs to upgrade or change the installed edition of SQL Server 2008 or SQL Server 2008 R2 (for example, upgrading from Standard Edition to Enterprise Edition without having to perform a complete reinstall).

IN THIS CHAPTER

- ▶ What's New in Upgrading SQL Server
- ▶ Using the SQL Server Upgrade Advisor (UA)
- ▶ Destination: SQL Server 2008 or SQL Server 2008 R2
- ▶ Upgrading Using a Configuration File
- ▶ Slipstreaming Upgrades⁷⁴
- ▶ Upgrading Other SQL Server Components

- ▶ A discovery report that provides a detailed information regarding all SQL Server components, features, and settings associated with an install or upgrade.
- ▶ The potential to automate SQL Server upgrades by using a configuration file.
- ▶ A tool that allows for a smooth transition of SQL Server Integration Services (SSIS) packages by automatically upgrading them from SQL Server 2005 to the SQL Server 2008 Integration Services format.

Also new in SQL Server 2008 is a refined Upgrade Advisor. The Upgrade Advisor tool allows a DBA to fully analyze existing SQL Server 2005 and SQL Server 2000 installations for issues that may surface when upgrading to SQL Server 2008 or SQL Server 2008 R2. Addressing these issues before conducting the upgrade should lead to a smoother experience when transitioning to SQL Server 2008.

With the release of Service Pack 1, SQL Server 2008 also now supports Slipstream installations. Slipstreaming is a method of integrating a SQL Server 2008 update (such as a service pack or cumulative update) with the original installation media so that the original media and update are installed at the same time. This can be a huge timesaver over having to manually apply service packs or cumulative updates after performing a full installation or upgrade.

NOTE

The focus of this chapter is on upgrade options and best practices rather than a screen-by-screen walkthrough of the upgrade process. An upgrade installation is not much different from a new installation. See Chapter 8, “Installing SQL Server 2008,” for a detailed walkthrough and description of the installer screens and options.

Using the SQL Server Upgrade Advisor (UA)

It would be a daunting task indeed to try to test every stored procedure and function, every table and view, every online analytical processing (OLAP) cube, every Data Transformation Services (DTS) or SQL Server Integration Services (SSIS) package, and so on that your team has built to make sure they still work after you migrate them to SQL Server 2008.

With the availability of the SQL Server Upgrade Advisor (UA), you can relax a bit and let the combined experience and testing of early adopters and the SQL Server development team go to work for you.

NOTE

Even though the UA is a great tool, if you have the resources to do so, it is a good idea to set up an additional test environment just for SQL Server 2008. Also, you should thoroughly test your upgraded objects and code *after the upgrade* on a dry run, just to be sure you don't miss anything. Remember to make full backups!

The UA advises on which aspects of your current setup should or need to be changed to become compatible with SQL Server 2008. Let's look at how it works.

Getting Started with the UA

Before running the Upgrade Advisor, you must first install it. The easiest way to install the Upgrade Advisor is to start the SQL Server 2008 Installer. On the Installer Landing page is an option to install the Upgrade Advisor (see Figure 9.1). Alternatively, the Upgrade Advisor is available in the Servers\redist\Upgrade Advisor folder of the SQL Server installation media, or from the Microsoft Download Center. The Upgrade Advisor has the following system requirements:

- ▶ Windows XP Service Pack 2 (SP2) or later, Windows Vista, Windows Server 2003 SP2 or later, or Windows Server 2008 SP2, Windows 7, and Windows Server 2008 R2.
- ▶ Windows Installer beginning with version 4.5 (required by the .NET Framework; you can install Windows Installer from the Windows Installer website)
- ▶ The .NET Framework

FIGURE 9.1 Installing the Upgrade Advisor from the SQL Server 2008 Installer.

NOTE

If not installed already, the .NET Framework 2.0 is available on the SQL Server 2008 product media, and from the SDK, redistributable, and service pack download website. To install the .NET Framework 2.0 from the SQL Server 2008 media, locate the root of the disk drive. Then double-click the \redist folder, double-click the \2.0 folder, and run Dotnetfx.exe (for 32-bit) or Dotnetfx64.exe (for 64-bit), depending on your operating system.

If you run the SQL Server Installer, it installs the Windows Installer and .NET Framework requirements automatically if they are not detected.

If upgrading from SQL Server 2000 Analysis Services, you need to install the SQL Server 2000 Decision Support Objects (DSOs) on the system where UA will be run to scan upgrade issues in Analysis Services. To install DSOs, run the SQL Server 2000 Setup program and click Install SQL Server 2000 Components. Click Analysis Services to start the Analysis Services Setup program. In Select Components, make sure that the Decision Support Objects component is selected.

Additionally, if you are upgrading SQL Server 2000 DTS packages, the SQL Server 2000 client components are required to scan SQL Server 2000 DTS packages. The SQL Server 2000 client components can be installed from the SQL Server 2000 installation disk.

If you are upgrading from SQL Server 2005 DTS packages that were migrated from SQL Server 2000, you need to install the SQL Server 2005 backward-compatibility components to scan SQL Server 2005 DTS. Use the SQL Server 2005 installation disk to install backward-compatibility components.

NOTE

The location where you can install SQL Server Upgrade Advisor depends on what you will be analyzing. Upgrade Advisor supports remote analysis of all supported components except Reporting Services. If you are not scanning instances of Reporting Services, you can install Upgrade Advisor on any computer that can connect to your instance of SQL Server and that meets the Upgrade Advisor prerequisites. If you are scanning instances of Reporting Services, you must install Upgrade Advisor on the Report Server.

As described in the following sections, the UA has two main functional areas: the Analysis Wizard and Report Viewer. The first time you use Upgrade Advisor, run the Upgrade Advisor Analysis Wizard to analyze SQL Server components. When the wizard finishes the analysis, you can view the resulting reports in the Upgrade Advisor Report Viewer.

The Analysis Wizard

You'll be glad to know that the analysis process does not modify any code or data; that is left for you to do (or not do) at a later time. As an example, let's run the UA's Analysis Wizard against all the SQL Server components of a locally installed SQL Server 2005 instance. The Analysis Wizard examines objects that can be accessed, such as scripts, stored procedures, triggers, and trace files. Upgrade Advisor cannot analyze desktop applications or encrypted stored procedures.

To start the process, click the Launch Upgrade Advisor Analysis Wizard hyperlink at the bottom of the Welcome page (see Figure 9.2). When the Analysis Wizard's Welcome page appears, click Next. When you reach the SQL Server Components screen, choose all the components to be analyzed by checking their corresponding check boxes (see Figure 9.3).

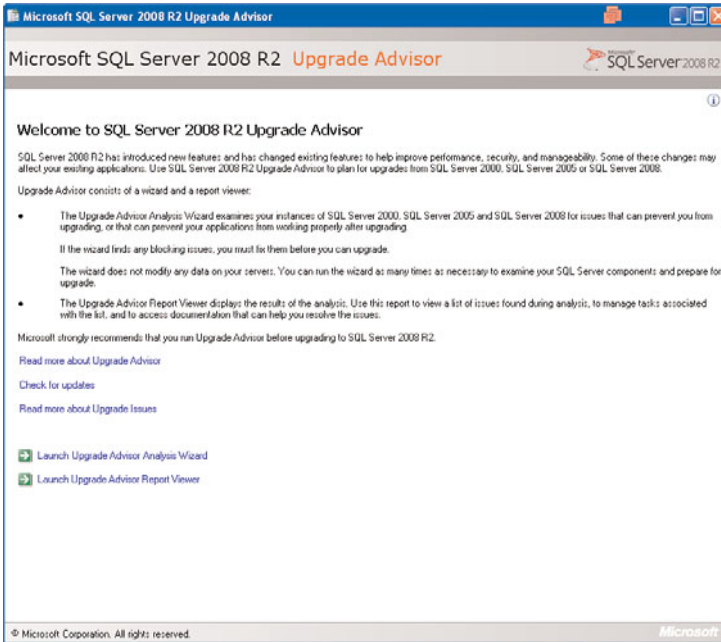

FIGURE 9.2 The Upgrade Advisor Welcome page.

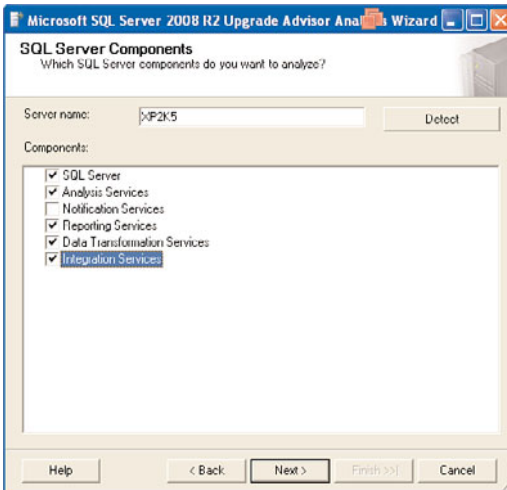

FIGURE 9.3 Choosing the components to be analyzed by the UA's Analysis Wizard.

NOTE

Be sure to select only components that are actually installed on the server being upgraded; otherwise, the Upgrade Advisor stalls at the appropriate feature screen with an error message that the feature could not be found on the specified server.

When the Connection Parameters screen appears, choose the target server, select an authentication method, and if using SQL Server authentication, enter your username and password so that the UA can connect to your instance. Click Next, and the SQL Server Parameters screen, shown in Figure 9.4, appears. Choose which (if any) databases to analyze.

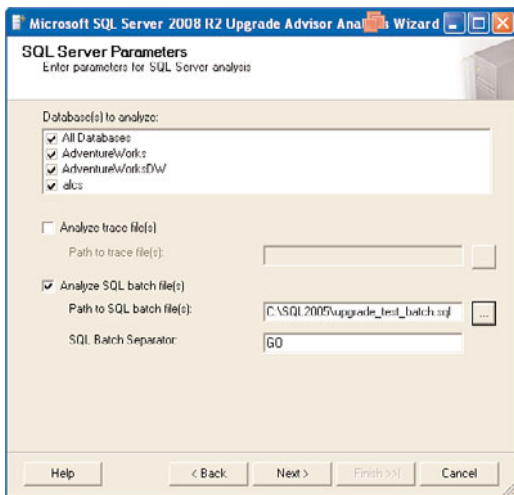

FIGURE 9.4 Choosing the databases and files for the UA to analyze.

You can also use this screen to ask the UA to analyze one or more SQL Profiler trace (.trc) files. This feature is useful for analyzing the T-SQL statements submitted from one or more applications for deprecated or discontinued features. You would want to set up and run a trace in SQL Profiler ahead of time to capture a representative sample of the T-SQL executed against the server. You can also scan T-SQL batch files (maintenance scripts, procedures, functions, triggers, and so on) to check for deprecated or discontinued features used in the SQL scripts.

For this example, create a SQL batch file that contains the following T-SQL commands, most of which are deprecated in SQL Server 2008, just to test the UA:

```
use bigpubs2008
go

EXEC sp_configure 'set working set size'
```

```

SELECT * FROM master..syslockinfo

DECLARE @ptr varbinary(16)

SELECT @ptr = TEXTPTR(pr_info)
FROM pub_info
WHERE pub_id = '6380'

SELECT *
FROM Stores s, Stores s2
WHERE s.Stor_Id *= s2.Stor_Id
AND s.Stor_name <> s2.Stor_name

READTEXT pub_info.pr_info @ptr 0 25

```

When you're ready, click Next, and the Upgrade Advisor presents screens for each of the SQL Server components you selected previously (refer to Figure 9.3) asking for login information or to select packages to analyze. Note that if you selected a component, but that component isn't installed on the server you are upgrading, the Upgrade Advisor reports that no instances of that component could be found on the server and you cannot proceed until you go back and deselect the component.

If you selected to analyze DTS or SSIS packages, the DTS and SSIS Parameters screens (shown in Figure 9.5) give you the option to analyze all the packages stored in the target instance or to specify one or more package files to be analyzed.

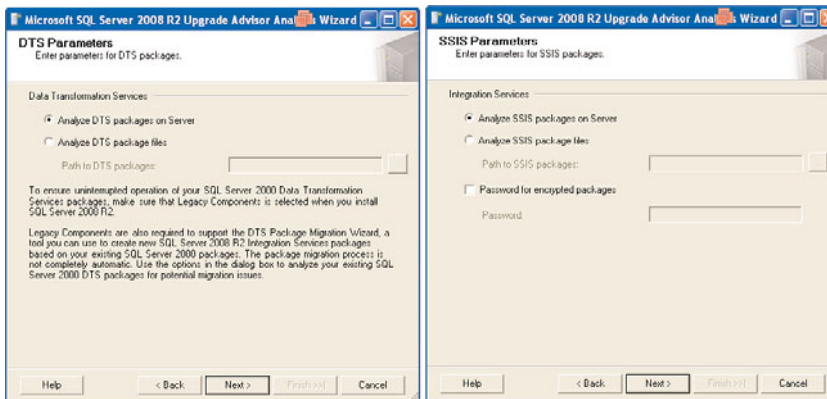

FIGURE 9.5 Choosing the DTS and SSIS packages to analyze.

Note that the DTS Parameters screen advises that you must install the Legacy Components feature when installing SQL Server 2008; otherwise, SQL Server 2008 will not be able to run your DTS packages (unless they are upgraded to the new SSIS format). To upgrade your DTS packages, you need to use the DTS Migration Wizard, which is installed with SSIS and discussed later in this chapter, in the section “Migrating DTS Packages.”

When you’re all set with your DTS and SSIS selections, click Next to reach the Confirm Upgrade Advisor Settings screen. Make sure that all the SQL Server services you are analyzing are running and (if you’re happy with your selections) click the Run button to begin the analysis.

As you can see from the Upgrade Advisor Progress screen that appears (see Figure 9.6), the wizard performs a task-based study of each component, providing per-step reporting, similar to the installer and the System Configuration Checker (both discussed in Chapter 8).

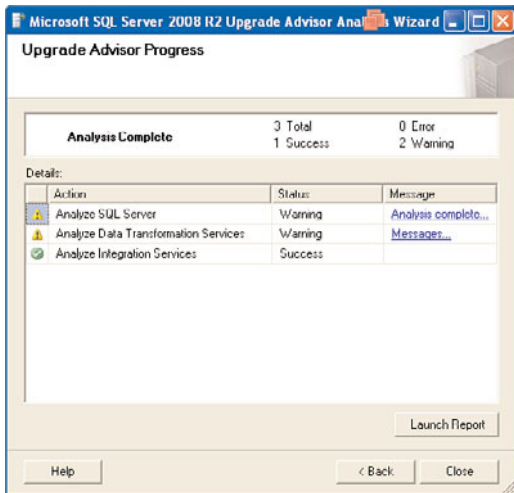

FIGURE 9.6 The Upgrade Advisor Progress screen.

When the analysis is complete, the UA Progress screen presents a Launch Report button. The output of the UA Analysis Wizard is an XML report that you can view via the second major component of the UA, the Report Viewer, described in the next section.

NOTE

You can view your last-generated report by using the Report Viewer; you can find the link to launch it on the main screen. If you run the UA more than once against the same SQL Server instance, however, you must save your previously generated reports to a directory other than the default output directory; otherwise, the previously generated report will be overwritten.

UA reports are saved by default to the folder `My Documents\SQL Server 2008 R2 Upgrade Advisor Reports\Servername`, and then they are broken down into separate XML files by component (for example, `AS.xml` for Analysis Services, `DE.xml` for the Database Engine).

You can launch the Report Viewer to figure out what to do about the issues the UA may have uncovered. Click the Launch Report button to proceed.

The Report Viewer

The Report Viewer is one of the most important tools in the upgrade process because it provides per-issue messaging, resolution tracking, and (in many cases) hyperlinks to the compiled help documentation distributed with the UA.

Issues are organized in the Report Viewer on a per-server and then per-component basis. They can be filtered by type (that is, all issues, all upgrade issues, pre-upgrade issues, all migration issues, and resolved issues), and you can track your resolution progress by checking the This Issue Has Been Resolved check boxes. Figure 9.7 shows the main user interface of the Report Viewer.

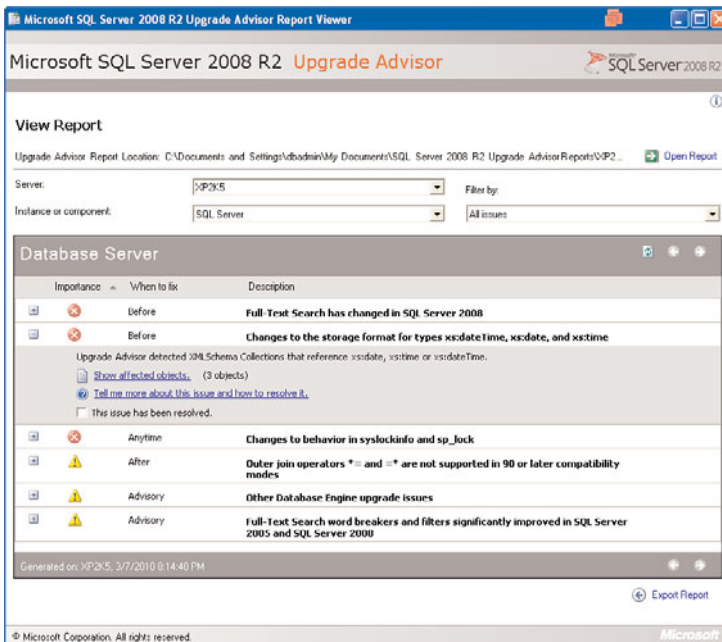

FIGURE 9.7 SQL Server UA's Report Viewer.

Destination: SQL Server 2008 or SQL Server 2008 R2

Now that you have become familiar with how to use the helpful Upgrade Advisor, you're ready to begin your extensive pre-upgrade testing phase. After you resolve all the issues you can, it's time to take the next step: install SQL Server 2008 (in your test and development environments first, of course).

Two different paths lead from SQL Server 2000 or 2005 to SQL Server 2008:

- ▶ You can upgrade your existing SQL Server 2000 SP4 or later and SQL Server 2005 SP2 or later instances in-place, using the SQL Server Installer.
- ▶ You can install SQL Server 2008 side by side with your current SQL Server instances and then migrate your data and other content to SQL Server 2008.

The same upgrade paths exist for upgrading from SQL Server 2008 to SQL Server 2008 R2.

The path you choose depends primarily on two factors: your comfort level with the new platform and the scope of feature use in your current environment. When you have become familiar with what it takes to travel either path, you'll find it much easier to make your decision. The first approach we explore in this chapter is the more conservative side-by-side migration path.

NOTE

If the server environment where your current SQL Server installation resides is not a supported platform for performing an in-place upgrade, a side-by-side migration may be your only option. For example, if you are upgrading from SQL Server 7 or running in a Windows 2000 server environment, an in-place upgrade is not supported. For a list of supported in-place upgrade paths, see the "Upgrading In-Place" section, later in this chapter.

Side-by-Side Migration

SQL Server 2008 can coexist without a problem on the same servers as any existing SQL Server 2000 or 2005 instances. SQL Server 2008 R2 can coexist on the same servers as any existing SQL Server 2000, 2005, or 2008 instances. This means you can install one or more instances of SQL Server 2008 or 2008 R2 without performing an in-place upgrade of any pre-2008 instances. You don't have to worry about whether you're breaking existing functionality. Side-by-side migration is therefore an easy option to investigate.

NOTE

If you are doing a side-by-side installation, be sure your server has sufficient resources (CPU, memory, disk space) to support running multiple instances of SQL Server.

Many administrators favor the side-by-side approach to upgrading because it gives everyone on the development team (including eager software folks) a chance to get comfortable

with the new features in the new SQL Server release *before* committing to it in production environments.

In addition, it is far easier to roll back to your previous-version SQL Server components because installing side by side leaves them intact (unlike upgrading in-place, which replaces them). When you are reasonably comfortable with the new SQL Server release, you can go forward confidently in migrating all your objects (presuming that, if you're leaving previous versions intact, you're also ready to perform necessary tasks, such as changing connection strings, server aliases, and so on).

Avoiding an Unintentional In-Place Upgrade During Setup

If you do intend to go ahead with a side-by-side installation, there's a small gotcha you need to watch out for when installing a new instance of SQL Server 2008. When you run the Setup program, the Instance Name screen is somewhat lengthy in its header's verbiage, and if you don't take the time to read it closely, you might unintentionally upgrade all your components. This is the lowdown:

- ▶ If you choose the Default Instance radio button and you already have a SQL Server default instance, that default instance is upgraded.
- ▶ If you choose the Named Instance radio button, you need to make sure to enter a name that you know is not in use as an instance name; otherwise, the existing named instance is upgraded.

Figure 9.8 shows an example of how to make the right choice and use an instance name, SQL2008R2, that makes it abundantly clear you are installing a new instance.

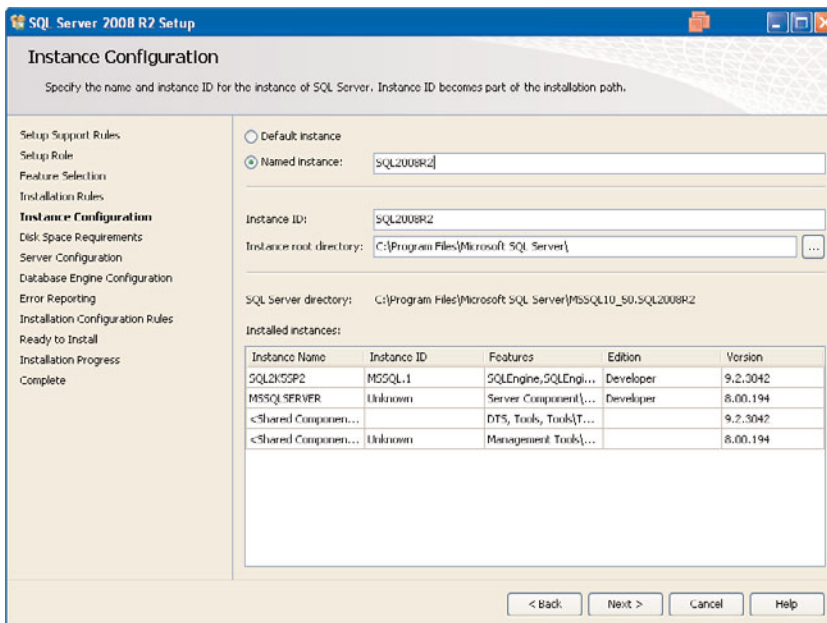

FIGURE 9.8 Installing a new named SQL Server 2008 R2 instance.

Migrating Databases

Now it's time for the most important task: migrating your databases to SQL Server 2008. One method of migrating to SQL Server 2008 or 2008 R2 is by backing up your SQL Server 2000 and 2005 databases and restoring them to SQL Server 2008. Another method is to attach or restore a database from a prior version of SQL Server to SQL Server 2008. When you migrate using either of these methods, the database is upgraded automatically during the attach/restore process.

NOTE

Database backups created by using SQL Server 7.0 or earlier are in an incompatible format and cannot be restored in SQL Server 2008 or 2008 R2. For information on how to migrate a database from SQL Server 6.5 or 7.0 to SQL Server 2008, see the section "Upgrading from SQL Server 7 or SQL Server 6.5," later in this chapter.

When you use backup and restore to copy a database to another instance of SQL Server, the source and destination computers can be any platform on which SQL Server runs. The general steps to upgrade using backup and restore are as follows:

1. Back up the source database that resides on an instance of SQL Server 2000, SQL Server 2005, SQL Server 2008, or SQL Server 2008 R2.
2. Restore the backup of the source database on the destination SQL Server. Restoring the database automatically creates all the database files and upgrades the database.

When restoring the database, you might need to use the `MOVE` option to relocate the database files because SQL Server 2008 and SQL Server 2008 R2 use a different default path than earlier versions. For more information on using backup and restore, see Chapter 14, "Database Backup and Restore."

In SQL Server 2008 R2, you can also use the detach and attach operations to migrate a user database from SQL Server 2000 or SQL Server 2005. After you attach a SQL Server 2005 or SQL Server 2000 or SQL Server 2008 database to SQL Server 2008 R2, the database is upgraded automatically and becomes available immediately. For more information on the syntax and options for detaching and attaching databases, see Chapter 23, "Creating and Managing Databases."

Another method of migrating an existing database is by using the SQL Server Copy Database Wizard to copy databases between multiple instances of SQL Server.

TIP

Before you use any of the methods described here, Microsoft recommends you run the appropriate DBCC consistency checks to make sure there is no data corruption within the databases to be migrated.

Using the Copy Database Wizard Using the Copy Database Wizard is probably the easiest approach to use to migrate your databases to SQL Server 2008 or 2008 R2. To run the

Copy Database Wizard, using SQL Server Management Studio (SSMS), connect the Object Explorer to your previous SQL Server version's instance. Expand Databases and then select and right-click the database you want to copy (or move) into SQL Server 2008. Then select Tasks, Copy Database.

When the wizard's initial Welcome page is displayed, click Next and then select your source server (the 2000 or 2005 instance). Click Next again and select your destination server (your newly installed SQL Server 2008 or SQL Server 2008 R2 instance). Click Next again to bring up the Select the Transfer Method screen. This screen provides two options for copying or moving your databases to SQL Server 2008:

- ▶ **Detach and Attach**—This option is the same as the detach/attach method described previously. It's fast, but it takes the database offline during the migration process.
- ▶ **Use the SQL Server Management Objects (SMO) to Import the Database**—This option is slower, but it keeps the source database online during the process.

NOTE

When you use the detach and attach method, SSIS uses the service account of SQL Server Agent that is running on the 2008 (destination) instance. This account must be able to access the file systems of both servers; otherwise, the wizard will fail.

Select the option that works best for you and then click Next. The Select Databases screen appears, and, as Figure 9.9 shows, you should check the Copy (not Move) check boxes for the databases you want to migrate.

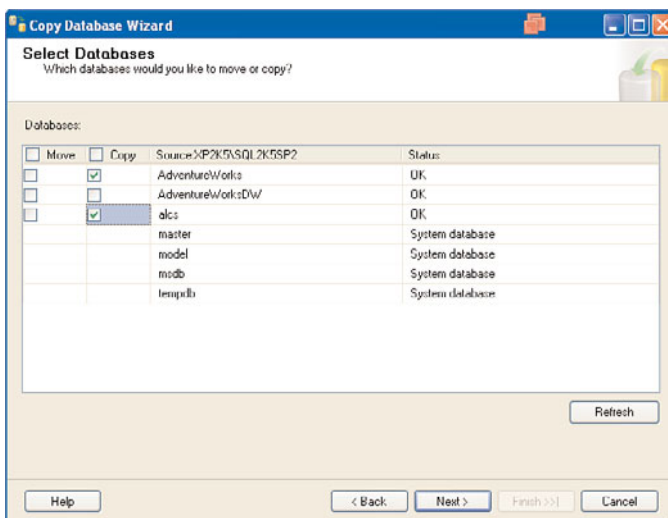

FIGURE 9.9 Selecting the databases to copy to SQL Server 2009.

CAUTION

After a pre-2008 database is upgraded (in case you choose the Move Database option or you perform an attach or restore and delete the original), it cannot be downgraded back to its former version—not even if you attempt to detach/attach or restore it to SQL 2000 or 2005. Thus, it is especially important to create full backup copies of all your databases before you upgrade. It's also a good idea to back up the entire Program Files/Microsoft SQL Server directory tree.

After you make your database selections, click Next, and the Configure Destination Database screen appears for each database you selected in the previous step. This screen allows you to rename the database on the destination server if you so desire (see Figure 9.10). It also provides options to overwrite any existing databases or MDF (data) and LDF (log) files on the destination server or to create new ones in the folders of your choice. Make your selections and click Next.

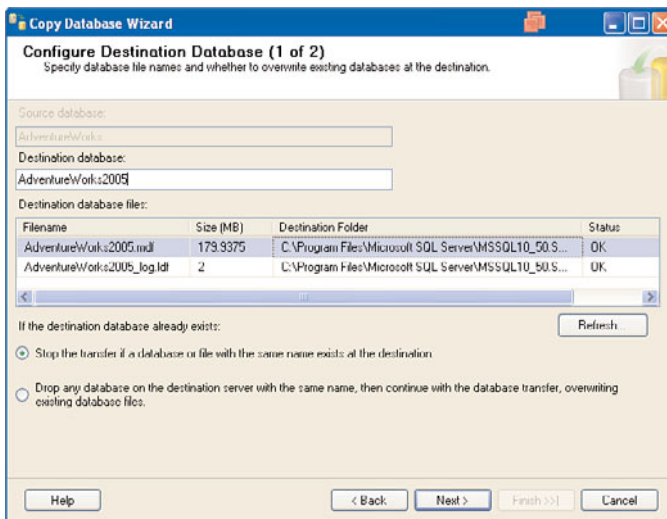

FIGURE 9.10 Copy Database Wizard Configure Destination Database screen.

The Select Database Objects screen that appears next (see Figure 9.11) provides some real power because it allows the server-wide objects (those stored in the system databases and source database) to be imported. These objects include stored procedures residing in master, SQL Server Agent jobs, custom user-defined error messages, SSIS packages, and SQL Server logins. You need to click the ellipsis button to choose the specific ones you want to import (rather than choosing them all, which is the default).

When you're finished selecting the objects you want brought over, click Next again. The Configure the Package screen that appears next provides the opportunity to name and save the SSIS package created for migrating the database, and to specify how you want to log the messages generated during the transfer. Click Next to present the Schedule the

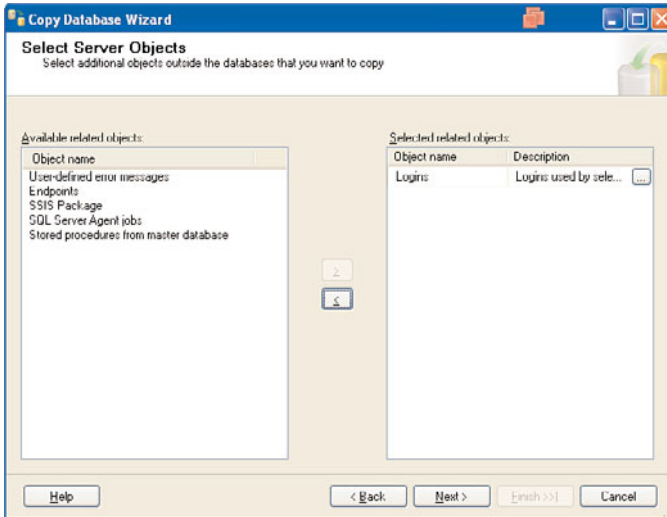

FIGURE 9.11 Importing server-wide objects, using the Copy Database Wizard.

Package screen, which allows you to run the transfer immediately or schedule it to run at a specific time. You are also given an opportunity to specify an SSIS proxy account to use to run the transfer (you should make sure it's an account that has appropriate permissions on both the source and destination servers to ensure a successful transfer).

After you make your scheduling choices, click Next to display the Complete the Wizard screen (see Figure 9.12). Here, you have an opportunity to review the choices you've made on the prior screens. If everything looks okay, click Finish to complete the wizard and start or schedule the Copy Database package.

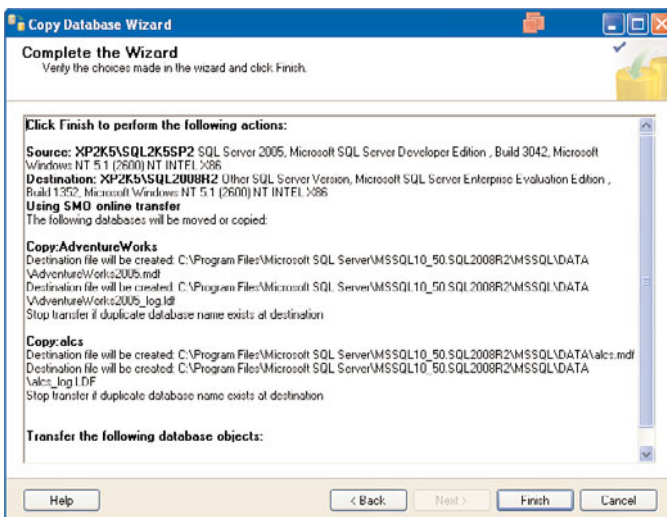

FIGURE 9.12 The Copy Database Complete the Wizard screen.

Database Compatibility Level Migrating pre-2008 databases into SQL Server 2008 brings up the question of compatibility issues and database compatibility levels. The compatibility level is a per-database setting that controls T-SQL execution behavior with regard to SQL Server's versioning system.

The T-SQL execution engine is flexible insofar as it has the capacity to switch between varying, version-dependent behaviors according to the current compatibility-level setting.

When a database is upgraded to SQL Server 2008 from any earlier version of SQL Server, the database retains its existing compatibility level if it is at least 80 (SQL Server 2000). Upgrading a database with a compatibility level below 80 sets the database to compatibility level 80.

Compatibility level affects behaviors only for the specified database, not for the entire server. An important point to understand about database compatibility levels, however, is that the database compatibility-level setting is intended to provide only partial backward compatibility with earlier versions of SQL Server. It does not prevent the use of new T-SQL features available in SQL Server 2008 such as new data types and statements.

The compatibility-level setting is provided primarily as an interim migration aid to work around version differences in the behaviors that are controlled by the relevant compatibility-level setting. Essentially, it allows T-SQL code that may be using deprecated features or expects pre-100 level behaviors for certain commands to continue operating as it did in the prior version of SQL Server. Using the compatibility-level setting should not be viewed as a permanent solution. It should be used only until the T-SQL code affected by behavioral differences in SQL Server 2008 can be converted to work properly in SQL Server 2008. Then you can use `ALTER DATABASE` to change the compatibility level to 100.

You can find a full list of the behavioral differences between the compatibility-level settings in the Books Online article associated with the "ALTER DATABASE Compatibility Level" topic. This option can be used to set the compatibility level for a particular database.

To view the current compatibility level of a database, query the `compatibility_level` column in the `sys.databases` catalog view:

```
select compatibility_level from sys.databases where name = db_name()
go

compatibility_level
-----
90
```

Upgrading In-Place

Now that you've seen how to migrate your databases to SQL Server 2008 by following the side-by-side migration path, let's look at the alternative: upgrading in-place. Unlike a side-by-side install, an in-place upgrade permanently modifies the SQL Server components, data, and metadata objects, and there is no going back. You will likely be more comfortable taking the side-by-side migration path than doing an in-place upgrade, unless a side-

by-side migration is not possible because of disk space limitations, you have very few SQL Server features in use, or you are fairly confident about the potential success of the upgrade process because you've done extensive issue resolution with the assistance of the Upgrade Assistant.

If you are performing an in-place upgrade of the Database Engine, it is strongly recommended that you first do the following:

- ▶ Create full, verified backups of your existing SQL Server databases.
- ▶ Run the appropriate DBCC consistency checks (for example, DBCC CHECKDB and DBCC CHECKFILEGROUP).
- ▶ Make sure the system databases on your pre-2008 instances (for example, master, msdb, tempdb, and model) are all set to auto-grow.
- ▶ Disable any startup stored procedures that get kicked off when the SQL Server service starts.
- ▶ Disable database replication and empty the replication log.

After you perform all these actions, you are ready to begin the upgrade process.

Upgrading the Database Engine

You perform an in-place upgrade by running the SQL Server Installation Center. On the Installation page, you can invoke the Upgrade Wizard to upgrade from SQL Server 2000, 2005, or 2008 (see Figure 9.13). After first running the Setup Rules check and installing the Setup Support Files, the Upgrade Wizard essentially runs the installation process. (The installation process and all its screens are described in Chapter 8 under the heading, "Install Screens, Step by Step.") The key differences between running a new install versus an upgrade is that during the upgrade process, you choose an existing default or named instance on the Select Instance screen (see Figure 9.14).

After selecting the instance to upgrade, you see the Feature Selection page. The features to be upgraded are preselected. You cannot change the features to be upgraded, and you cannot add features during an upgrade operation. To add features, you need to run the Installation Center again after the upgrade operation is complete.

After making choices on the Features Selection page, step through the Instance Configuration, Disk Space Requirements, and Server Configuration screens, making changes as necessary. For example, authentication and login information are carried forward from the previous instance of SQL Server. You can assign the same login account to all SQL Server services, or you can configure each service account individually. You can also specify whether services start automatically, are started manually, or are disabled.

Next, you are presented with options for upgrading your full-text catalogs. In SQL Server 2005 and earlier versions, each full-text index resided in a full-text catalog that belonged to its own filegroup and was treated as a database file. In SQL Server 2008, a full-text catalog is a logical concept that refers to a group of full-text indexes and is no longer treated as a separate database file with a physical path. However, during upgrade of any

FIGURE 9.13 Running the Upgrade Wizard from the Installation Center.

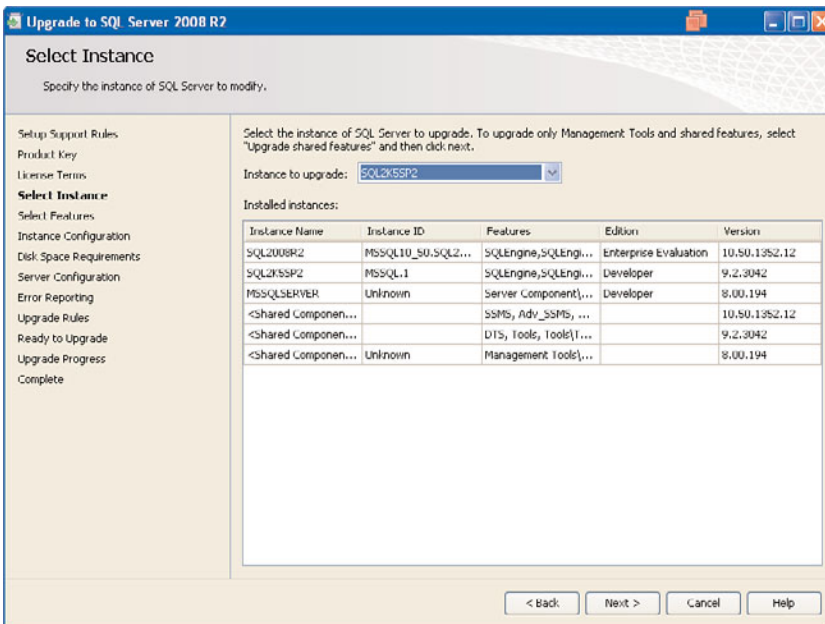

FIGURE 9.14 The Select Instance screen in the SQL Server Installation Center.

full-text catalog, a new filegroup is still created on the same disk to maintain the pre-upgrade disk I/O behavior. If the old full-text catalog path is invalid, though, the upgrade places the full-text index in the same filegroup as the base table or in the primary filegroup if the table is partitioned.

Three options are available for upgrading your existing full-text catalogs:

- ▶ **Import**—Typically, import is the fastest method of upgrading, but an imported full-text catalog does not use the new and enhanced word breakers introduced in SQL Server 2008, so you might want to rebuild your full-text catalogs eventually if not during the upgrade.
- ▶ **Rebuild**—This method uses the new SQL Server 2008 word breakers, but rebuilding indexes can take awhile.
- ▶ **Reset**—When you use this method, SQL Server 2005 full-text catalog files are removed, but the metadata for full-text catalogs and full-text indexes is retained. The catalog remains empty until you manually issue a full population after the upgrade completes.

After choosing your full-text upgrade option, you next choose your Error Reporting options, and then the Upgrade Rules check is run to validate your system configuration with the options and features chosen during the upgrade process. If all the rules pass, you can review the upgrade operation on the Ready to Upgrade page, which also displays the path to the upgrade configuration file (this is useful for setting up and performing unattended upgrades from the command line, as discussed later in this chapter). If everything looks okay, click Upgrade to begin the upgrade process. The upgrade process automatically upgrades all objects that are common to all databases, including the following:

- ▶ Tables, views, indexes, and constraints
- ▶ Stored procedures, functions, and triggers
- ▶ User-defined types, rules, and defaults
- ▶ Logins, users, and permissions
- ▶ Database diagrams

You can monitor the upgrade progress on the Upgrade Progress screen. Depending on your hardware configuration and the features to be upgraded, the upgrade operation can take from approximately 30 minutes to several hours. The databases on the instance being upgraded remain unavailable until the upgrade is complete.

When the upgrade finishes, it displays the upgrade status of each component and also provides the location of the upgrade log. A system restart may be required in some cases if any upgraded components were in use during the upgrade process.

When your upgrade of the Database Engine is complete, it is recommended that you perform the following on all databases (also recommended for side-by-side migration):

- ▶ Repopulate your full-text catalogs if you chose not to rebuild them during the upgrade.
- ▶ Run the `sp_updatestats` system stored procedure to update statistics.
- ▶ Reregister your server in SSMS.

The SQL Server 2008 Upgrade Matrix

No software upgrade section would be complete without an illustrative table showing the versions and editions of SQL Server for which the upgrade methods described thus far are supported. They are presented in Table 9.1.

TABLE 9.1 Supported Upgrade Paths to SQL Server 2008 and 2008 R2

NOTE

As you see in Table 9.1, direct upgrades from versions prior to SQL Server 2000 SP4 or SQL Server 2005 versions prior to SP2 are not supported. Options for migrating databases from these versions of SQL Server are presented later in this chapter.

Upgrading Using a Configuration File

If you need to upgrade multiple SQL Server 2008 instances, you'll likely want to do so without having to run the Installation Center utility each time and manually select the same options over and over. Fortunately, you can run an upgrade via the Installation Center using a configuration file. Using a configuration file, you have a couple options for how you run the upgrade: using the Upgrade Wizard with options prefilled by the configuration file or as a fully automated and unattended installation from the command line. If you run using the GUI with the options prefilled by the configuration file, you have the opportunity to review and change options along the way as necessary.

NOTE

If you've never run a SQL Server installation using the setup feature of SQL Server, you should refer to the "Installing SQL Server Using a Configuration File" section in Chapter 8 for a detailed description of the process and options available.

Following are a few of the parameters relevant to running an upgrade using a configuration file:

- ▶ **/ACTION=UPGRADE**—Specifies that you are running an upgrade.
- ▶ **/INSTANCENAME**—Specifies the SQL Server instance to be upgraded. For the default instance, you use the special value `MSSQLSERVER`.
- ▶ **/CONFIGURATIONFILE**—Specifies the configuration file to use for the upgrade.
- ▶ **/INSTANCEDIR**—Specifies a nondefault installation directory for shared components to be upgraded.
- ▶ **/UIMODE**—Specifies whether to present only the minimum number of dialog boxes during setup. Normal presents all setup dialogs; AutoAdvance skips nonessential dialog boxes.
- ▶ **/FTUPGRADEOPTION**—Specifies the full-text catalog upgrade option. Valid values are `REBUILD`, `RESET`, and `IMPORT`.

To create an upgrade configuration file, run the Upgrade Wizard as described previously and follow it all the way through to the Ready to Install page where the location of the generated `Configuration.ini` file is specified. At this point, you can click the Cancel button if you don't want to actually perform the upgrade. Then copy the `Configuration.ini` file to another location so you can make any necessary edits to it.

To run an upgrade using a configuration file, you need to run the `setup.exe` program, which can be found at the root level of the installation media. If you want to override any of the values in the configuration file or provide values not specified in the configuration file, you can provide additional command-line parameters. For example, to avoid having to enter the service account passwords during the installation, you can enter them on the command line using the password parameters to `config.exe`. Following is a sample execution to upgrade the default instance and specify the account and password for Reporting Services and the service account for Integration Services:

```
Setup.exe /q /ACTION=upgrade /INSTANCENAME=MSSQLSERVER
  /RSUPGRADEDATABASEACCOUNT="myRSaccount" /RSUPGRADEPASSWORD="myRSpassword"
  /ISSVCAccount="NT Authority\Network Service" /IACCEPTSQLSERVERLICENSETERMS
```

Note also that the preceding example specifies the `/q` parameter, which runs the upgrade in Full Quiet mode, which is intended for running unattended installations. With this switch provided, Setup runs without any user interface. Another option is to run with the `/QS` switch, which shows progress via the GUI but does not accept any input and displays no error messages if encountered.

Slipstreaming Upgrades

If you are upgrading to SQL Server 2008, you'll likely want to install Service Pack 1 as well and possibly the latest cumulative update. In the past, this meant running the upgrade and then running the Service Pack 1 (SP1) install and cumulative update separately. This

process can be tedious and time consuming. Fortunately with the release of SP1, SQL Server 2008 supports Slipstream installations and upgrades. As mentioned previously, slipstreaming is a method of integrating a SQL Server 2008 update with the original installation media so that the original media and the update are installed at the same time.

Because slipstreaming was introduced with SQL Server 2008 SP1 and not with the initial release, a slipstream upgrade must be run from the `setup.exe` program provided with SQL Server 2008 SP1. If you run from the SP1 media folder, you need to specify the location of the SQL Server 2008 installation media using the `MEDIASOURCE` parameter, as shown in the following example:

```
setup.exe /PCUSource=C:\SQLServer2008SP1 /ACTION=UPGRADE /MEDIASOURCE=D:\
/INSTANCENAME=MSSQLSERVER
```

The `/PCUSource` parameter is used to specify the location of the SP1 package. You use the `/CUSource` parameter to specify the location of a Cumulative Update package you want to apply as well, if any.

NOTE

A slipstream install cannot be used to update a SQL Server 2008 instance to SQL Server 2008 R2.

For a full description and more detailed examples on how to set up and run a Slipstream installation, refer to Chapter 8.

Upgrading from SQL Server 7 or SQL Server 6.5

SQL Server supports upgrading from SQL Server 2000 SP4 and later and SQL Server 2005 SP2 and later. Unfortunately, upgrading directly from SQL Server 7.0 or earlier versions is not supported. The supported migration path is to first migrate your SQL Server 7.0 (or earlier) databases to SQL Server 2000 SP4 or 2005 SP2 (upgrades that are supported) and then upgrade from one of these versions to SQL Server 2008 or 2008 R2.

If you have a SQL Server 2000 SP2 or SQL Server 2005 SP4 instance available, the easiest way to upgrade your SQL Server 7.0 or earlier databases is to detach them from the source server and then attach the databases to an instance running either SQL Server 2000 SP2 or SQL Server 2005 SP4. When the database is attached, it is upgraded to that version, and then you can upgrade the database to SQL Server 2008 R2. Generally, this is the preferred method.

Another option is to use the SQL Server Import and Export Wizard to copy data from a 7.0 or earlier instance of SQL Server. The main disadvantage of this approach is that it brings over only tables and data. You have to manually script your stored procedures, functions, triggers, views, and other database objects and re-create them on the upgraded target database.

Upgrading Other SQL Server Components

Now that you've seen how to migrate databases, jobs, logins, custom error messages, and full-text catalogs, let's discuss how you can migrate the rest of your SQL Server objects. First, let's look at Analysis Services.

Upgrading Analysis Services

The following sections highlight some important considerations you should be aware of when upgrading Analysis Services.

Upgrading from SQL Server 2005 Analysis Services

You can upgrade an existing instance of SQL Server 2005 Analysis Services to SQL Server 2008 Analysis Services using the Upgrade Wizard. The wizard automatically migrates existing databases from the old instance to the new instance. The metadata and binary data is compatible between the SQL Server 2005 and SQL Server 2008, so the data is retained after you upgrade. You do not have to manually migrate the data. To upgrade an existing instance of SQL Server 2005 Analysis Services, run the Upgrade Wizard and specify the name of the existing AS instance as the name of the new AS instance. The AS databases are upgraded automatically.

NOTE

Users running in a 64-bit environment must upgrade Analysis Services *before* upgrading the SQL Server Database Engine. You can, of course, run setup more than once, so in this situation it is recommended that you upgrade Analysis Services first (separately) and then upgrade your other components on subsequent runs.

Upgrading from SQL Server 2000 Analysis Services

Because of changes to the underlying architecture of Analysis Services between SQL Server 2000 and SQL Server 2008, you cannot perform an in-place upgrade. You have to migrate your SQL Server 2000 AS databases to SQL Server 2008.

The first task is to install a new named instance of SQL Server 2008 Analysis Services (SSAS) by using the SQL Server 2008 Installation Center program. When this process is complete, you can use the Analysis Services Migration Wizard to import your SQL Server 2000 Analysis Services content into the SQL Server 2008 AS format. This wizard re-creates your existing OLAP structures on the new instance, without altering the original source material.

If you remove the prior instance of SQL Server 2000 Analysis Services after you have migrated its databases, you can use the Analysis Services Instance Rename tool to make the named instance of SQL Server 2008 Analysis Services the default instance on the server.

To launch the Analysis Services Migration Wizard, open the Object Browser and connect to Analysis Services. Then navigate to the top-level Analysis Services node to find the wizard. You can also simply select Start, Run and then enter the command `MigrationWizard.exe`. You need to make sure that `MSSQLServerOLAPService` is running before you begin; you can verify this by using the SQL Server Service Manager.

Click Next on the Welcome page, and the Specify Source and Destination screen appears (see Figure 9.15). You need to enter the name of your SQL Server 2000 Analysis Services server as the source. Then you have two options:

- ▶ **Server**—You can choose this radio button and enter the name of your new SSAS instance to immediately migrate your OLAP databases.
- ▶ **Script File**—If you select this radio button and enter a filename, the wizard can generate an XML for Analysis (XMLA) script, which you can later run to perform the same migration.

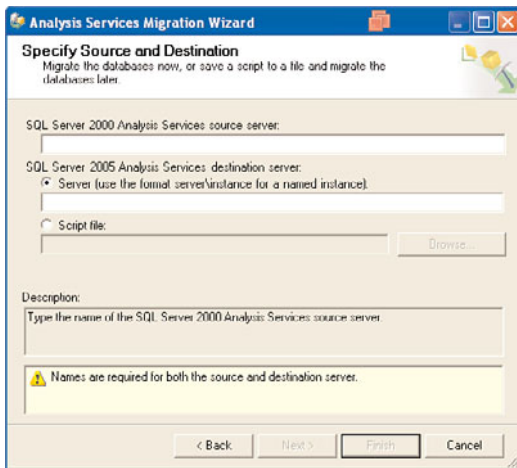

FIGURE 9.15 The Analysis Services Migration Wizard's Specify Source and Destination screen.

Click Next, and the Select Databases to Migrate screen appears; this screen is fairly self-explanatory. Make your selections and then click Next. The Validating Databases screen appears. At this point, the wizard performs the migration and reports on its progress, noting any issues along the way.

When the wizard is done, click Next, and the Completing the Wizard screen appears, showing a summary report.

NOTE

According to Microsoft, the Analysis Services Migration Wizard is unable to migrate three OLAP constructs: linked cubes, drill-through options, and remote partitions. You need to manually re-create these constructs.

When your migration is complete, you need to remember to reprocess your cubes; otherwise, you are unable to query the new database. In addition, the migrated database doesn't yet exploit the features of SSAS's Unified Dimensional Model (UDM) in your exist-

ing cubes. To fully explore that topic and learn more about other new features and functionality in Analysis Services, check out Chapter 51, “SQL Server 2008 Analysis Services.”

Upgrading Reporting Services

SQL Server 2008 supports upgrading from the following earlier editions of Reporting Services:

- ▶ SQL Server 2000 Reporting Services with Service Pack 2 (SP2)
- ▶ SQL Server 2005 Reporting Services

You can choose to perform an in-place upgrade or migrate a Reporting Services Installation to SQL Server 2008. You can run the Upgrade Advisor tool on the Report Server computer to determine any issues that might prevent a successful upgrade. Known upgrade issues currently include the following:

- ▶ There is no upgrade support for a Report Server that uses a remote SQL Server 2000 Database Engine instance to host the Report Server database.
- ▶ There is no support for the SQL Server 2000 Report Server Web service in SQL Server 2008 because this endpoint is discontinued, and any custom features that point to the ReportServer2000 endpoint no longer run.
- ▶ There is no support for earlier versions of the Reporting Services WMI provider because the Reporting Services WMI provider is not backward compatible with previous versions. You cannot use the SQL Server 2008 Reporting Services WMI provider with earlier versions of Reporting Services.

Performing an In-Place Upgrade of Reporting Services

If you've run the Upgrade Advisor and it doesn't report any issues that would prevent a successful upgrade (or you've addressed any issues it raises), you can perform an in-place upgrade of any instance of SQL Server 2000 Reporting Services SP2 or SQL Server 2005 Reporting Services.

Before upgrading Reporting Services, you should first back up the following:

- ▶ The symmetric key (by using the RSKEYMGMT tool)
- ▶ Your Report Server databases
- ▶ Configuration files: `Rsreportserver.config`, `Rswebapplication.config`, `Rssvrpolicy.config`, `Rsmgrpolicy.config`, `Reportingservicesservice.exe.config`, `Web.config` (for both the Report Server and Report Manager ASP.NET applications), and `Machine.config` (for ASP.NET if you modified it for Report Server operations)
- ▶ Any customizations to existing Reporting Services virtual directories in IIS
- ▶ Your reports

Before running the upgrade, you first need to stop IIS and the Report Services Windows service on each machine on which you will be running the in-place upgrade. (For a Web farm [now known as a *scale-out* implementation] the upgrade must be run on every node.)

Then run the Installation Center and select your existing instance for upgrade at the appropriate screen. The Installation Center upgrades the instance in-place, including all its components and any published reports and snapshots.

Upgrading Reporting Services also requires updates to your Report Server databases. Because the Report Server database schema can change with each new release of Reporting Services, it is required that the database version match the version of the Report Server instance you are using. In most cases, a Report Server database can be upgraded automatically with no specific action on your part. The following list identifies all the conditions under which a Report Server database is upgraded:

- ▶ After a Reporting Services instance is upgraded, the database schema is automatically upgraded after service startup and the Report Server determines that the database schema version does not match the server version.
- ▶ At service startup, the Report Server checks the database schema version to verify that it matches the server version. If the database schema version is an older version, it is automatically upgraded to the schema version that is required by the Report Server. Automatic upgrade is especially useful if you restored or attached an older Report Server database. A message is entered in the Report Server trace log file indicating that the database schema version was upgraded.
- ▶ The Reporting Services Configuration tool upgrades a local or remote Report Server database when you select an older version to use with a newer Report Server instance. In this case, you must confirm the upgrade action before it happens.

NOTE

The Reporting Services Configuration tool no longer provides a separate Upgrade button or upgrade script. Those features are obsolete in SQL Server 2008 due to the automatic upgrade feature of the Report Server service.

After the database schema is updated, you cannot roll back the upgrade to an earlier version. Always back up the Report Server database in case you need to re-create a previous installation.

SQL Server 2008 introduces changes to the Report Definition Language (RDL), the report object model, and the rendering object model that affect reports created in earlier versions of the software. When you upgrade a Reporting Services installation from a prior version to a SQL Server 2008 Reporting Services installation, existing reports and snapshots that have been uploaded to a Report Server are automatically upgraded to the new schema the first time they are processed. If a report cannot be automatically upgraded, the report is processed using the backward-compatibility mode. Also, if you open an `.rdl` file in Report Designer that was created for the SQL Server 2000 or SQL Server 2005 namespace, Report Designer automatically upgrades the report to the current namespace. After you save the report, you cannot open it in earlier versions of Report Designer.

If you are unable to perform an in-place upgrade of your existing installation for any reason, your other option is to install a new instance of SQL Server 2008 Reporting Services and then migrate your Report Server database and configuration files to the new instance.

Migrating to Reporting Services 2008

The migration process for Reporting Services includes a combination of manual and automated steps. The following tasks are required to perform a Reporting Services migration:

- ▶ Back up your Report Server databases, applications, and configuration files.
- ▶ Back up the encryption key.
- ▶ If it is not installed already, install a new instance of SQL Server 2008 or 2008 R2.
- ▶ Move your Report Server database(s) from your SQL Server 2000 or 2005 installation to your new installation using the detach/attach or backup/restore method.
- ▶ Move any custom report items, assemblies, or extensions to the new installation.
- ▶ Configure the Report Server.
- ▶ Edit the `RSReportServer.config` file to include any custom settings from your previous installation.
- ▶ Optionally, configure custom Access Control Lists (ACLs) for the new Reporting Services Windows service group.
- ▶ Remove unused applications and tools after you have confirmed that the new instance is fully operational.

When you are backing up the Report Server configuration files, the files to back up include

- ▶ `Rsreportserver.config`
- ▶ `Rswebapplication.config`
- ▶ `Rssvrpolicy.config`
- ▶ `Rsmgrpolicy.config`
- ▶ `Reportingservicesservice.exe.config`
- ▶ `Web.config` for both the Report Server and Report Manager ASP.NET applications
- ▶ `Machine.config` for ASP.NET if you modified it for Report Server operations

During the install of your new instance of Reporting Services, when you reach the Reporting Services screen, you need to be sure to select the Install but Do Not Configure option. After moving your Report Server databases, launch the new Reporting Services Configuration tool and select the Report Server database that you've moved from the previous installation to automatically upgrade it. Then restore your backed-up encryption key.

Just as with an in-place upgrade, to upgrade the reports themselves, all you need to do is open them in the Report Designer, which automatically converts them to the new Report Definition Language format.

After you successfully migrate your Report Server to a SQL Server 2008 Reporting Services instance, you might want to perform the following steps to remove programs and files that are no longer necessary:

- ▶ Uninstall the previous version of Reporting Services if it's no longer needed.
- ▶ Remove IIS if you no longer need it on the computer (it's no longer needed by Reporting Services 2008).
- ▶ Delete `RSActivate.exe` (if you migrated from SQL Server 2000 installations only).

Upgrading SSIS Packages

When you upgrade an instance of SQL Server 2005 to SQL Server 2008, your existing SQL Server 2005 Integration Services packages are not automatically upgraded to the package format that SQL Server 2008 Integration Services uses. You have to manually upgrade your SQL Server 2005 packages.

There are multiple methods to upgrade SQL Server 2005 packages. Some of the methods are only temporary. For others, the upgrade is permanent. Table 9.2 lists each of the upgrade methods and whether the upgrade is temporary or permanent.

TABLE 9.2 SSIS Upgrade Methods

Upgrade Method	Type of Upgrade
Using the <code>dtexec</code> utility installed with SQL Server 2008	The package upgrade and script migration are temporary. The changes are not saved.
Adding a SQL Server 2005 package to an existing project or opening a SQL Server 2005 package in SQL Server 2008 Integration Services	The package upgrade is permanent if you save the package. The script migration is permanent if you add the package to an existing project or if you open the package and save the conversion changes.
Using the SSIS Package Upgrade Wizard	The package upgrade and script migration are permanent.
Using the Upgrade method to upgrade one or more Integration Services packages.	The package upgrade and script migration are permanent.

The SSIS Package Upgrade Wizard is the recommended approach for upgrading your SQL Server 2005 SSIS packages. Because you can configure the wizard to back up your original packages, you can continue to use the original packages if you experience upgrade difficulties. You can run the SSIS Package Upgrade Wizard from SQL Server Management Studio, from SQL Server Installation Center, or at the command prompt.

To run the wizard from SQL Server Management Studio, connect to Integration Services, expand the `Stored Packages` node, right-click the `File System` or `MSDB` node, and then click `Upgrade Packages`. To run the wizard from SQL Server Installation Center, click

Tools and then click Upgrade Integration Services packages. At the command prompt, run the SSISUpgrade.exe file from the C:\Program Files\Microsoft SQL Server\100\DTS\Binn folder.

Migrating DTS Packages

SSIS is a complete rewrite of the DTS runtime, and this is why your DTS packages are not automatically migrated to SQL Server 2008 when running an in-place upgrade. You essentially have two options for how to handle your existing DTS packages:

- ▶ Install runtime support for DTS packages so you can continue to run your existing DTS packages.
- ▶ Migrate your DTS packages to SSIS using the DTS Package Migration Wizard.

Full DTS support in SQL Server 2008 consists of multiple components. The first component is the Client Tools Backward Compatibility option. During an installation or upgrade, on the Feature Selection page, select Integration Services and choose to install the Client Tools Backward Compatibility option. This option installs the Execute DTS 2000 Package task for SSIS.

The next component you need to install is DTS runtime support. To install runtime support for Data Transformation Services packages, go to the Microsoft Download Center and locate the Microsoft SQL Server 2008 Feature Pack page. From there, download the Microsoft SQL Server 2005 Backward Compatibility Components (this component has not been updated for SQL Server 2008). If you also want to use the SQL Server 2008 tools to open and view DTS packages, you have to download and install the design-time support as well. This support can also be found in the Microsoft Download Center on the Feature Pack for Microsoft SQL Server 2005 page.

After you install the DTS runtime support, your DTS packages can run as before. You can run your DTS packages one of the following ways:

- ▶ From the command prompt using the dtstrun.exe utility
- ▶ Via SQL Server Agent Jobs by setting the job step to Operating system (CmdExec) and use the dtstrun utility (dtstrun.exe) to run the package
- ▶ Via Integration Services Packages using the Execute DTS 2000 Package task

If you also installed the design-time support, you are able to continue to edit and manage your DTS packages. You can manage your DTS packages from SQL Server Management Studio under the Data Transformation Services node, which is available in the Management/Legacy folder. Here, you can open existing DTS packages stored on the file system or in the msdb database, or add additional packages to the server by clicking the Import button. Although DTS packages can be modified and renamed, you cannot create new DTS packages within SSMS.

The DTS runtime support is intended to be used only on a temporary basis until you have the opportunity to migrate your DTS packages to SSIS. To migrate your DTS packages to SSIS, you can use the DTS Package Migration Wizard.

To run the DTS Package Migration Wizard, you first need to make sure that the SSIS service is in the running state. In SSMS, open the Object Explorer and navigate to the Legacy node, under Management. Then right-click the Data Transformation Services (DTS) node and select the Package Migration Wizard option to migrate one or more packages (those stored on a server or as files) to SSIS.

NOTE

The Package Migration Wizard is available only in the Developer, Standard, and Enterprise Editions of SQL Server 2008.

When you run the Package Migration Wizard, you first need to select the source and destination servers (the source must be a SQL Server 7 or 2000 instance, and the destination must be a 2008 instance with SSIS running) on the Choose Source Location and Choose Destination Location screens.

Then click Next to reach the List Packages screen (see Figure 9.16), where you check the check boxes for the packages you want to bring over. The name for each imported package is listed in the Destination Package column, and you can click there to edit it.

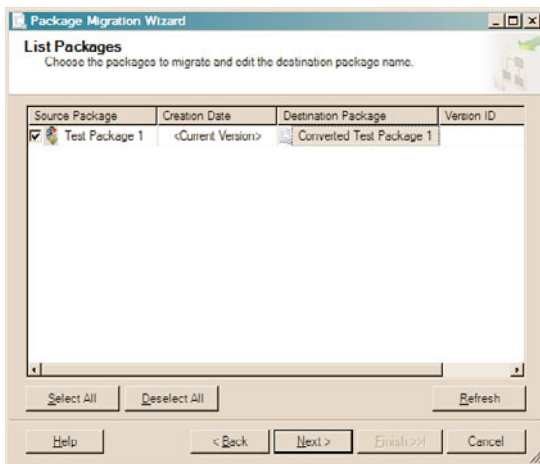

FIGURE 9.16 The Package Migration Wizard's List Packages screen.

At the next screen, you can specify a log file for the process. You click Next again and then click Finish to complete the migration.

As with all the other wizards provided with SQL Server 2008, the Package Migration Wizard reports progress and any issues on a per-package basis, offering an exportable report at the end.

After migration is complete, the original DTS package is still available on the SQL Server 7 or 2000 instance, in unmodified form. You can import packages into SQL Server in SSMS by connecting to SSIS in the Object Explorer and then navigating to the Stored Packages node and then the MSDB node. If you selected a file system folder as the destination, right-click the File System node and then select Import Package to display the migrated packages.

Summary

Now that you've taken in a great deal of information to help your organization transition to SQL Server 2008, it's time to put that knowledge to work by actively taking the plunge.

If you need even more documentation, you can look to the many other chapters in this book and even more resources on the Web that can assist you. Of course, there's an abundance of content on Microsoft's website (after all, it's in Microsoft's interests that customers upgrade to SQL Server 2008), including webcasts, TechNet, and online learning courses available to MSDN subscribers.

When your new environment is ready to go, you can move on to Chapter 10, "Client Installation and Configuration," to learn how to get your clients up and running with your new installation of SQL Server 2008.

This page intentionally left blank

CHAPTER 10

Client Installation and Configuration

SQL Server 2008 offers a robust client/server architecture that provides speed and security, simple configuration and maintenance, and enhanced management capabilities.

This chapter contains the latest information on how to install, configure, and connect to SQL Server 2008 from the client side, and it offers key server-side insights that will help provide a complete understanding of what you need to do establish a database connection.

What's New in Client Installation and Configuration

Client installation and configuration in SQL Server 2008 is similar to SQL Server 2005 but does have its share of changes. First and foremost is the introduction of a new net-library named SQL Native Client 10.0 (SNAC10). SNAC10 gives applications access to the new features and data types available with SQL Server 2008. It builds on the data access component distribution strategy introduced in SQL Server 2005 that was simply called SQL Native Client (SNAC or SNAC9).

The good news is that your applications can continue to access SQL Server 2008 with the older SNAC components. Both SNAC9 and SNAC10 can be used on the same client system. SNAC9 is not able to reference new features in SQL Server 2008, however, so you have to upgrade to SNAC10 to gain access to them.

Another big change in SQL Server 2008 is the removal of the Surface Area Configuration (SAC) tool. The SAC tool

IN THIS CHAPTER

- ▶ What's New in Client Installation and Configuration
- ▶ Client/Server Networking Considerations
- ▶ Client Installation
- ▶ Client Configuration
- ▶ Client Data Access Technologies

was introduced in SQL Server 2005 and was a key part of client configuration. The functionality made available in this tool has now been replaced with Policy-Based Management features and changes in the SQL Server Configuration Manager (SSCM) tool. For example, the option to allow Remote Connections that was available in SAC is no longer there. You should look to the SSCM tool and enable or disable the protocols for which you want to allow connections. The details of this change are discussed later in this chapter, and a full discussion of Policy-Based Management is provided in Chapter 22, “Administering Policy Based Management.”

One last change in SQL Server 2008 Client Installation and Configuration that may rear its head relates to the BUILTIN\Administrators windows group. By default, this group is no longer included in the SQL Server sysadmin fixed server role on new SQL Server 2008 installations. So, by default, network administrators and administrators of the machine where SQL Server is running are not able to log in to SQL Server and administer it. In past versions of SQL Server, the BUILTIN\Administrators windows group was added to the sysadmin role. To grant administrators permission to SQL Server, you can manually add the BUILTIN\Administrators group to the sysadmin SQL Server role, or you can add each individual network administrator that needs to access SQL Server to that role.

The change to the BUILTIN\Administrators windows group is in line with Microsoft’s strategy to “secure by design, secure by default, and secure in deployment.” This strategy relates to many aspects of SQL Server, including installation, security, and client installation and configuration. The strategy is a good one but can cause you, as the administrator, some extra grief if you are not aware of the impact that these changes can have on you and your users.

Client/Server Networking Considerations

Before we delve into the features on the client side in SQL Server, it’s important to make note of a few server-side features. This information will help you gain an understanding of which networking features are initially configured on the server (after an installation or upgrade) as well as how incoming connections are dealt with. Such knowledge can be invaluable in diagnosing connectivity issues.

If you’ve been following along chapter by chapter, you’ve learned how to install or upgrade an instance of SQL Server 2008. To get your clients up and running fast, you must be sure the Database Engine is listening for them.

The following sections describe how to set up the server’s basic network configuration, including configuring it to accept remote connections, learning which protocols it supports, and understanding how it listens for and responds to client requests.

Server Network Protocols

The first and most basic step after a SQL Server installation or upgrade is to make sure the appropriate network protocols are configured on the server.

NOTE

Note that the term *server* is used here to refer to an instance of the SQL Server 2008 Database Engine. The term *client* is used generally to mean any program that needs to communicate with a server. The server and client may reside on the same physical machine (especially when using SQL Server Mobile and Express Editions).

First, you should ensure that the protocols your clients once used to connect to SQL Server 7, 2000 or 2005 (or that your clients would like to use) are still supported by SQL Server 2008 and configured.

You might be surprised to learn that the following protocols that were supported in SQL Server 2000 are not supported by SQL Server 2005 or SQL Server 2008:

- ▶ AppleTalk
- ▶ Banyan VINES
- ▶ Multiprotocol
- ▶ NW Link IPX/SPX

If you were using these protocols and you've upgraded from SQL Server 2000, your clients are no longer able to connect. Following are the only protocols that SQL Server 2008 supports:

- ▶ Named pipes
- ▶ Shared memory
- ▶ TCP/IP
- ▶ Virtual Interface Adapter (VIA)

If you were using any of these protocols and you just upgraded, Setup copies your pre-upgrade settings over to SQL Server 2008, including the enabled state, IP addresses, TCP ports, pipe names, and so on. Clients can simply test their connections to be sure the upgrade was successful, and in most cases, no changes need to be made.

NOTE

The Shared memory protocol works only for connections both to and from the same machine hosting the Database Engine. Shared memory is used by client tools such as SQL Server Management Studio (SSMS) and SQLCMD, and it's also a good choice for use by locally running custom applications because it is secure by design. (It is the default protocol used by local applications that do not specify otherwise.)

All remote connections to SQL Server are thus disabled by default. Following is an extremely common client-side error message illustrating connection failure due to disabled remote connectivity:

A network-related or instance-specific error occurred while establishing a connection to SQL Server. The server was not found or was not accessible. Verify that the instance name is correct and that SQL Server is configured to allow remote connections.

The exact wording of this message varies slightly, depending on the particular client or connection method used. The same error also occurs when the Database Engine service is stopped.

In SQL Server 2008, remote connections must be enabled for each network protocol on which you want the server to communicate. This is easily accomplished using the SQL Server Configuration Manager (SSCM). You launch SSCM from the SQL Server 2008 Configuration Tools menu group. In SSCM, you expand SQL Server Network Configuration and then select the Protocols entry for the SQL Server instance that you want to configure. In the Details pane, right-click on one of the available protocols (for example, Named Pipes) and select Enable to allow connections for this protocol (see Figure 10.1). SSCM serves many purposes and is discussed in detail later in this chapter.

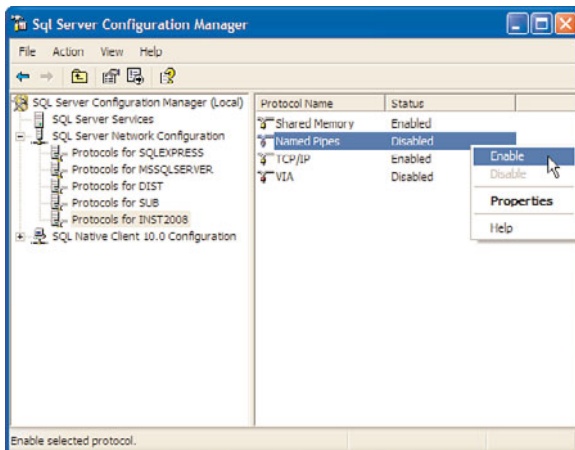

FIGURE 10.1 Enabling remote connections over named pipes using SSCM.

When the protocol is enabled, SQL Server is configured to listen for connections from clients using the same protocol. You must restart the SQL Server instance for the changes to take effect and for SQL Server to actually start listening for connections. You can verify that SQL Server is listening on the protocol that you have enabled by looking at the SQL Server error log. Each time the SQL Server instance is restarted, messages are written to the log indicating which protocols it is listening on. The following sample error log messages show what SQL Server is listening for:

```
Server is listening on [ 'any' <ipv4> 1719].
Server named pipe provider is ready to accept connection on
[ \\.\pipe\MSSQL$INST2008\sql\query ].
```

SQL Server listens on all configured protocols simultaneously, giving no preference or priority to any. This is in contrast to the explicitly prioritized manner in which clients attempt to connect via all configured protocols. The client configuration is discussed in detail later in this chapter.

NOTE

In SQL Server 2005, the Surface Area Configuration (SAC) tool also could be used to allow remote connections and to configure the protocols on which they communicate. The SAC tool has been removed in SQL Server 2008, so you need to look to the SSCM to configure your protocols.

The Server Endpoint Layer

A networking feature in SQL Server 2008 adds an additional layer to the client/server network structure: Tabular Data Stream (TDS) endpoints. When you install (or upgrade to) SQL Server 2008, a default system endpoint is created on the server for each available protocol on the server. These endpoints cannot be dropped, and they are created regardless of whether the protocol is disabled or otherwise unavailable.

NOTE

The term *endpoint* in this context refers to the combination of a protocol selection, one or more IP addresses (or pipe names), and any associated port numbers.

These are the default system endpoints:

- ▶ TSQL Local Machine (for shared memory)
- ▶ TSQL Named Pipes
- ▶ TSQL Default TCP
- ▶ TSQL Default VIA
- ▶ Dedicated Admin Connection (also known as the DAC)

You can view these endpoints and check their status by executing the following T-SQL statement:

```
Use Master
GO
SELECT * FROM sys.endpoints WHERE principal_id = 1
```

By default, all users are granted access to these endpoints (except the DAC, which is only for members of the sysadmin role). Administrators can create new endpoints on the server to increase connection security by stopping (or disabling) the default system endpoints and then creating new user-defined endpoints that only specific clients can access.

(Creating a new system endpoint automatically revokes permission on the default endpoint of the same protocol to the public group.)

NOTE

Only one named pipe and one shared memory endpoint can exist per instance, but multiple VIA or TCP endpoints (with different port and address settings) can coexist.

Each endpoint communicates with clients via TDS packets, which are formatted on the server side by SNAC and on the client side by SNAC or another of the net-libraries.

Administrators have the option of stopping and starting endpoints while sessions are still active, preventing new connections from being made while still supporting existing ones.

An administrator can grant or revoke endpoint access to specific users or groups (for example, preventing backdoor access through client tools). It is therefore important for clients to know that this structure exists and to learn how they receive permission to connect to endpoints through a server-side process known as *provisioning*.

Client Access Provisioning

There are three fairly straightforward rules of access provisioning. If any one of these rules is met by an incoming client, that client may access the endpoint. If none are met, the client is denied access. These are the rules:

- ▶ If the client specifies an IP address and a TCP port that match those of a specific endpoint, the client may connect to it, if the client has permission to do so.
- ▶ If only the TCP port specified by the client matches that of a specific endpoint, and the endpoint is configured to listen on all IP addresses, the client may connect to it, if the client has permission to do so.
- ▶ If neither the TCP port nor IP address is specified, but the default endpoint for the protocol is enabled, the client may attempt to connect to the endpoint.

NOTE

If the endpoint to which access is successfully provisioned is currently stopped, or if the user does not have permission to connect to it, no further endpoints are tried and the client cannot continue.

For example, let's say a server has three TCP/IP endpoints defined:

- ▶ The default (TSQL Default TCP), which listens on all IP addresses and Port 1433 (a default SQL Server 2008 instance)
- ▶ A user-created endpoint called TCP_UserCreated_101_91, configured to listen on IP address 192.168.1.101 and Port 91

- ▶ A second user-created endpoint, called `TCP_UserCreated Any_91`, which is configured to listen on all IP addresses and Port 91

A client attempts to connect specifically to `192.168.1.101:91`. Because this is an exact address and port match, the client can try to connect to `TCP_UserCreated 101_91`. Having an exact address and port match meets the first provisioning rule.

A second client attempts to connect to any IP address on Port 91. Because there is no exact address match, the client cannot attempt to connect to `TCP_UserCreated 101_91`. However, the client can attempt to connect to `TCP_UserCreated Any_91` because it is configured to listen on all IP addresses. This meets the second provisioning rule.

A third client attempts to connect on any port and any address. If `TSQL Default TCP` is started, the client is granted permission to attempt to connect. This meets the third provisioning rule.

NOTE

Settings such as IP addresses and TCP ports are used to implicitly connect to specific endpoints. These values are specified by clients in connection strings, data source names (DSNs), and server aliases, all of which are discussed later in this chapter in the “Client Configuration” section.

TIP

If, at any time, you want to discover which protocol and endpoint a connected client is currently using, you can run the following T-SQL to list the current connections and related protocols. The `session_id` identifies the server process ID (SPID), and an additional `WHERE` clause can be added to the `SELECT` statement that selects only the SPID you are interested in:

```
SELECT name, net_transport, session_id, e.endpoint_id
FROM sys.dm_exec_connections d
JOIN sys.endpoints e
ON e.endpoint_id = d.endpoint_id
go
name                net_transport      session_id  endpoint_id
TSQL Local Machine  Shared memory      53         2
```

Following is an example of the client-side error message that results if the `TSQL Default TCP` endpoint is stopped and you try to connect to it:

A connection was successfully established with the server, but then an error occurred during the login process

Now that you know a bit about endpoints, let's go a bit deeper and explore how client connections are facilitated on the server.

The Role of SQL Browser

You might be surprised to learn that when clients try to connect to SQL Server 2008, their first network access is made over UDP Port 1434 to the SQL Browser service.

NOTE

Regardless of the encryption status of the connection itself, login credentials are always encrypted when passed to SQL Server 2008 (to foil any malicious packet sniffing). If a certificate signed by an external authority (such as VeriSign) is not installed on the server, SQL Server automatically generates a self-signed certificate for use in encrypting login credentials.

SQL Browser is the upgrade to the SQL Server Resolution Protocol (SSRP) and its job is to hand out instance names, version numbers, and connection information for each (nonhidden) instance of the Database Engine (and Analysis Services) residing on a server—not only for SQL Server 2008 instances, but for SQL Server 2000 and 2005 instances as well.

When clients connect by name, SQL Browser searches for that name in its list and then hands out the connection data for that instance. It can also provide a list of available servers and help make connections to the correct server instance or to make a connection on the dedicated administrator connection (DAC).

Ports, Pipes, and Instances

Default instances of SQL Server 2008 are automatically configured (just as in previous editions) to listen on all IP addresses and TCP Port 1433.

Named instances, on the other hand, are automatically configured to listen on all IP addresses, using dynamic TCP port numbers that change when the Database Engine is restarted. (Most often, these change only when the port number last used by the service is in use by a different application.)

If the SQL Browser service is not running, the client might need to provide additional connection information to be able to connect to SQL Server. The additional connection information includes the specific port or pipe that the SQL Server instance may be listening on. The only exception to this is if the server is listening on the default port of 1433. Otherwise, the client must specify the port when connecting with TCP/IP. When dynamic ports are used, the port number can change at any given time and cause your clients to have to change their port to match the new server port.

SQL Browser, therefore, is configured to autostart on servers that contain one or more named instances so that clients can connect by simply providing the server name. The complexity associated with providing additional port or pipe information is avoided when

the SQL Browser service is running. SQL Browser is also required for enumerating the server lists used to connect with client tools such as SMSS.

NOTE

If named instances have fixed port numbers known to clients, or if a pipe name is well known, SQL Browser is not required to connect.

NOTE

For named pipes, the default instance's pipe name is `\sql\query`; for named instances, the pipe name is `MSSQL$instancename\sql\query`.

When a link is made, endpoint provisioning kicks in to finalize (or reject) the connection.

Client Installation

Now that you have acquired some knowledge about the most important server-side networking considerations, it's time to learn how to install and configure the client-side half of the equation.

Installation Requirements

All SQL Server 2008 installations (including client-tools-only or SNAC-only installations) require Windows Installer 4.5, which is freely downloadable from Microsoft. It can also be installed as part of the SQL Server Installation Wizard or manually installed from the SQL Server media. The location of the installer media varies depending on the media you are using but an example of the location is as follows:

```
D:\English\SQL2008\Enterprise\X86\redist\Windows Installer\x86
```

The same operating system requirements for server installations apply to client tools and SNAC installations, with one exception: When you install SNAC by itself on top of Windows XP, only SP1 is required, and when you install SNAC on top of Windows Server 2003, SP1 is not required. You can review the complete list of requirements in Chapter 8, "Installing SQL Server 2008," in the section "Installation Requirements."

Note that SNAC and the client tools both depend on the presence of the .NET Framework 3.5 SP1, and the client tools in turn depend on SNAC. Setup automatically installs both Framework 3.5 SP1 and SNAC, when required, on the target machine. If incompatible or beta versions exist that must be uninstalled first, Setup lets you know to use Installer 4.5.

Installing the Client Tools

To install the SQL Server 2008 client tools, you start Setup normally and follow the prompts as described in Chapter 8. When the Feature Selection screen appears, you check only the Client Tools Connectivity check box, as shown in Figure 10.2.

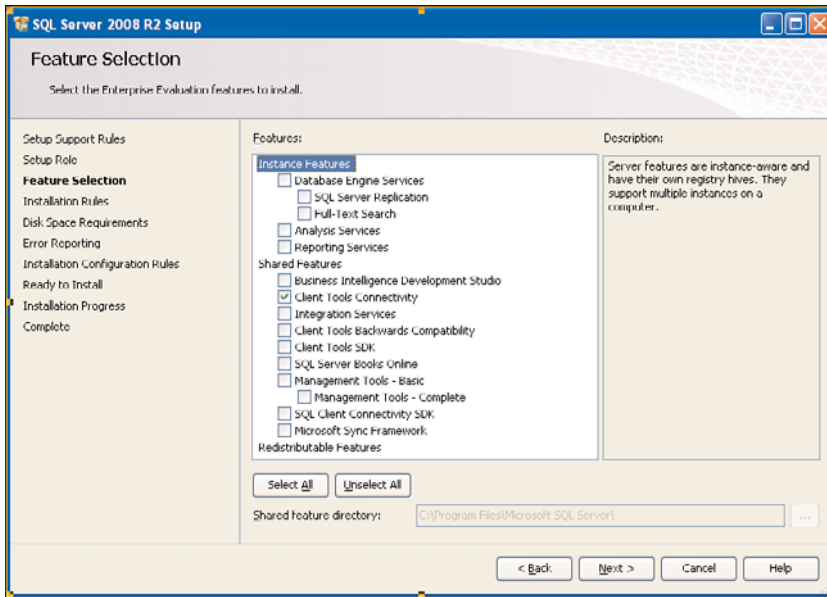

FIGURE 10.2 Performing a client-tools-only installation.

The same kind of install can be done quietly from the command line (Setup doubles as a command-line application), using the following:

```
driveletter:\Servers\Setup> Setup.exe /q /ACTION=Install /FEATURES=CONN
/INSTANCENAME=INST2008
```

That's all there is to it!

You will be happy to learn that the SQL Server 2008 client tools can safely be installed side by side with your SQL Server 2000 or 2005 client tools. You can even access databases and other objects created in either edition (with a few notable exceptions, such as database diagrams) by using either toolset.

The sections that follow describe how to install and use a few of the client tools for client configuration and testing.

Installing SNAC

This section shows how easy it is to install SNAC, the key net-library for SQL Server 2008 and beyond.

As mentioned earlier, both the SQL Server 2008 Database Engine and the client tools depend on SNAC. SNAC is installed when you install the SQL Server connectivity tools, or you can simply launch it on its own from the SQL Server installation medium by running `driveletter:\Servers\Setup\sqlncli.msi`.

Table 10.1 describes the files that the Microsoft Installer (MSI) package installs.

TABLE 10.1 Files Installed by the SNAC MSI Package

Filename	Purpose	Installed To
Sqlnccli.h	C++ header file (replaces sqloledb.h)	<i>Program Files</i> \Microsoft SQL Server\100\SDK
sqlnccli10.lib	C++ library file for calling BCP functions (replaces odbcbcp.lib)	<i>Program Files</i> \Microsoft SQL Server\100\SDK
sqlnccli10.dll	Main library, containing both the ODBC driver and OLE DB provider (houses all functionality)	WINDIR\system32
sqlnccli10.rll	Resource file	WINDIR\system32
s10ch_sqlnccli.chm	Compiled help file for creating data sources using SNAC	WINDIR\system32

TIP

For detailed information on how to write C++ code by using the header and library files included in the SNAC software development kit (SDK), see the Books Online topic “Using the SQL Native Client Header and Library Files.”

The SNAC installer has two primary options (shown in Figure 10.3):

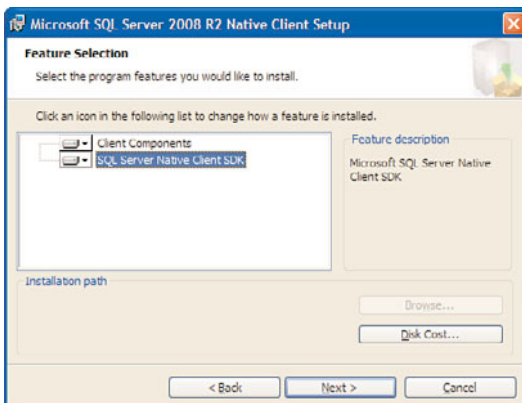

FIGURE 10.3 SNAC's installation options.

- ▶ Install SNAC by itself
- ▶ Install the SNAC SDK files along with it

NOTE

By default, all network protocols except for VIA are enabled on the client during installation.

That's all there is to installing SNAC!

Redistributing SNAC with Custom Client Applications

If you build an application that relies on SNAC, you need to be aware that it can be redistributed in two ways:

- ▶ As part of any SQL Server 2008 installation or upgrade
- ▶ As a custom application installation dependency

When you are building MSI files for an application, it is important that you register `sqlncli.msi` as a package dependency (and, of course, to install it as well, if it is not present on the destination machine). This helps ensure that SNAC will not be accidentally uninstalled from the destination machine without first flashing a warning to users, indicating that any application that relies on it will break. To do this, you execute the following command early in your application's installation process:

```
msiexec /i sqlncli.msi APPGUID={unique identifier for your product}
```

NOTE

The program name for SNAC found in the Add or Remove Programs Control Panel applet is Microsoft SQL Server 2008 Native Client, not SQL Native Client, as it is commonly known.

Client Configuration

Client configuration is a many-leveled beast, consisting of operating system tasks such as installing protocols, application tasks such as choosing or coding to a specific Application Programming Interface (API), provider, or driver, and maintenance tasks such as configuring network settings, building connection strings, and so on. The following sections cover a broad range of these tasks, focusing on the most common. Many examples utilize TCP/IP both because it is the default protocol for remote clients and because it is the most widely used.

No chapter can cover all the possible ways of connecting, but this one is designed to give you the tools you need to get set up right from the start and to navigate your way in case specific issues arise.

The first client configuration tool we look at is SSCM.

Client Configuration Using SSCM

The Client Network Utility available prior to SQL Server 2005 has been decommissioned, and all its functionality is now built into SSCM. This includes the capability to create server aliases, to enable and prioritize network protocols, to control the various SQL Server services, and more.

NOTE

One thing Microsoft is keen on including in Books Online is that neither Setup nor `sqlIncli.msi` installs the actual network protocols themselves, nor do they enable them at the operating system level. This means that if you do not have TCP/IP installed and you need to start using it, you have to first set it up by using the Network Connections Control Panel applet (if you're using Windows, that is).

You can launch SSCM directly from its Start menu icon, or you can access it in the Services and Applications node of the Computer Management console. When you have SSCM up and running, to access its client-side functionality, you expand its top-level node (SQL Server Configuration Manager (*servername*)) and then you click the SQL Native Client 10.0 Configuration node. Below it, you click the Client Protocols node to reveal the enabled state and priority order of each protocol, in grid format, in the right pane (see Figure 10.4).

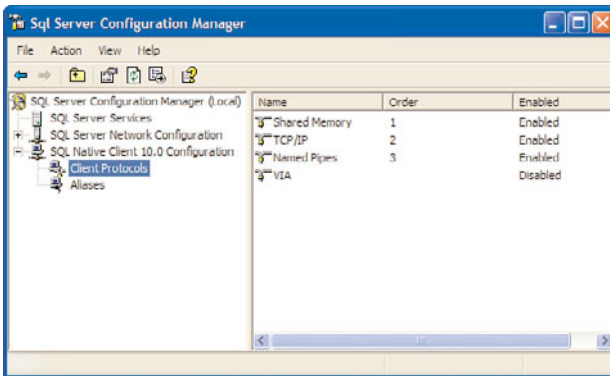

FIGURE 10.4 SSCM's Client Protocols screen.

From this screen, you can right-click any of the protocols to change their enabled state, view Properties pages, or change the default connection order (except that of shared memory, which is always tried first and whose order cannot be changed). The following is the default connection order for clients connecting without the benefit of a server alias, connection string, or other means:

- ▶ Shared memory
- ▶ TCP/IP
- ▶ Named pipes

(As the grid shows, VIA is disabled by default.) When you are connecting remotely, TCP/IP is the first protocol attempted because shared memory is local only.

NOTE

When a client does not specify a connection protocol, SNAC automatically tries each protocol in the list in sequence, according to the Order column. The first protocol to connect successfully wins.

If the winning connection is subsequently rejected by the server for any reason, no other protocols are tried.

Note also that local clients using MDAC 2.8 or lower cannot connect using shared memory, and they are automatically switched to named pipes if they attempt to do so.

Let's examine one of the protocols. To start, you need to double-click TCP/IP under the Name column to open the TCP/IP Properties screen (see Figure 10.5).

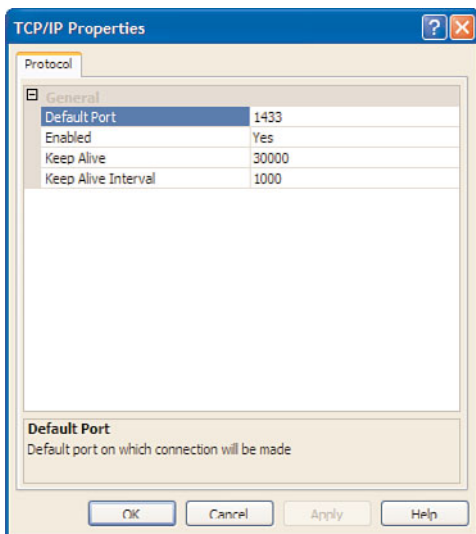

FIGURE 10.5 The TCP/IP Properties screen.

The values stored here are used by TCP/IP clients as default connection values, and they are applied only when a specific server alias or other configuration mechanism is not in use. They are also used by the SQL Server 2008 client tools when shared memory is not available.

As you can see, the default port, 1433, is set up to connect to the more commonly configured default instances of SQL Server. By editing the values on this page, you can change the default port number, enabled state, keep-alive values, and other settings (when editing other protocols). You should edit and enable the protocols according to your specific needs.

Server Aliases

A *server alias* is a name that is used like a server name that represents a group of server settings for use by connecting clients. Server aliases are very handy because of the way they simplify connection parameters: clients need only specify the alias name, and SNAC pulls the rest of the information (such as the IP address, TCP port number, and pipe name) from SSCM at connection time.

To create a server alias, you right-click the Aliases node under SQL Native Client Configuration and choose New Alias. On the Alias - New screen that appears (see Figure 10.6), you specify the alias name, protocol (except shared memory, for which you cannot create an alias), and server name. (*local*, *.*, and *localhost* also work for local connections over TCP/IP or named pipes.)

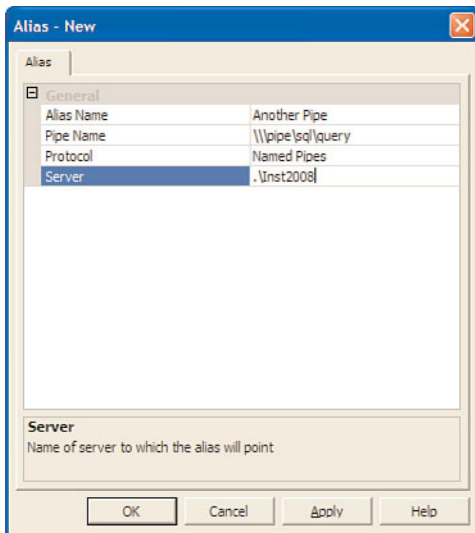

FIGURE 10.6 Alias properties for a new named pipe server alias.

When you make your protocol selection, the grid rows change to dynamically reveal the settings particular to that protocol. When you are finished, you click OK, and your alias is ready for use.

Connection Encryption

With SQL Server 2008, it is easy to set up Secure Sockets Layer (SSL) encrypted client/server communication over all protocols. The SNAC net-library handles the tasks of encryption and decryption on both the server and client ends. (Note that this process does cause a slight decrease in performance.) Setting it up requires both server-side and client-side configuration changes; this section covers only the client-side changes in detail.

SQL Server 2008 enables encryption using two types of certificates:

- ▶ Certificates generated by and obtained from an external certification authority such as VeriSign
- ▶ Certificates generated by SQL Server 2008 (known as *self-signed certificates*)

The bit strength of the encryption (40-bit or 128-bit) depends on the bit strength of the operating systems of the computers involved in the connection.

To set up the server for encryption, your administrator registers a certificate on the server operating system (using the Certificates Management console) and then installs it in the Database Engine.

If an externally signed certificate is not installed on the server, SQL Server uses its built-in self-signed certificate. (A server administrator may also create and save a self-signed certificate by using SQL Server 2008 via the new `CREATE CERTIFICATE` and `BACKUP CERTIFICATE` T-SQL syntax.) It is also up to the server to decide whether encryption is required or optional for connecting clients.

The client's half of the job is to have installed what is known as a *root-level certificate* that is issued by the same certification authority as the server's certificate. To install a root-level certificate, you right-click the certificate itself (a `.cer` or `.crt` file) and select `Install Certificate` to launch the Certificate Import Wizard. You click `Next` on the welcome screen to reach the Certificate Store screen (see Figure 10.7). Then you select the first radio button (`Automatically Select the Certificate Store`) and then click `Next`. Finally, you click `Finish`.

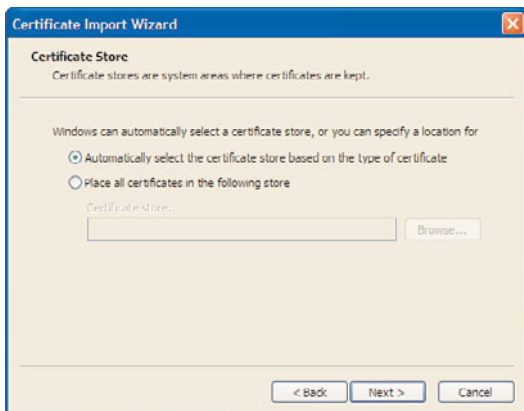

FIGURE 10.7 Importing a certificate on the client computer using the Certificate Import Wizard.

Next, you launch SSCM, right-click the SQL Native Client 10.0 Configuration node, and then select Properties. The Flags tab appears (see Figure 10.8) in the Properties window.

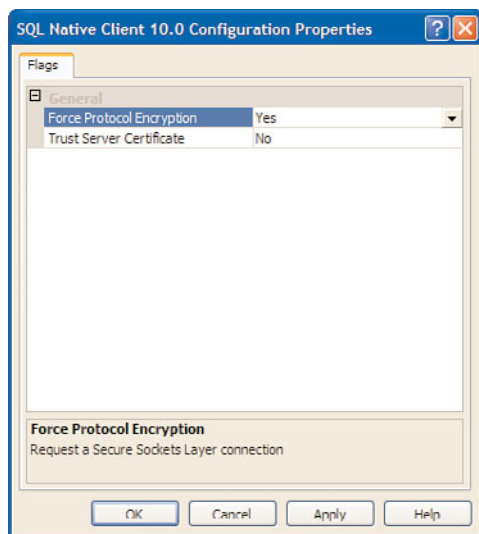

FIGURE 10.8 Forcing clients to request an encrypted connection using SSCM.

You set the Force Protocol Encryption property value to Yes. This causes clients to request an SSL-encrypted connection when communicating with the Database Engine. If the server does not respond in kind, the connection is killed.

The Trust Server Certificate property gives clients a choice in how they deal with server certificates:

- ▶ To use a self-signed certificate, you set the property value to Yes. This option prevents SNAC from validating the server's certificate.
- ▶ To use an externally signed certificate, you set the property value to No, which causes SNAC to validate the server's certificate.

SSMS can also connect over an encrypted connection. When connecting using the Connect to Server dialog, you click the Options button and then click the Connection Properties tab. Then you choose your database and protocol and, at the bottom left, check the Encrypt Connection check box.

Client Data Access Technologies

The question of which data access technology to use with SQL Server 2008 is a common one, with a seemingly easy answer: you use SNAC because it has all the latest and greatest functionality, all rolled into one. (You learn how to use SNAC in the sections that follow.)

A more correct answer is that your choice depends on which software technologies your clients currently use and what their specific needs are.

Your data access options consist of providers and drivers, whose functionality is often encapsulated inside code libraries known as *net-libraries* (such as SNAC's `sqlncli10.dll`). In addition to these net-libraries, supporting services such as MDAC's OLE DB Core Services are also available, providing useful functionality not found in the net-libraries, such as connection pooling. (ADO.NET also functions as a service, to a certain degree.)

NOTE

The Microsoft Data Access Components (MDAC) has a new name that started with the Vista operating system. The data access components are now called Windows Data Access Components or Windows DAC or WDAC. References to MDAC in this chapter also apply to the Windows DAC.

Provider Choices

A *provider* is software used for accessing various data stores in a consistent manner conforming to a specification, such as OLE DB. A provider may contain an API. Clients that use providers are known as *consumers*. SMSS and SQLCMD, for example, are consumers of the SNAC OLE DB provider.

You can choose from the following providers:

- ▶ **SQL Native Client OLE DB provider**—This is the latest OLE DB provider, and it is built into SNAC; it is also known as SQLNCLI. COM applications might want to switch to this provider to access the latest functionality; doing so also provides access to SQL Server 7 and 2000 databases.
- ▶ **.NET Framework data provider for SQL Server**—This data provider is built in to the `System.Data.SqlClient` namespace in the .NET Framework. Managed code applications should use it to access the latest SQL Server 2008 functionality from .NET 3.5 applications. .NET 1.0, 1.1, and 2.0 applications do not have access to all the latest SQL Server 2008 functionality through this provider.
- ▶ **Microsoft OLE DB provider for SQL Server**—This OLE DB provider, known as `SQLOLEDB`, is specialized for accessing SQL Server data and is distributed with MDAC. COM applications may continue to use it to access SQL Server 2008, or they can switch to `SQLNCLI` for the latest functionality.
- ▶ **Microsoft OLE DB provider for ODBC**—This deprecated OLE DB provider, known as `MSDASQL`, is distributed with MDAC. ADO applications can continue to use it to access SQL Server 2008, but SQL Server does not support the latest SNAC-specific OLE DB functionality.

Microsoft has also made available a few implementation-specific OLE DB providers, such as the OLE DB provider for DB2, a COM component for integrating IBM DB2 and SQL Server 2008 data.

Driver Choices

A *driver* in this context can be defined as software that conforms to a standard such as Open Database Connectivity (ODBC) and provides an API for accessing a specific type of data store. `osql.exe` is a good example of an application that uses an ODBC driver (the SNAC driver).

These are the available drivers:

- ▶ **SQL Native Client ODBC driver**—This is the latest ODBC driver, and it is built into SNAC. COM applications might want to switch to this driver to access the latest functionality.
- ▶ **Microsoft ODBC driver for SQL Server**—This is the ODBC driver distributed with MDAC for accessing SQL Server databases. COM applications can continue to use it to access SQL Server 2008, or they can switch to the SNAC ODBC driver for the latest functionality. This driver also provides access to SQL Server 7, 2000, and 2005 databases.
- ▶ **Java Database Connectivity (JDBC) driver**—The JDBC driver was built specifically for accessing SQL Server data from Java code.

CAUTION

Although it is still possible to connect to SQL Server 2008 by using DB-library and Embedded SQL, Microsoft has deprecated them both, and they will not be supported in future editions.

Connecting Using the Various Providers and Drivers

Now that you know what your options are in terms of providers and drivers, the following sections detail them one by one, with a special focus on putting the features in SQL Server 2008 to work.

Using SNAC

SNAC is a net-library that contains both the latest OLE DB provider and ODBC driver for using the rich features in SQL Server 2008 databases. It is compatible for accessing SQL Server 7, 2000, and 2005 databases as well.

The code for SNAC is contained in the single dynamic link library `sqlncli10.dll`, and it serves as provider, driver, and API for applications that call its underlying COM functions from unmanaged code (that is, from C or C++).

The bottom line with SNAC is that if you're building applications that need to exploit the latest features of SQL Server 2008, you need to use its APIs. If you don't, your application will continue to work without SNAC, but those new features will not be available.

NOTE

A large number of connection keywords are available for use with SNAC connections. A few of them are illustrated in the examples that follow, but for a complete reference, see the Books Online topic “Using Connection String Keywords with SQL Native Client.”

Using OLE DB with SNAC Applications that call the COM APIs for OLE DB need to have the connection provider value changed from `SQLOLEDB` to `SQLNCLI10`. You also need to use the SNAC header file, as in the following example:

```
include "sqlncli.h";
```

`sqlncli.h` contains the latest function prototypes and other definitions for use with SNAC. This file is named the same as it was in SQL Server 2005, but it is installed in a different location.

NOTE

The SNAC OLE DB provider is OLE DB version 2.0 compliant.

Using ODBC with SNAC To connect to SQL Server 2008 using ODBC, you use a connection string or a DSN that is accessible to the client application at runtime. The ODBC driver used with SQL Server 2000 (simply called SQL Server) can still be used but is not the best option for SQL Server 2005 or 2008. To get the latest SNAC functionality, you must use the driver called SQL Native Client 10.0 (for example, `DRIVER={SQL Native Client 10.0}`).

To create a SNAC ODBC DSN, you run the Data Sources (ODBC) applet found in your operating system’s administrative tools. You create a system, file, or user DSN, and you need to be sure to select the SQL Server Native Client 10.0 driver on the Create New Data Source screen that appears. On this screen, you click the Advanced button to enter any SNAC-specific connection string keyword-value pairs, as shown in Figure 10.9.

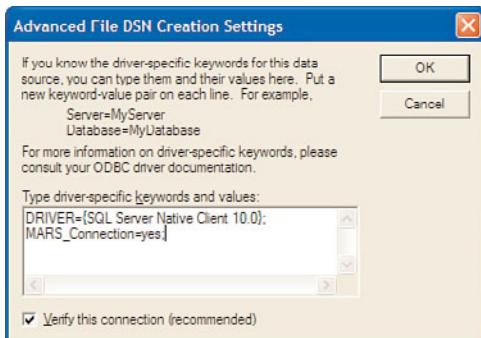

FIGURE 10.9 Using the Data Sources (ODBC) tool to configure MARS with a SNAC ODBC DSN.

You finish the wizard by entering the configuration data as you normally would, and you can use your new DSN just as you would any other. For more information on building COM applications that utilize SNAC, see the Books Online topic “Creating a SQL Native Client ODBC Driver Application.”

Using ADO with SNAC Of course, the first recommendation is that if you’re still using ADO, you should switch to ADO.NET if you can. If that isn’t feasible, you can still access SQL Server 2008 from your ADO applications. But you should do so only if you need the new features; in this case, you need to start using the SNAC OLE DB provider in your code. To do so, you first install SNAC, and then you update your connection strings (or DSNs) to use the new SQLNCLI value for the Provider connection string keyword. Then you set the `DataTypeCompatibility` keyword to 80. Here’s an example (in Visual Basic 6 code):

```
Dim MyConnection As New ADODB.Connection
Dim MyFirstOpenRecordset As New ADODB.Recordset
Dim MySecondOpenRecordset As New ADODB.Recordset
Dim ConnString As String
Dim SelectResultsCount As Integer

ConnString =
    "Provider=SQLNCLI; DataTypeCompatibility=80; Database=MyAppsDB;" & _
    "Server=.\SQLEXPRESS; AttachDBFileName=c:\MyDBs\MyAppsDB.mdf;" & _
    "MARS Connection=true; Integrated Security=SSPI;"
MyConnection.ConnectionString = ConnString
MyConnection.Open
' Using 2 open recordsets on one connection puts MARS to work:
Set MyFirstOpenRecordset =
    MyConnection.Execute(
        "SELECT TOP 10 * FROM MyTable",
        SelectResultsCount,
        adCmdText
    )
Set MySecondOpenRecordset =
    MyConnection.Execute("SELECT TOP 10 * FROM MySecondTable", _
        SelectResultsCount, adCmdText)

' and so on...
```

Note the use of the `AttachDBFileName` connection string keyword, which instructs SQL Server 2008 to attach the specified Microsoft data file (`MyAppsDB.mdf`).

Using the .NET Framework Data Provider for SQL Server

.NET applications that use the `System.Data.SqlClient` namespace rely on the .NET Framework data provider and ADO.NET. To use this provider, you simply add the following statement to your C# code file:

```
using System.Data.SqlClient;
```

For VB .NET, you use this:

```
Imports System.Data.SqlClient
```

And for JScript .NET, you use this:

```
import System.Data.SqlClient;
```

Note that the .NET provider supports a variety of connection string styles, including ODBC, OLE DB, and OLE DB/SNAC, and you can mix and match some of their respective connection string keywords. For example, `Database` and `Initial Catalog` mean the same thing to ADO.NET, and so do `Server` and `Data Source`. But don't let this fool you: Under the covers, only the .NET provider is always in use. (This is probably why changing the value passed to the `Provider` keyword seems to have no noticeable effect.)

Applications built on .NET Framework 1.0 and 1.1 can access SQL Server 2008 databases without issue. The only caveat is that those earlier versions of ADO.NET can't make use of certain SQL Server 2008 features, such as asynchronous command execution, cache synchronization, bulk copy, and the new data types. (However, implicit conversions such as from `varchar` to `xml` and from UDTs to `varbinary` allow their use as T-SQL input from .NET Framework 1.1 applications.) ADO.NET 2.0 applications, however, have access to the full gamut of new functionality in SQL Server 2008.

The following is an example of two connection strings (in different styles) that both turn on the MARS feature for ADO.NET 2.0 applications:

The following is in ODBC style:

```
Driver={SQL Native Client 10.0}; Database=AdventureWorks2008;  
Server=MyServer/SQL08;  
Encrypt=yes; Trusted_Connection=yes; MARS_Connection=yes
```

The following is in OLE DB style:

```
Provider=SQLNCLI10; Database=AdventureWorks2008; Server=MyServer/SQL08;  
Encrypt=yes; Trusted_Connection=yes; MultipleActiveResultSets=true
```

Notice the use of the keywords `MARS_Connection` (`MultipleActiveResultSets` also works) and `Encrypt` (which requests connection encryption from the server).

The SQLCLR Context Connection When you need to connect to SQL Server 2008 from within a managed stored procedure, function, or trigger (known as *SQLCLR code*), which is possible only with .NET 2.0 or greater, you use a special type of connection, known as a *context connection*. This feature prevents you from having to open a new connection because the code itself is already running within the context of an open connection.

The connection string for context connections is extremely easy to use ("`context connection=true`"), as the C# example in Listing 10.1 illustrates.

LISTING 10.1 Using the Context Connection from a Managed Stored Procedure

```

using System;
using System.Data;
using System.Data.SqlClient;
using System.Data.SqlTypes;
using Microsoft.SqlServer.Server;

public partial class StoredProcedures
{
    [Microsoft.SqlServer.Server.SqlProcedure]
    public static void ContextConnectionTest()
    {
        using (SqlConnection Context =
            new SqlConnection("context connection=true"))
        {
            using (SqlCommand TestCommand =
                new SqlCommand("SELECT TOP 10 * FROM Person.Person", Context))
            {
                using (SqlDataAdapter Adapter =
                    new SqlDataAdapter(TestCommand))
                {
                    using (DataSet MyData = new DataSet())
                    {
                        Adapter.Fill(MyData);
                    }
                }
            }
        }
    }
}

```

For more information on building SQLCLR client libraries, see Chapter 43, “SQLCLR: Developing SQL Server Objects in .NET”

Using MDAC

MDAC contains the OLE DB provider for SQL Server (SQLOLEDB) and the ODBC driver for SQL Server. MDAC is officially part of the operating system, and, as mentioned earlier, MDAC and SNAC are distributed and developed on separate tracks: MDAC with the operating system and SNAC with SQL Server. They do interrelate, however, in that applications that use SNAC can make use of the core services provided by MDAC, including support for connection pooling, client-side cursors, ADO support, and memory management. As mentioned earlier, to make use of the latest SQL Server 2008 functionality, you need to use SNAC.

TIP

If, at any time, you want to discover which version of MDAC is installed on a machine, you can simply check the value of the following Registry key (using `regedit.exe` or from code):

```
HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\DataAccess\Version
```

Note also that the planned MDAC version 10.0 release has been killed and superseded by SNAC.

If you choose to upgrade from MDAC to SNAC, it's important to note some key differences between the two that could affect your applications:

- ▶ Return values from SQL Server 2008 to MDAC applications are implicitly type converted, as shown in Table 10.2.

TABLE 10.2 Implicit Type Conversions for SQL Server 2008 Data Types

SQL Server 2008 Data Type	Converted to Data Type
varbinary(MAX)	Image
xml	ntext
nvarchar(MAX)	ntext
varchar(MAX)	text
UDTs	varbinary

- ▶ Warning and error messages and message handling differ between MDAC and SNAC.
- ▶ SNAC requires that T-SQL parameters begin with the `@` character; MDAC does not.
- ▶ SNAC, unlike MDAC, is not compatible with Visual Studio Analyzer or PerfMon.

For further details, see the Books Online topic “Updating an Application to SQL Native Client from MDAC.”

Using ODBC with MDAC You can configure an ODBC connection by using a connection string or DSN that specifies the Microsoft ODBC driver for SQL Server.

For connection strings, you use the keyword-value pair `Provider={SQL Server}`.

To use a DSN, you run the Data Sources (ODBC) applet, as mentioned earlier. When choosing a driver, you select the one simply named SQL Server.

Using OLE DB with MDAC You can access SQL Server 2008 databases by using the Microsoft OLE DB provider for SQL Server (SQLOLEDB). In connection strings or property values, you use the `Provider` keyword and the value `SQLOLEDB`.

NOTE

Unlike with SNAC's OLE DB provider, with SQLOLEDB you can access both SQL Server data and data from non-SQL Server data sources. Also, SNAC is not dependent on any particular version of MDAC because it expects that a compatible MDAC version will be present on the operating system, as enforced by its own installation requirements.

Using JDBC

Microsoft released a freely downloadable, JDBC 4.0-compliant, Type 4 driver for use with SQL Server 2008. It can be used from all types of Java programs and servers via the J2EE connection API.

The following is the basic syntax for a JDBC connection string:

```
jdbc:sqlserver://ServerName\InstanceName:port;property=value[;property=value]
```

For complete details on using JDBC, check out Microsoft's JDBC product documentation at [http://msdn.microsoft.com/en-us/library/ee229547\(v=SQL.10\).aspx](http://msdn.microsoft.com/en-us/library/ee229547(v=SQL.10).aspx). You might also find the newsgroup `microsoft.public.sqlserver.jdbcdriver` helpful.

General Networking Considerations and Troubleshooting

This section provides guidelines for solving some common connectivity issues. You can perform the following steps as a first line of defense when your connections fail:

1. Check whether the server is configured (via SSCM, as detailed earlier in this chapter, in the section "Server Network Protocols") to accept remote connections.
2. Ensure that the SQL Browser service is started.
3. Determine whether clients are specifying the correct port (for using fixed ports with named instances) in the server alias or connection string.
4. Check whether the client's network protocols are enabled and configured to correctly handshake with those of the server. They should use SSCM on both sides, as explained earlier in this chapter, in the section "Client Configuration Using SSCM."
5. Be sure you have permission to connect on the server's endpoints.
6. When using encryption, be sure the server and client certificates match (that is, check their *Common Name* (CN) and any other relevant attributes) and are installed and configured correctly on both sides. (See the section "Connection Encryption," earlier in this chapter.)
7. Make certain that your firewalls are configured to permit the required network traffic. (See the following section, "Firewall Considerations.")
8. Check to see whether your users have permission to log in to the server and access the specified database.
9. Make sure that your clients' choices of providers support the SQL Server 2008 features they are trying to use.
10. Make sure the provider, driver, DSN, server alias, or other connection mechanism is still valid and hasn't been altered or removed from the system.

11. Network administrators are no longer added to the SQL Server sysadmin role by default. If the user trying to connect is a network administrator, he or she must be granted explicit permission with SQL Server 2008. See the topic named “Database Engine Configuration - Account Provisioning” in Books Online for more information.

Firewall Considerations

For clients to successfully connect through a firewall, it must be configured to allow the following:

- ▶ **Bidirectional traffic on UDP Port 1434**—This is required only for communications to and from the SQL Browser service; when SQL Browser is not in use, you can close this port.
- ▶ **Bidirectional traffic on any TCP port used by SQL Server**—Be sure to open port 1433 for default instances and also open any fixed ports assigned to your named or default instances. (TCP high port numbers must be opened only when dynamic ports are used by named instances. Using dynamic port numbers for named instances is not recommended.) You can determine the ports currently in use via SSCM.

When using Windows Firewall, you can easily open these ports. To do this, you run Windows Firewall from the Control Panel, and on the main screen that appears, you click the Exceptions tab. Then you click the Add Port button and enter the required names (either SQL Server or SQL Browser, for example) and port numbers, one at a time, on the Add a Port screen that appears (see Figure 10.10).

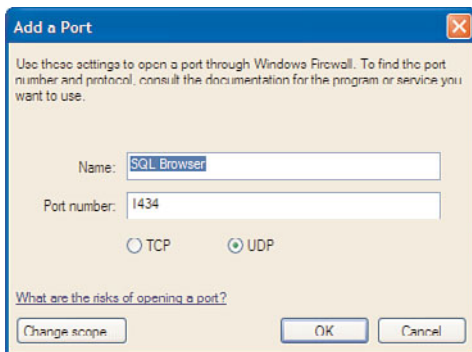

FIGURE 10.10 Creating port exceptions for SQL Server 2008, using Windows Firewall.

Tools for Testing Connections

It's always helpful to have a few tools on your belt for testing client connectivity.

SSCM is a tool that is usually easily accessible, and you can use its Connect to Server dialog to select a protocol to test (as described earlier in this chapter, in the section “Client Data Access Technologies”). You can also use SQLCMD with the `-S` parameter to connect to a particular server. This is the syntax:

```
SQLCMD -Sprotocol_prefix:ServerName,PortNumber -E
```

In this syntax, *protocol_prefix* takes one of the following values:

- ▶ np (for named pipes)
- ▶ tcp (for TCP/IP)
- ▶ lpc (for shared memory)
- ▶ via (for VIA)

In the following example, -E indicates the use of a trusted connection:

```
SQLCMD -Stcp:.\SQL08,1435 -E
```

When all else fails, you can use `telnet` to test the openness of a port on the firewall. Here's an example:

```
telnet IP_Address Port_Number
```

Summary

This chapter covers a lot of ground regarding client-side (and even a bit of server-side) communication with SQL Server 2008. Some of the sections are admittedly dense enough to bear rereading, and you probably have questions about your specific setup. You can always refer to the sections presented in this chapter to pick up tips on how to best configure and troubleshoot the varying environments you may encounter. And you can (and should) use the extremely helpful Usenet groups that are devoted to the subject (for example, `microsoft.public.sqlserver.clients` or `microsoft.public.sqlserver.programming`).

Now that your client configuration is complete, you can move on to Chapter 11, "Security and User Administration," to learn how to securely administer the Database Engine.

This page intentionally left blank

CHAPTER 11

Security and User Administration

Securing your database environment and providing the right type of access to your users are critical administrative tasks. This chapter examines the security features in SQL Server 2008 that relate to user administration and the objects that users can access.

What's New in Security and User Administration

Several new security enhancements have been added to SQL Server 2008 to help make it more secure than any prior version. These enhancements build upon the myriad of security-related changes made in SQL Server 2005 and follow the policy of “least privileges” that Microsoft has been pushing. Several of these new changes follow:

- ▶ **BUILTIN\Administrators**—This local Windows group is no longer included in the SQL Server `sysadmin` fixed server role. In prior versions, the `BUILTIN\Administrators` account was part of this role, which meant that network administrators could access the SQL Server instance even though they were not given explicit permission. You still have the option of manually adding this group to the `sysadmin` role, but it is not installed this way by default.
- ▶ **Surface Area Configuration (SAC)**—This GUI tool, which was introduced in SQL Server 2005, has been removed in SQL Server 2008. It was used to enable or disable SQL Server features and options, but it has been replaced in part by the new Policy-Based

IN THIS CHAPTER

- ▶ Managing SQL Server Users
- ▶ Managing Database Roles
- ▶ Managing SQL Server Permissions
- ▶ The Execution Context

Management feature and in part by an enhanced SQL Server Configuration Manager. Right-click on the server instance in Object Explorer and choose Facets. You get a quick look at the number of settings available via facets that are part of Policy-Based Management. If you select Server Configuration from the drop-down, you see features such as CLR Integration (that is, `CLRIntegrationEnabled`) that you could have set in the past with the Surface Area Configuration tool.

- ▶ **Local Groups Removed from `sysadmin`**—Several local network groups that were added to the `sysadmin` server role in past versions are no longer added to this role. These accounts include `SQLServerMSSQLUser$ COMPUTERNAME $ INSTANCENAME` and `SQLServerSQLAgentUser$ COMPUTERNAME $ INSTANCENAME`. Only the SQL Server Service and SQL Server Agent Service accounts are added to the `sysadmin` role.

An Overview of SQL Server Security

The SQL Server 2008 security model is the best place to start to understand SQL Server security. The model is based on three categories that separate the basic elements of security:

- ▶ **Principals**—Principals are the entities that request security to SQL Server resources. They include Windows users, SQL Server users, and database users.
- ▶ **Securables**—Securables are the SQL Server resources to which permissions can be granted.
- ▶ **Permissions**—Permissions link principals with securables.

Table 11.1 shows the security components contained in each tier of the SQL Server 2008 security model. The columns are ordered from left to right, based on the way security is established.

TABLE 11.1 SQL Server 2008 Security Components

Principals	Permissions	Securables
Windows:	GRANT/REVOKE/DENY	Server Scope
Groups	CREATE	Login
Domain Login	ALTER	Endpoint
Local Login	DROP	Database
SQL Server:	CONTROL	Database Scope
SQL Login	CONNECT	User
Server Role	SELECT	Role

TABLE 11.1.1 SQL Server 2008 Security Components

Principals	Permissions	Securables
Database:	EXECUTE	Application role
User	UPDATE	Assembly
Database Role	DELETE	Message Type
Application Role	INSERT	Route
	REFERENCES	Service
	RECEIVE	Remote Service
		Binding
	VIEW DEFINITION	Fulltext Catalog
	TAKE OWNERSHIP	Certificate
	CONTROL	Asymmetric Key
	VIEW CHANGE TRACKING	Symmetric Key
		Contract
		Schema
		Schema Scope
		Table
		View
		Function
		Procedure
		Queue
		Type
		Synonym
		Aggregate
		XML Schema
		Collection

The implementation of the security model is relatively straightforward: you choose the principal from Column 1, the desired permission from Column 2, and the securable to assign the permission from Column 3. For example, a SQL LOGIN (the principal) needs to CREATE (the permission) databases (the securable). Together, these three elements represent a complete security assignment.

Some complexity has been introduced, based on the hierarchical nature of some of the security components. Security can be established on these hierarchical components, which in turn cascades the security to the underlying components. In addition, not all the permission components apply to every securable. Many of the securables have a select number of permissions that apply to them; conversely, many permissions apply only to a select number of securables. For example, `SELECT` permission is applicable to securables such as tables and views but would not be appropriate for stored procedures.

The following sections discuss the tiers of the security model and their underlying components.

Authentication Methods

The first level of security encountered when accessing SQL Server is known as *authentication*. The authentication process performs the validation needed to allow a user or client machine to connect to SQL Server. This connection can be granted via a Windows login or SQL Server login.

Windows Authentication Mode

Windows Authentication mode validates the account name and password, using information stored in the Windows operating system. A Windows account or group must be established first, and then security can be established for that account in SQL Server. This mode has the advantage of providing a single login account and the capability to leverage domain security features, such as password length and expiration, account locking, encryption, and auditing. Microsoft recommends this approach.

Mixed Authentication Mode

Mixed authentication allows for both Windows authentication and SQL Server authentication. SQL Server authentication is based on a login that is created in SQL Server and lives in SQL Server only. No Windows account is involved with SQL Server authentication. The account and password are established and maintained in SQL Server. SQL Server logins can be created with stronger password enforcement that help better protect the login. This topic is discussed in more detail in the section “Managing SQL Server Logins,” later in this chapter.

SQL Server authentication is useful in environments in which a Windows domain controller does not control network access. It can also be useful for Web applications or legacy applications, where it may be cumbersome to establish a Windows user account for every connection to the database server.

Setting the Authentication Mode

You can select the authentication mode when you install SQL Server, and you can change it after the installation. To change the authentication mode after installation, you right-click the server node in the Object Explorer and choose the Properties option. When the Server Properties dialog appears, you select the Security page (see Figure 11.1). The Security page allows you to specify Windows Authentication mode or SQL Server and Windows Authentication mode (that is, mixed authentication). Any changes to the authentication mode require a restart of SQL Server to make the change effective.

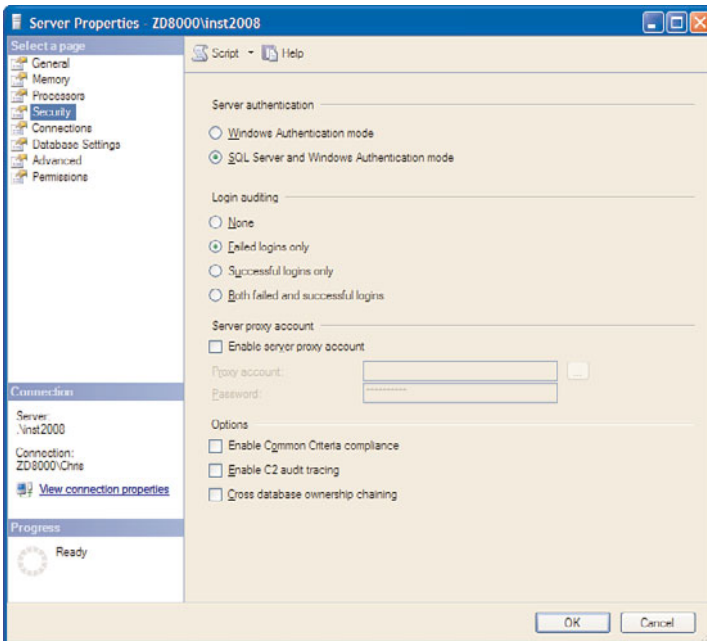

FIGURE 11.1 Changing the authentication mode.

Managing Principals

Principals are the entities that can request permission to SQL Server resources. They are made up of groups, individuals, or processes. Each principal has its own unique identifier on the server and is scoped at the Windows, server, or database level. The principals at the Windows level are Windows users or groups. The principals at the SQL Server level include SQL Server logins and server roles. The principals scoped at the database level include database users, data roles, and application roles.

Logins

Every principal granted security to SQL Server must have an associated login. The login provides access to SQL Server and can be associated with principals scoped at the Windows and server levels. These logins can be associated with Windows accounts, Windows groups, or SQL Server logins.

Logins are stored in the master database and can be granted permission to resources scoped at the server level. Logins provide the initial permission needed to access a SQL Server instance and allow you to grant access to the related databases. Permissions to specific database resources must be granted via a database user. The important point to remember is that logins and users are directly related to each other but are different entities. It is possible to create a new login without creating an associated database user, but a new database user must have an associated login.

To better understand logins, you can look at the `sys.server_principals` catalog view. This view contains a row for every server-level principal, including each server login. The following example selects from this view and displays the results:

```
select left(name,25) name, type, type_desc
  from sys.server_principals AS log
 WHERE (log.type in ('U', 'G', 'S', 'R'))
  order by 3,1
```

/*Results from previous query

name	type	type_desc
bulkadmin	R	SERVER_ROLE
dbcreator	R	SERVER_ROLE
diskadmin	R	SERVER_ROLE
processadmin	R	SERVER_ROLE
public	R	SERVER_ROLE
securityadmin	R	SERVER_ROLE
serveradmin	R	SERVER_ROLE
setupadmin	R	SERVER_ROLE
sysadmin	R	SERVER_ROLE
sa	S	SQL_LOGIN
DBSVRXP\LocalUser1	U	WINDOWS_LOGIN
HOME\Administrator	U	WINDOWS_LOGIN
NT AUTHORITY\SYSTEM	U	WINDOWS_LOGIN

*/

The results from the `sys.server_principals` selection include the name of the server principal as well as the type of principal. The rows that have a `type_desc` value of `SQL_LOGIN`, `WINDOWS_GROUP`, or `WINDOWS_LOGIN` are all logins established on the SQL Server instance. A login with a `type_desc` of `SQL_LOGIN` represents a login created with SQL Server authentication. Logins with a `type_desc` of `WINDOWS_GROUP` or `WINDOWS_LOGIN` are

Windows groups or individual Windows users granted logins to SQL Server. The other entries with `type_desc` of `SERVER_ROLE` are fixed server roles discussed later in this chapter.

The logins established for Windows logins or groups can be part of the local domain of the SQL Server machine, or they can be part of another domain. In the previous example, `DBSVRXP\LocalUser1` is a login established for a local user on a database server named `DBSVRXP`. The `HOME\Administrator` login is also a Windows login, but it is part of a network domain named `HOME`. Both logins are preceded by the domain that they are part of and are displayed this way in SQL Server.

NOTE

In SQL Server 2000, logins were stored in the `syslogins` system table in the master database. The `syslogins` table is still available for selection as a view, but it is available only for backward compatibility. The catalog views (including `sys.server_principals`) are recommended for use instead.

You might have noticed in the earlier `sys.server_principals` output that two other logins are listed that we have not discussed yet. These logins (`SA` and `NT AUTHORITY\SYSTEM`) are system accounts installed by default at installation time. Each of these accounts serves a special purpose in SQL Server.

The `SA` account is a `SQL_LOGIN` assigned to the `sysadmin` fixed server role. The `SA` account and members of the `sysadmin` fixed server role have permission to perform any activity within SQL Server. The `SA` account cannot be removed, and it can always be used to gain access to SQL Server. The `SA` account should always have a strong password to prevent malicious attacks, and it should be used only by database administrators. Users or logins requiring full administrative privileges can be assigned a separate SQL Server login that is assigned to the `sysadmin` fixed server role. This improves the audit trail and limits the amount of use on the `SA` account.

The `NT AUTHORITY\SYSTEM` login is an account related to the local system account under which SQL Server services can run. It is also added as a member of the `sysadmin` fixed server role and has full administrative privileges in SQL Server. This account can also be removed if the SQL Server services are not running with the local system account. This should be done with caution, however, because it can affect applications such as Reporting Services.

One other special account was not listed, but it would have been in SQL Server 2005. The `BUILTIN\Administrators` login is a Windows group that corresponds to the local administrators group for the machine that SQL Server is running on. The `BUILTIN\Administrators` group is no longer added by default as a SQL Server login during installation. In SQL Server 2005, it was also added as a member of the `sysadmin` fixed server role, but this is no longer the case. This change improves the security of SQL Server out of the box by limiting the number of people that have access (by default) to the SQL Server instance.

NOTE

The BUILTIN\Administrators group can be manually added in SQL Server 2008 if desired. This allows domain administrators and anyone else who has been added to the local administrators group to have sysadmin privileges. Adding this group is not recommended but can be done if you want to set network privileges that are similar to past versions of SQL Server.

SQL Server Security: Users

Database users are principals scoped at the database level. Database users establish a link between logins (which are stored at the server level) and users (which are stored at the database level). Database users are required to use the database and are also required to access any object stored in the database.

Generally, the login name and database username are the same, but this is not a requirement. If desired, you could add a login named Chris and assign it to a user named Kayla. This type of naming convention would obviously cause some confusion and is not recommended, but SQL Server has the flexibility to allow you to do it. In addition, a user can be associated with a single person or a group of people. This capability is tied to the fact that a login can be related to a single account or group. For example, a login named training could be created and tied to a Windows group (that is, *domain\training*) that contains all the training personnel. This login could then be tied to a single database user. That single database user would control database access for all the users in the Windows group.

TIP

The relationship between logins and users can be broken when databases are moved or copied between servers. The reason is that a database user contains a reference to the associated login. Logins are referenced based on a unique identifier called a security identifier (SID). When a database is copied from one server to another, the users in that database contain references to logins that may not exist on the destination server or that may have different SIDs.

You can use the `sp_change_users_login` system stored procedure to identify and fix these situations. You can run the following command against a newly restored or attached database to check for orphaned users:

```
EXEC sp_change_users_login 'Report'
```

If orphaned users are shown in the results, you can rerun the procedure and fix the problems. For example, if the results indicate that a user named Chris is orphaned, you can run the following command to add a new login named Chris and tie the orphaned database user to this newly created login:

```
EXEC sp_change_users_login 'Auto_Fix', 'Chris', NULL, 'pw'
```

Refer to SQL Server Books Online for full documentation on the `sp_change_users_login` system stored procedure.

You can use the `sys.database_principals` catalog view to list all the users in a given database. The following example shows a `SELECT` statement using this view and the results from the `SELECT`:

```
SELECT
left(u.name,25) AS [Name],
type,
left(type_desc,15) as type_desc
FROM
sys.database_principals AS u
WHERE
(u.type in ('U', 'S', 'G'))
ORDER BY 1

/*Results from previous query
Name                type type_desc
-----
dbo                  S    SQL_USER
DBSVRXP\LocalUser1  U    WINDOWS_USER
guest                S    SQL_USER
INFORMATION_SCHEMA  S    SQL_USER
sys                  S    SQL_USER
*/
```

The `SELECT` statement in this example returns five rows (that is, five users). This `SELECT` was run against the `AdventureWorks2008` database, and the only user explicitly added to the database was the Windows user `DBSVRXP\LocalUser1`. The other users are special users who are added by default to each database. These users do not have corresponding server logins named the same. These users are discussed in the following sections.

The `dbo` User

The `dbo` user is the database owner and cannot be deleted from the database. Members of the `sysadmin` server role are mapped to the `dbo` user in each database, which allows them to administer all databases. Objects owned by `dbo` that are part of the `dbo` schema can be referenced by the object name alone. When an object is referenced without a schema name, SQL Server first looks for the object in the default schema for the user that is connected. If the object is not in the user's default schema, the object is retrieved from the `dbo` schema. Users can have a default schema that is set to `dbo`.

Schemas and their relationship to users are discussed in more detail in the section "User/Schema Separation," later in this chapter.

The `guest` User

The `guest` user is created by default in each database when the database is created. This account allows users that do not have a user account in the database to access the database. By default, the `guest` user does not have permission to connect to the database. To allow logins without a specific user account to connect to the database, you need to grant

CONNECT permission to the guest account. You can run the following command in the target database to grant the CONNECT permission:

```
GRANT CONNECT TO GUEST
```

When the guest account is granted CONNECT permission, any login can use the database. This opens a possible security hole. The default permissions for the guest account are limited by design. You can change the permissions for the guest account, and all logins that use it will be granted those permissions. Generally, you should create new database users and grant permissions to these users instead of using the guest account.

If you want to lock down the guest account, you can. You cannot drop the guest user, but you can disable it by revoking its CONNECT permission. The following example demonstrates how to revoke the CONNECT permission for the guest user:

```
REVOKE CONNECT FROM guest
```

If you decide to grant additional access to the guest account, you should do so with caution. The guest account can be used as a means for attacking your database.

The INFORMATION_SCHEMA User

The INFORMATION_SCHEMA user owns all the information schema views installed in each database. These views provide an internal view of the SQL Server metadata that is independent of the underlying system tables. Some examples of these views include INFORMATION_SCHEMA.COLUMNS and INFORMATION_SCHEMA.CHECK_CONSTRAINTS. The INFORMATION_SCHEMA user cannot be dropped from the database.

The sys User

The sys account gives users access to system objects such as system tables, system views, extended stored procedures, and other objects that are part of the system catalog. The sys user owns these objects. Like the INFORMATION_SCHEMA user, it cannot be dropped from the database.

TIP

If you are interested in viewing the specific objects owned by any of the special users discussed in these sections, you can use a SELECT statement like the following:

```
--Find all objects owned by a given user
SELECT name, object_id, schema_id, type_desc
FROM sys.all_objects
WHERE OBJECTPROPERTYEX(object_id, N'OwnerId') = USER_ID(N'sys')
ORDER BY 1
```

The SELECT in this example shows all the objects owned by the sys user. To change the user, you simply change the parameter of the USER_ID function in the SELECT statement from 'sys' to whatever user you want.

User/Schema Separation

The changes to schema security introduced in SQL Server 2005 have been carried forward to SQL Server 2008. Versions of SQL Server before SQL Server 2005 had schemas, but they did not conform to the American National Standards Institute (ANSI) definition of schemas. ANSI defines a schema as a collection of database objects that one user owns and that forms a single namespace. A single namespace is one in which each object name is unique and there are no duplicates. So, for example, if you have two tables named `customer`, they cannot exist in the same namespace.

To fully understand the user/schema changes in SQL Server 2008, you need to understand how schemas were used in prior versions of SQL Server. In SQL Server 7.0 and 2000, a default schema was created for each user, and it had the same name as the user. For example, if you created a new user named `Rachael`, a corresponding schema named `Rachael` would be created as well. There was no option in those releases to change the default schema for a user, and each user was forever bound to a schema with the same name. When the user created new objects, the objects were created by default in that user's schema, which is always the name of the user. So, if `Rachael` created an object named `customer`, it was placed in the `Rachael` schema, and the object was owned by `Rachael`. When `Rachael` wanted to reference the object, she could use a three-part name with the format `database.owner.object`. If a linked server was used, according to the SQL Server 2000 documentation, the object in the linked server could be referenced with the four-part name `linked_server.catalog.schema.object`. (for example `myserver.AdventureWorks2008.Rachael.Customer`). You can see that the schema name is used prior to the object name when the object is outside the local server. The bottom line is that the schema and owner were basically the same thing in SQL Server 7.0 and 2000.

With SQL Server 2005 and SQL Server 2008, the owner and schema have been separated. This is made possible in part by allowing a database user to have a default schema different from the name of the user. For example, our sample user `Rachael` could be assigned the default schema `Sales`. When `Rachael` creates objects in the database, her objects are created, by default, in the `Sales` schema. If `Rachael` wants to reference an object that she created, she can reference the table in a number of different ways. She can use the full four-part name (`server.database.schema.object`) that includes the `Sales` schema name to reference the object via a linked server. She can simply refer to the object with the object name alone, and the `Sales` schema will be searched first for the object. She can also use a three-part name or a two part name. If the object name is not found in the `Sales` schema,

the `dbo` schema will be searched. This concept is illustrated in the following sample `SELECT` statements that all retrieve the same rows from the `Region` table that was created by Rachael in the `Adventureworks2008` database.

```
select * from region
select * from sales.region
select * from AdventureWorks2008.Sales.Region
```

The important point to remember is that owners and schemas are different from one another in SQL Server 2008. For example, you can have a `customer` table created in the `Sales` schema, and that table can be owned by a user named `Chris`. The object should be referenced with the schema name qualifier, such as `Sales.Customer`, not `Chris.Customer`. This has the distinct advantage of allowing object ownership to change without affecting the code that references the object. The reason is that database code that references an object uses the schema name instead of the object owner.

The schema enhancements in SQL Server 2008 go well beyond the user/schema separation. Schemas are an integral part of all the database objects that exist in SQL Server. As we delve into more details about SQL Server security and the assignment of permissions, you will see that schemas play a very important part.

Roles

Roles provide a consistent yet flexible model for security administration. Roles are similar to the groups used in administering networks. Permissions are applied to a role, and then members are added to the role. Any member of the role has all the permissions that the role has.

The use of roles simplifies the administrative work related to security. Roles can be created based on job function, application, or any other logical group of users. With roles, you do not have to apply security to each individual user. Any required changes to permissions for the role can be made to the role security, and the members of the role receive those changes.

SQL Server has the following three types of roles:

- ▶ **Fixed server and fixed database roles**—These roles are installed by default and have a predefined set of permissions.
- ▶ **User-defined roles**—These roles are created in each database, with a custom set of permissions for each set of users assigned to it.
- ▶ **Application roles**—These special roles can be used to manage database access for an application.

These roles are discussed in the following sections.

Fixed Server Roles

Fixed server roles are scoped at the server level, which means that the permissions for these roles are oriented toward server-level securables. These roles contain a variety of fixed permissions geared toward common administrative tasks. Logins (not users) are assigned to these roles.

The same fixed server roles available in SQL Server 2000 and SQL Server 2005 are also available in SQL Server 2008. There is, however, one new role named `public` that has been added. Server principals, by default, are granted the permissions that have been granted to the `public` role. There are a limited number of permissions that are initially granted to the `public` role, but you can change the permissions if you like. A complete list of all the fixed server roles and their related permissions is shown in Table 11.2.

TABLE 11.2 Fixed Server Roles

Role	Permission
<code>bulkadmin</code>	Allowed to run the <code>BULK INSERT</code> statement.
<code>dbcreator</code>	Allowed to use <code>CREATE</code> , <code>ALTER</code> , <code>DROP</code> , and <code>RESTORE</code> on any database.
<code>diskadmin</code>	Allowed to manage disk files that are used by SQL Server.
<code>processadmin</code>	Allowed to terminate SQL Server processes.
<code>public</code>	Assigned to all logins. Permissions granted to this role are assigned to every login by default.
<code>securityadmin</code>	Allowed to use <code>GRANT</code> , <code>DENY</code> , and <code>REVOKE</code> permissions for logins at the server and database levels. Members of this role can reset passwords for SQL Server logins.
<code>serveradmin</code>	Allowed to change server-wide configuration properties and shut down the server, if needed.
<code>setupadmin</code>	Allowed to add and remove linked servers and execute some system stored procedures.
<code>sysadmin</code>	Allowed to perform any activity in the server.

A single login can be assigned to one or more of these fixed server roles. When multiple roles are assigned, the combination of all the permissions is allocated to the login.

NOTE

Keep in mind that when a login is assigned to certain fixed server roles, they have implied permissions that cascade to the database level. For example, if a login is assigned to the sysadmin role, that login can perform any activity on the server, and it can also perform any action on any database on that server. Similarly, if a login is added to the securityadmin role, the login can change permissions at the database level as well as the server level.

All the fixed server roles are listed in the SQL Server Management Studio (SSMS) Object Explorer. Figure 11.2 shows the Object Explorer with the Server Roles node expanded. You can right-click any of the roles and select Properties to display the logins that are currently members of the role.

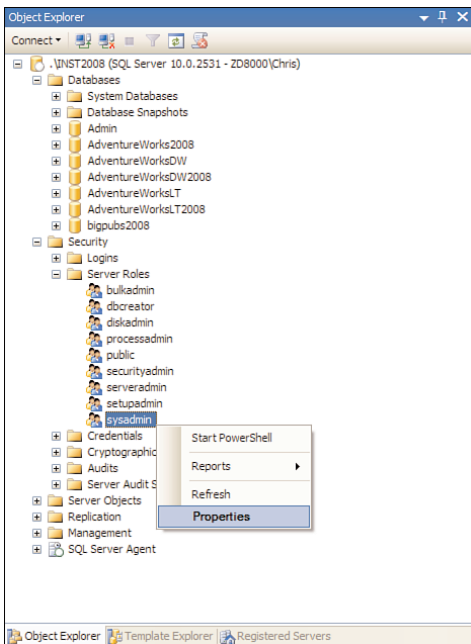

FIGURE 11.2 Fixed server roles in Object Explorer.

Fixed Database Roles

SQL Server provides fixed roles that define a common set of permissions at the database level. These fixed database roles are assigned to database users. The permissions defined for the fixed database roles cannot be changed. Table 11.3 shows the fixed database roles and their permissions.

TABLE 11.3 Fixed Database Roles

Role	Permission
db_accessadmin	Allowed to add or remove database access for logins.
db_backupoperator	Allowed to back up the database.
db_datareader	Allowed to read all user table data.
db_datawriter	Allowed to change the data in all user tables.
db_ddladmin	Allowed to run any Data Definition Language (DDL) command against the database. This includes commands to create, alter, and drop database objects.
db_denydatareader	Denied the right to read all user table data.
db_denydatawriter	Denied the right to change the data in any of the user tables.
db_owner	Allowed to perform any action on the database. Members of the sysadmin fixed server role are mapped to this database role.
db_securityadmin	Allowed to manage permissions for database users, including membership in roles.
dbm_monitor	Allowed to view the most recent status in the Database Mirroring Monitor.

NOTE

You can find a more granular breakdown of permissions associated with fixed database roles in the SQL Server Books Online documentation. Look for the subject “Permissions of Fixed Database Roles.” The extensive table in this documentation defines the specific permissions for each role. For example, the table shows that the db_backupoperator role is granted the BACKUP DATABASE, BACKUP LOG, and CHECKPOINT permissions. This gives you more insight into what the members of this role can do. Some fixed database roles have a large number of permission defined for them, such as db_ddladmin, which has more than 30 individual permissions. The types of permissions and improved granularity available with SQL Server 2008 are discussed in the “Managing Permissions” section, later in this chapter.

You can also find a list of fixed database roles in the Object Explorer. Figure 11.3 shows the fixed database roles for the AdventureWorks2008 database. The roles are found under the Security node within each database. You can right-click a fixed database role and select Properties to view the member users.

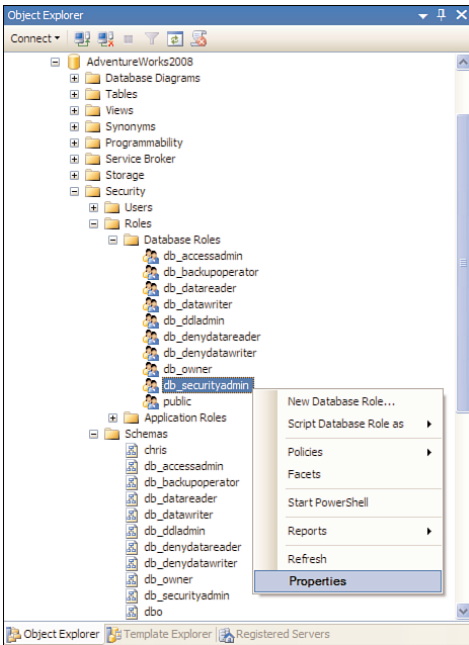

FIGURE 11.3 The fixed database roles in Object Explorer.

Fixed database roles and schemas are related. Figure 11.3 shows the expanded Schemas node for the AdventureWorks2008 database. You can see that there is a corresponding schema for each of the fixed database roles. These schemas are automatically created, and each is owned by the related database role.

The public Role

The public role is a special database role that is like a fixed database role except that its permissions are not fixed. The permissions for this role can be altered. Every user in a database is automatically made a member of the public role and in turn receives any permissions that have been granted to the public role. Database users cannot be removed from the public role.

The public role is similar in function to the guest user that is installed by default in each database. The difference is that the permissions granted to the guest user are used by any login that does not have a user account in the database. In this case, the login is allowed to enter the database via the guest account. In the case of the public role, the login has been added as a user of the database and in turn picks up any permissions that have been granted to the public role.

To view the permissions associated with the public role, you can use a SELECT statement like the following:

```
SELECT top 5 g.name,
       object_name(major_id) as 'Object',
```

```

    permission_name
from sys.database_permissions p
join sys.database_principals g
    on p.grantee_principal_id = g.principal_id
    and g.name = 'public'
order by 1,2

/*Results from the previous select
name    Object          permission_name
-----  -
public  all_columns         SELECT
public  all_objects         SELECT
public  all_parameters      SELECT
public  all_sql_modules     SELECT
public  all_views           SELECT
*/

```

This SELECT utilizes two catalog views that contain security information. The SELECT returns only the first five permissions for the public role, but the TOP clause can be removed to return all the permissions.

User-Defined Roles

SQL Server enables you to create your own custom database roles. Like the fixed roles, user-defined roles can be used to provide a common set of permissions to a group of users. The key benefit behind using user-defined roles is that you can define your own set of custom permissions that fit your needs. User-defined roles can have a broad range of permissions, including the more granular set of permissions made available with SQL Server 2008.

To demonstrate the power of a user-defined database role, let's look at a simple example. Let's say that you have a group of users who need to read all the tables in a database but should be granted access to update only one table. If you look to the fixed database roles, you have the db_datareader and db_datawriter roles, which give you a partial solution. You can use the db_datareader role to allow the read capability you need, but the db_datawriter role gives write permission to all the tables—not just one.

One possible solution would be to give every user in the group membership to the db_datareader group and assign the specific UPDATE permission to each user as well. If the group contains hundreds of users, you can see that this would be rather tedious. Another solution might be to create a Windows group that contains every user who needs the permissions. You can then assign a login and database user to this group and grant the appropriate permissions. The Windows group is a viable solution but can sometimes be difficult to implement in a complex Windows domain.

Another approach to this challenge is to use a user-defined database role. You can create the role in the database that contains the tables in question. After you create the role, you can include it in the db_datareader role, and you can establish the UPDATE permission to the single table. Finally, you can assign the individual users or group of users to

the role. Any future permission changes for this set of users can be administered through the user-defined database role. The script in Listing 11.1 steps through a process that demonstrates and tests the addition of a database role. This is similar to the example we just walked through. Parts of the script need to be run by an administrator, and other parts should be run in a query editor window that is connected to the database with the newly created testuser.

LISTING 11.1 An Example of User-Defined Database Roles

```
--The following statements must be run by an administrator to add
--a login and database user with no explicit permissions granted
CREATE LOGIN [TestUser] WITH PASSWORD=N'pw',
DEFAULT_DATABASE=[master], CHECK_EXPIRATION=OFF, CHECK_POLICY=OFF
GO

GO
USE [AdventureWorks2008]
GO
CREATE USER [TestUser] FOR LOGIN [TestUser]
go
--the following statement fails when executed by the TestUser
--which has no explicit permissions defined in the AdventureWorks2008 database
select top 5 * from person.person
UPDATE person.person SET suffix = 'Jr.'
WHERE FirstName = 'Ken'
--The following statement is run by an administrator to:
--1)add a new TestDbRole with permission to UPDATE
--2)grant UPDATE permission on the Person.person table
--3)add the TestUser to the TestDbRole database role
USE [AdventureWorks2008]
GO
--1)
CREATE ROLE [TestDbRole] AUTHORIZATION [dbo]
--2)
GRANT UPDATE ON [Person].[Person] TO [TestDbRole]
GRANT SELECT ON [Person].[Person] TO [TestDbRole]
--3)
EXEC sp_addrolemember N'TestDbRole', N'TestUser'

--the following statements now succeed when executed
--by the TestUser because the role that it
--was added to has SELECT and UPDATE permission
--on that table
select top 5 * from person.person
UPDATE person.person SET suffix = 'Jr.'
WHERE ContactID = 1
```

```
--the following select fails because 'testdbrole'
--does not permit SELECT on any table but person.person
select * from person.ContactType
--The following statement is run by an administrator
--to add the TestDbRole database role to the db_datareader
--fixed-database role
EXEC sp_addrolemember N'db_datareader', N'TestDbRole'
GO
--Finally, the testuser can update the Person.person table
-- and select from any other table in the database
select * from person.ContactType
```

Database roles and permissions are discussed in more detail later in this chapter, in the sections “Managing Database Roles” and “Managing Permissions.”

Application Roles

Unlike other roles, application roles contain no database users. When an application role is created (see the section “Managing Database Roles,” later in this chapter), rather than add a list of users who belong to the role, you specify a password. To obtain the permissions associated with the role, the connection must set the role and supply the password. This is done using the stored procedure `sp_setapprole`. You set the role to the sales application role (with the password `PassW0rd`) as follows:

```
EXEC sp_setapprole 'sales', 'PassW0rd'
```

You can also encrypt the password:

```
EXEC sp_setapprole 'sales', {ENCRYPT N ' PassW0rd'}, 'odbc'
```

When an application role is set, all permissions from that role apply, and all permissions inherited from roles other than `public` are suspended until the session is ended.

So why is it called an application role? The answer is in how it is used. An application role is used to provide permissions on objects through an application, *and only through the application*. Remember that you must use `sp_setapprole` and provide a password to activate the role; this statement and password are not given to the users; rather, they are embedded in the application’s `CONNECT` string. This means that the user can get the permissions associated with the role only when running the application. The application can have checks and balances written into it to ensure that the permissions are being used for the forces of good and not evil.

Managing Securables

Securables are the entities in SQL Server on which permissions can be granted. In other words, principals (for example, users or logins) obtain permission to securables. This chapter describes many examples of securables, including tables, databases, and many

entities that have been part of the SQL Server security model in past versions. SQL Server 2008's security model contains a granular set of securables for applying permissions.

Securables are hierarchical in nature and are broken down into nested hierarchies of named scopes. Three scopes are defined: at the server, database, and schema levels. Table 11.4 list the securables for each scope.

TABLE 11.4 SQL Server 2008 Securables

Server	Database	Schema
Logins	User	Table
Endpoints	Role	View
Databases	Application role	Function
	Assembly	Procedure
	Message Type	Queue
	Route	Type
	Service	Synonym
	Remote Service Binding	Aggregate
	Fulltext Catalog	XML Schema Collection
		Certificate
		Asymmetric Key
		Symmetric Key
	Contract	
	Schema	

As mentioned earlier, a hierarchy exists within each scope; in addition, relationships cross scope boundaries. Servers contain databases, databases contain schemas, and schemas contain a myriad of objects that are also hierarchical. When certain permissions are granted on a securable at the server level the permissions cascade; meaning permission is granted at the database and schema levels. For example, if a login is granted `control` permission at the server level, `control` is implicitly granted at the database and schema levels. The relationships between securables and permissions can be complicated. The next section details the different types of permissions and sheds some light on how these permissions affect securables.

Managing Permissions

Database security is mainly about managing permissions. Permissions are the security mechanisms that tie principals (for example, logins) to securables (for example, tables). With SQL Server 2008, permissions can be applied at a granular level that provides a great deal of flexibility and control.

Permissions in SQL Server 2008 revolve around three commands: GRANT, REVOKE, and DENY. These three commands were also used in SQL Server 2005 and SQL Server 2000. When permission is granted, the user or role is given permission to perform an action, such as creating a table. The DENY statement denies permission on an object and prevents the principal from gaining GRANT permission based on membership in a group or role. The REVOKE statement removes a permission that was previously granted or denied.

When specifying permissions, you need to carefully consider the hierarchy that exists between GRANT, REVOKE, and DENY. This is particularly important when the principal (for example, user or login) is part of a group or role and permissions have been granted on securables at different scopes of the security model. Following are some examples of the precedence that exists between these statements:

- ▶ A GRANT of a permission removes any REVOKE or DENY on a securable. For example, if a table has SELECT permission denied on it and then the SELECT permission is granted, the DENY permission is then removed on that table.
- ▶ DENY and REVOKE remove any GRANT permission on a securable.
- ▶ REVOKE removes any GRANT or DENY permission on a securable.
- ▶ Permissions denied at a higher scope in the security model override grants on that permission at a lower scope. Keep in mind that the security model has the server scope at the highest level, followed by database and schema. So, if INSERT permission is denied on tables at the database level, and INSERT on a specific table in that database is granted at the schema level, the result is that INSERT is denied on all tables. In this example, a database-level DENY overrides any GRANT at the lower schema level.
- ▶ Permissions granted at a higher scope in the security model are overridden by a DENY permission at a lower level. For example, if INSERT permission is granted on all tables at the database scope, and INSERT is denied on a specific table in the database (schema scope), INSERT is then denied on that specific table.

The assignment of a permission includes the GRANT, DENY, or REVOKE statements plus the permission that these statements affect. The number of available permissions increased in SQL Server 2005 and has been carried forward to SQL Server 2008. Familiar permissions such as EXECUTE, INSERT, and SELECT that were available in SQL Server 2000 are still around, plus the new permissions that were added in SQL Server 2005. Following are some of the new types that were added in SQL Server 2005:

- ▶ **CONTROL**—This type confers all defined permissions on the securable. This ownership-like capability also cascades to any lower-level objects in the security hierarchy.
- ▶ **ALTER**—This type confers the capability to change the securable’s properties but does not include the capability to make ownership changes. If ALTER is applied on a scope such as a database or a schema, the capability to use ALTER, CREATE, or DROP on any object in the scope is allocated as well.
- ▶ **IMPERSONATE**—This type allows the principal to impersonate another user or login.
- ▶ **VIEW DEFINITION**—This type allows access to SQL Server metadata. This type of data is not granted by default in SQL Server 2008; therefore, the VIEW DEFINITION permission was added to manage access.

The combination of available permissions and the securables that they can be applied to is extensive. The permissions that are applicable depend on the particular securable. SQL Server Books Online lists the permissions for specific securables. You can use the index feature at Books Online to look for “permissions [SQL Server].” There, you will find a section named “Permissions Applicable to Specific Securables” as well as a section named “SQL Server Permissions” that lists each securable and its related permissions.

You can also view the available permissions by using system functions and catalog views. The following example uses the `sys.fn_builtin_permissions` function to retrieve a partial listing of all the available permissions:

```
SELECT top 5 class_desc, permission_name, parent_class_desc
FROM sys.fn_builtin_permissions(default)
order by 1,2
/* Results from previous query

The granularity with which permissions can be applied with SQL Server 2008 is impressive and, to some degree, challenging. When you look at all the available permissions, you will see that some planning is needed to manage them. In the past, fixed database roles were simple to use but in many cases provided permissions that went beyond what the user needed. Microsoft has supplied the tools to facilitate the concept of “least privileges,” which means providing only the privileges that are needed and nothing more. The tools to help you manage permissions are discussed later in this chapter, in the section “Managing SQL Server Permissions.”

Managing SQL Server Logins

You can create and administer logins easily using SSMS. You can use T-SQL as well, but the GUI screens are often the best choice. The GUI screens present the configurable properties for a login, including the available options, databases, and securables that can be assigned to a login. The number of configurable options is extensive and can be difficult to manage with T-SQL.

Using SSMS to Manage Logins

The visual tools for managing logins in SSMS are accessible via the Object Explorer. You need to expand the Security node in Object Explorer and right-click the Logins node. Then you select the New Login option, and the new login screen, shown in Figure 11.4, appears.

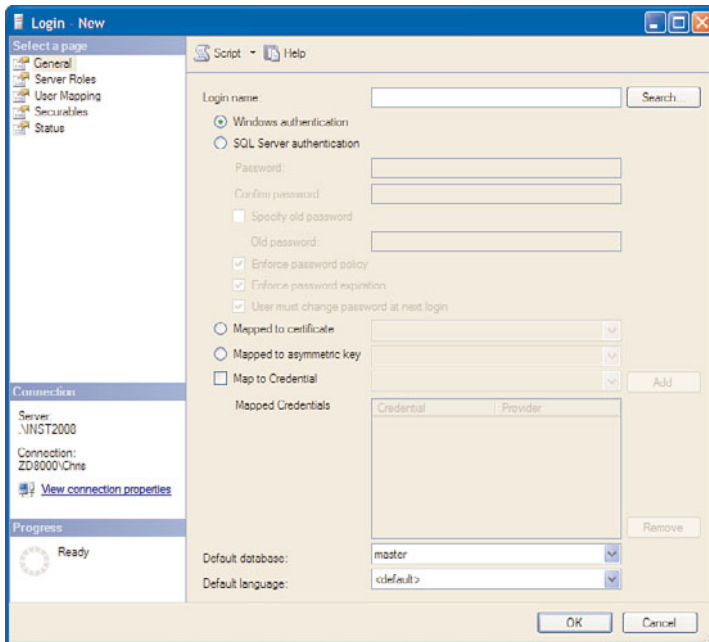

FIGURE 11.4 Creating a login in SSMS with Windows Authentication.

The default authentication mode for a new login is Windows Authentication. If you want to add a login with Windows Authentication, you need to type the name of your Windows user or group in the Login Name text box. You can also click the Search button to search for Windows logins. In either case, the login entered for Windows Authentication should be in the form `<DOMAIN>\<UserName>` (for example, `mydomain\Chris`) or in the form `user@company.com`.

With Windows Authentication, you have an option to restrict access to the server for the new login when it is created. If you select Deny Server Access, a command to deny access to SQL Server is issued immediately after the login is created (for example, `DENY CONNECT SQL TO [DBSVRXP\Chris]`). This option can be useful for staging new logins and waiting until all the appropriate security has been applied prior to allowing the login to access your SQL Server instance. After you completing the security setup for the login, you can select the login properties and choose the `GRANT SERVER ACCESS` option.

You can use the same new login screen shown in Figure 11.4 to add a login with SQL Server Authentication. Again, you need to provide a login name, but with the standard SQL Server login, there is no domain associated with the user. The login is independent of any Windows login and can be named as desired. The login and password for SQL Server Authentication are stored and maintained in SQL Server.

When SQL Server Authentication is selected, several options related to passwords are enabled. These options, as shown in Figure 11.5, include Enforce Password Expiration, Enforce Password Policy, and User Must Change Password at Next Login. These options are all associated with a more rigid password policy. They are similar to options available with Windows accounts and provide a more robust security solution for SQL Server logins. The catch is that the new password options are enforced only on the Windows 2003 Server operating system and versions above. You can select these options when running SQL Server on a machine that has an operating system that is lower than Windows 2003 Server, but the hooks between SQL Server and the operating system are not in place to enforce the password policy.

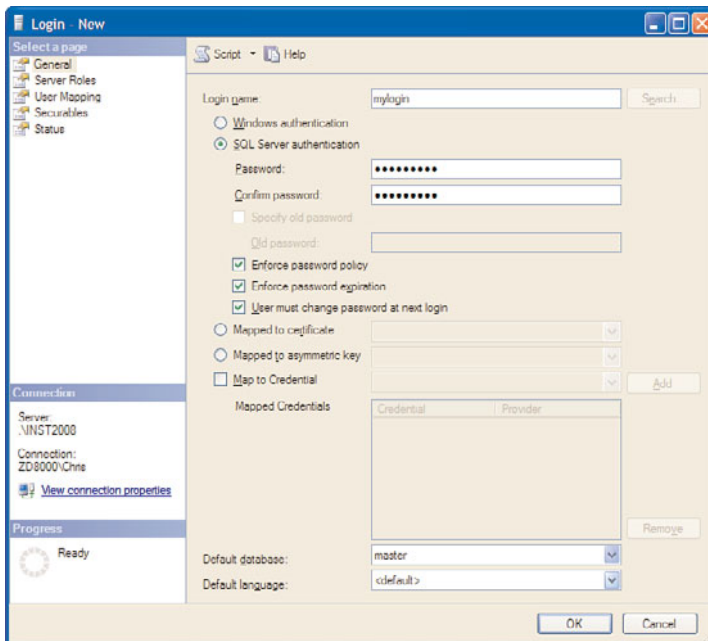

FIGURE 11.5 Creating a login in SSMS with SQL Server Authentication.

The next set of options on the General page of the new login allows you to map the login to a certificate, asymmetric key, or credential. The certificate and asymmetric key selections allow you to create a certificate-mapped login or an asymmetric key-mapped login. A certificate-mapped login and an asymmetric key-mapped login are used only for code signing and cannot be used to connect to SQL Server. If these options are used, the certificate or asymmetric key must exist on the server before you map the logins to them. The capability to map the login to a credential on the General page is new to SQL Server 2008. This option simply links the login to an existing credential, but its capabilities may be expanded.

The default database and default language are the final options located on the General page of the new login screen. These options are available regardless of the authentication method selected. The default database is the database that the login will connect to by default. The `master` database is selected, but it is generally not the best database to select for your default. You should choose the default database that your login will use most often and avoid using any of the system databases as your default. This helps prevent database users from executing statements against the wrong database, and it also removes the step of having to change the database every time the user connects. You should make sure that the login is given access to whatever database you select as the default. (The Database Access page is discussed later in this chapter.)

The default language determines the default language used by the login. If no default language is specified and the `<default>` entry is left in the Language drop-down, the server's default language is used. The default language for the server can be retrieved or set by using the `sp_configure` system stored procedure. The language selection affects many things, including date formats, month names, and names of days. To see a list of languages available on the server and the related options, you use the `sys.syslanguages` catalog view.

The new login screen has four other pages available for selection when creating your new login: Server Roles, User Mapping, Securables, and Status. The Server Roles page allows you to select one or more fixed server roles for the login to participate in. Figure 11.6 shows the new login screen with the Server Roles page selected. For a more detailed review of the permissions related to each server role, refer to the section "Fixed Server Roles," earlier in this chapter.

The User Mapping page allows you to select the databases that the login will have access to. When the Map check box is selected for a database, the Default Schema and User cells are enabled. The default schema is the schema that will contain the database objects created by the login. The login can create objects in schemas other than the default if the login has permission to use the other schemas. If no schema is specified, the default schema is used. The default schema also comes into play when you're retrieving database objects. If no schema is specified on database retrievals, the default schema is searched first for the database object. If no Default Schema is specified on the Database Access screen, the default schema is set to `dbo`. The User data entry area allows you to enter a database username that is different from the login name. By default, the database username is the same as the login name, but you can change it.

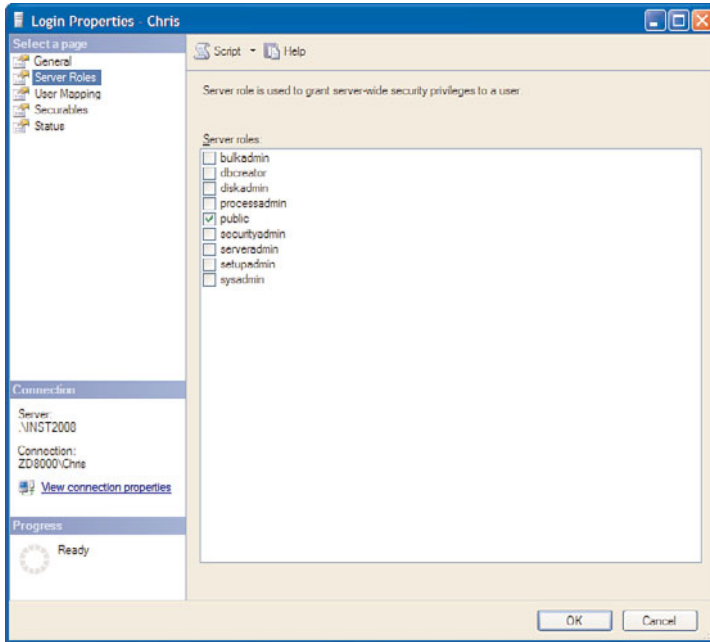

FIGURE 11.6 Choosing a server role.

The other thing that happens when you select the Map check box on the database is that the list of database roles is enabled in the bottom portion of the screen. You can select one or more database roles for the login. Both fixed and user-defined database roles are available for selection. The `public` database role is selected by default and cannot be deselected.

The Securables page allows you to select server objects for login permissions. The server objects are limited to object types scoped at the server level. They include Servers, Endpoints, Logins, and Server Roles object types. The management of all permissions, including those for Logins, is discussed in detail in the “Managing Permissions” section, earlier in the chapter.

The last page listed for selection is the Status page, which allows you to configure some authorization and authentication options. You can grant or deny access to the database engine on this page, and you can enable or disable the login. You also might need to visit this page if the login gets locked out. If this happens, you have an option on this page to reenable the login so that it is not longer locked out.

To modify a login, you right-click the login in the Security node and select Properties. The same set of property pages available when you create a new login are displayed. You cannot change the authentication mode after the login has been created, but you can change all the other settings, if desired.

To delete a login, you right-click the login and select Delete. The Delete Object screen appears, and you can click OK to delete the login. A warning message appears, stating “Deleting server logins does not delete the database users associated with the logins.” If the login has associated database users, and the login deletion is performed, database users are orphaned, and you have to manually delete the users associated with the login in each database.

Using T-SQL to Manage Logins

You can manage logins by using T-SQL statements. This approach is generally not as easy as using the user-friendly GUI screens that come with SSMS, but sometimes using T-SQL is better. For example, with installations and upgrades that involve changes to logins, you can use T-SQL to script the changes and produce a repeatable process.

SQL Server 2008 includes system stored procedures and an ALTER LOGIN statement that you can use to manage logins. The same system stored procedures available in prior versions are still available in SQL Server 2008, but they have been deprecated and will not be available in a future version. Table 11.5 lists the available system stored procedures and the basic function and current state of each one. The state indicates whether the procedure has been deprecated and whether an alternative exists in SQL Server 2008.

TABLE 11.5 System Stored Procedures for Managing Logins

Store Procedure	Function	Status
sp_addlogin	Add a SQL Server login.	Deprecated; use CREATE LOGIN
sp_defaultdb	Change the default database.	Deprecated; use ALTER LOGIN instead.
sp_defaultlanguage	Change the default language.	Deprecated; use ALTER LOGIN instead.
sp_denylogin	Deny server access to a Windows login.	Deprecated.
sp_droplogin	Drop a SQL Server login.	Deprecated; use DROP LOGIN instead.
sp_grantlogin	Add a Windows login.	Deprecated.
sp_password	Change a login's password.	Deprecated; use ALTER LOGIN instead.
sp_revokelgin	Drop a Windows login.	Deprecated; use DROP LOGIN instead.

The system stored procedures have a variety of parameters, which are documented in Books Online. Because they have been deprecated, they are not the focus of this section. Instead, this section focuses on a number of examples that utilize the CREATE, ALTER, and DROP statements. The following example creates a SQL Server login with a password that must be changed the first time the login connects:

```
CREATE LOGIN Laura WITH PASSWORD=N'mypassw0rd$'
    MUST_CHANGE, CHECK_EXPIRATION=ON
```

You can then use the following ALTER LOGIN statement to change the default database, language, and password for the new Laura login:

```
ALTER LOGIN [Laura] WITH
    DEFAULT_DATABASE=[AdventureWorks2008],
    DEFAULT_LANGUAGE=[British],
    PASSWORD=N'myStr0ngPW'
```

Finally, you can drop the Laura login by using the following:

```
DROP LOGIN [Laura]
```

As you can see, the T-SQL statements for Logins are relatively easy to use. To simplify matters, you can generate T-SQL statements from SSMS. To do so, you click the Script button available on the screen that appears after you specify a login action. For example, if you right-click a login and select Delete, the Delete Object screen appears. At the top of this screen is a Script button. When you click this button, SSMS scripts the related T-SQL statements into a query editor window for you to review and execute.

Managing SQL Server Users

The SSMS has a set of friendly user interfaces to manage SQL Server users as well. The screens are similar to the screens for logins and are also launched from the Object Explorer. You can also use a set of T-SQL statements to manage users.

Using SSMS to Manage Users

To manage users via SSMS, you open the Object Explorer and expand the Security node followed by the Users node. The Users node contains a list of the current database users. To add a new database user, you can right-click the Users node and select New User. Figure 11.7 shows the Object Explorer window with the option to create a new user selected for the AdventureWorks2008 database.

Figure 11.8 shows the new database user screen displayed after you select the New User option. In this figure, a login named Chris is used, and the database user name is Chris as well. These two names do not need to match but are often the same for consistency. The login must exist before you can create the user. You can click the ellipsis button next to the login name to view a list of available logins. After you click the ellipsis, you can click the Browse button to see the logins that have already been added to SQL Server.

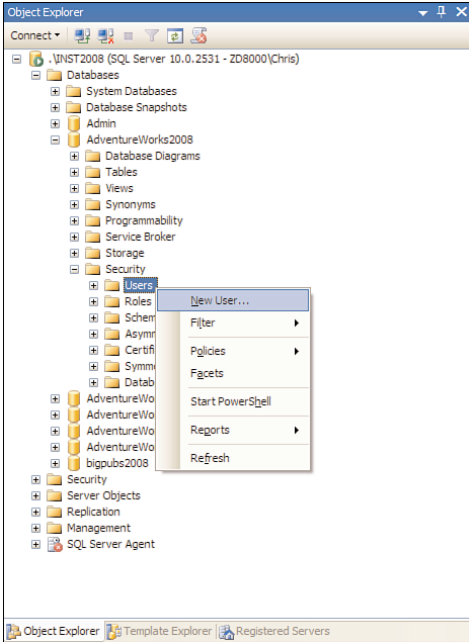

FIGURE 11.7 The New User option in Object Explorer.

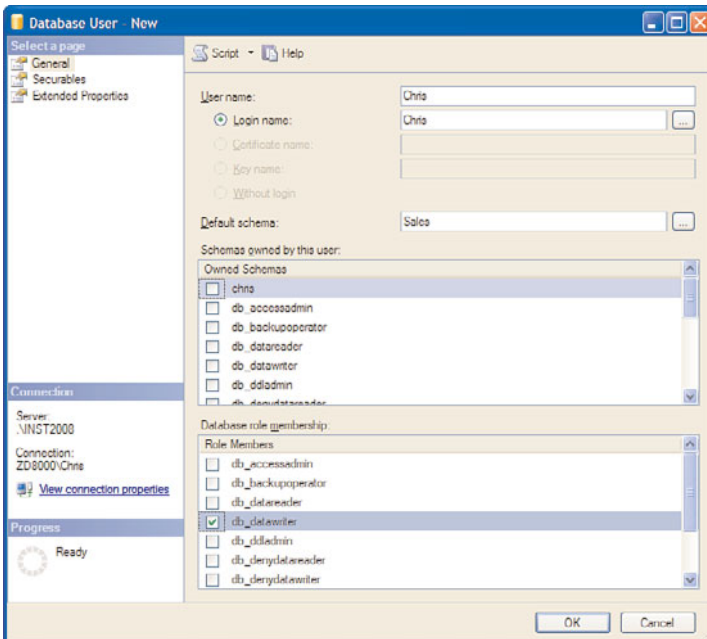

FIGURE 11.8 Using SSMS to create a new user.

The default schema must be a valid schema created in the database. If the default schema is left blank, it defaults to `dbo`. After the default schema has been set, it is used as the default location for storing and retrieving database objects.

You can select one or more schemas to be owned by the user, but a given schema can be owned by only one user in the database. When a schema is selected for ownership for a user, the previous owner loses ownership, and the new user gains ownership. The following example shows the type of T-SQL statement that you can run to accomplish the ownership change. This example changes the ownership on the `Person` schema to the user `Laura`:

```
ALTER AUTHORIZATION ON SCHEMA::[Person] TO [Laura]
```

When you select the `Permissions` page, you can assign permissions to securables scoped at the database and schema levels. The management of all permissions, including those for users, is discussed in detail in the “Managing Permissions” section, earlier in the chapter.

To modify or delete an existing database user, you can right-click the user in the Object Explorer and choose the related option. To modify the user, you select `Properties`, and a screen similar to the one you use to add the user is displayed. To delete the user, you select the `Delete` option.

Using T-SQL to Manage Users

`CREATE USER`, `ALTER USER`, and `DROP USER` are the T-SQL commands you use most often to manage database users. These commands are replacements for the system stored procedures used in prior versions. The system stored procedures, such as `sp_adduser`, `sp_dropuser`, `sp_grantdbaccess`, and `sp_revokedbaccess`, have been deprecated and will be removed in a future version. They are still available for use now, but you should avoid them when possible.

The following example demonstrates the use of the `CREATE USER` statement to create a new database user named `Laura`, with a default schema `Sales`:

```
CREATE USER Laura FOR LOGIN Laura
WITH DEFAULT_SCHEMA = Sales
```

You can use the `ALTER USER` statement to change the default schema or the username. The following example uses the `ALTER USER` statement to change the name of the database user currently named `Laura` to `LauraG`:

```
ALTER USER Laura WITH NAME = LauraG
```

If you want to delete a database user, you use the `DROP USER` command. The following example demonstrates how to delete the `LauraG` from the previous example:

```
DROP USER [LauraG]
```

When dropping database users, you must keep in mind that you cannot drop them if they are the owners of database objects. An object's ownership must be transferred to another database user before that object can be deleted. This applies to schemas that can be owned by the user as well.

Managing Database Roles

Database roles are custom roles that you can define to group your users and simplify the administration of permissions. Generally, custom database roles (non-fixed) are created if the fixed database roles do not meet the security needs of the administrator. (The assignment of logins and users to fixed server and fixed database roles is covered earlier in this chapter.)

Using SSMS to Manage Database Roles

You can find database roles in the Object Explorer for each database, under the **Security** node, which contains a **Roles** node. The **Roles** node contains a **Database Roles** node, which lists both fixed and nonfixed database roles. To add a new custom database role (nonfixed), you right-click the **Database Roles** node and select **New Database Role**. A new database role dialog box appears, as shown in Figure 11.9.

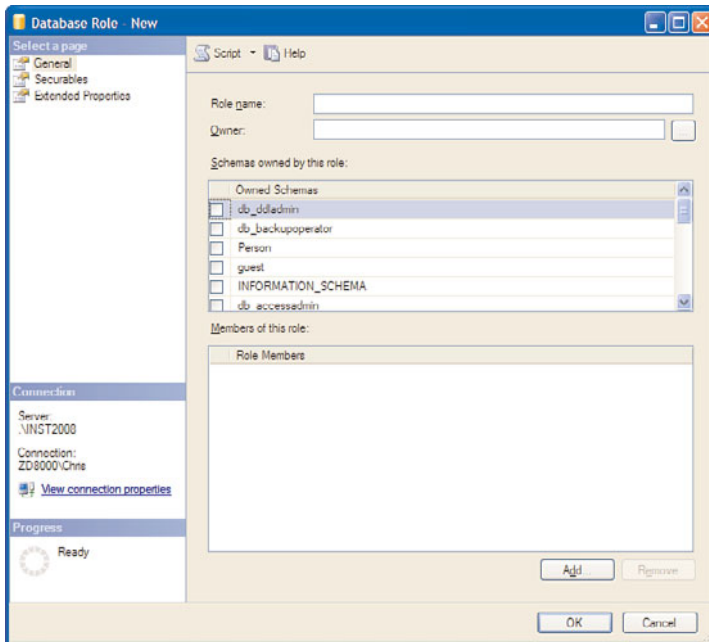

FIGURE 11.9 The new database role dialog box.

You need to enter a name for the role and name for the owner of the role. Like a database user, a database role can also own schemas. If you click the Add button, you can add database users from the current database to the role.

If you select the Permissions page, you can define the permission for the database role. This definition includes the selection of database objects scoped at the database and schema levels. These permissions are discussed in detail in the “Managing Permissions” section, earlier in this chapter.

Using T-SQL to Manage Database Roles

Some of the T-SQL system stored procedures used in prior versions to manage roles have been deprecated, including `sp_addrole` and `sp_droprole`. The `sp_addrolemember` and `sp_droprolemember` procedures have not been deprecated and are still good choices for adding members to a role.

The `CREATE ROLE` and `DROP ROLE` statements are the new replacements for `sp_addrole` and `sp_droprole`. The following example uses the `CREATE ROLE` statement to create a new database role named `DevDbRole`:

```
CREATE ROLE [DevDbRole]
```

To assign a user named `Chris` to the new `DevDbRole` role, you can use the following:

```
EXEC sp_addrolemember N'DevDbRole', N'chris'
```

Role membership is not limited to database users. It is possible to assign database roles as members of another role. The following adds the `TestDbRole` database role to the `DevDbRole` role created in the previous example:

```
EXEC sp_addrolemember N'DevDbRole', N'TestDbRole'
```

You cannot use `sp_addrolemember` to add a fixed database role, a fixed server role, or `dbo` to a role. You can, however, add a nonfixed database role as a member of a fixed database role. If, for example, you want to add the `DevDbRole` database role as a member of the fixed database role `db_dataread`, you use the following command:

```
EXEC sp_addrolemember N'db_datareader', N'DevDbRole'
```

The `ALTER ROLE` statement exists but is limited to changing the name of a role. To drop a database role, you use the `DROP ROLE` statement. Keep in mind that all role members must be dropped before a role can be dropped.

Managing SQL Server Permissions

You can use T-SQL or the visual tools available in SSMS to manage permissions. Based on the number of available permissions and their complexity, it is recommended that you use the SSMS tools. The following sections cover these tools from several different angles and

look at the management of permissions at different levels of the security model. You learn how to use T-SQL to manage the permissions as well.

Using SSMS to Manage Permissions

The Object Explorer in SSMS enables you to manage permissions at many different levels of the permission hierarchy. You can manage permissions at a high level, such as the entire server, or you can manage permissions at the very lowest level, including a specific object, such as a table or stored procedure. The degree of granularity you use for permissions depends on your security needs. To demonstrate the scope of permissions, let's look at managing permissions at several different levels, starting at a high level and working down to the object level.

NOTE

There are many different ways to achieve a security goal in SSMS. For example, you can manage permissions for a database user from the database or from the user. You can apply permissions on schema objects for the entire schema or to individual objects. You should always try to choose the permission solution that allows you to achieve your security goals with the least amount of administrative overhead.

Using SSMS to Manage Permissions at the Server Level

Logins can be granted explicit permissions at the server level. Earlier we looked at fixed server roles as one means for assigning permissions, but you can manage individual server-level securables as well. Figure 11.10 shows the Login Properties window for a login named Chris. You launch this window by right-clicking the login and selecting Properties. Figure 11.10 shows the Securables page, which allows you to add specific securables to the grid.

NOTE

You can open a Permissions page like the one shown in Figure 11.10 from many different places in the Object Explorer. The title of the dialog box and the content of the grid vary, depending on the object selected, but the screen is generally the same, no matter where it is launched. This provides consistency and simplifies the overall management of permissions.

You can click the Search button shown toward the top of Figure 11.10 to add objects to the securables grid. When you click this button, the Add Objects window shown in Figure 11.11 is displayed. This window allows you to choose the types of objects you want to add. If you select Specific Objects, you are taken directly to the Select Objects window. If you choose All Objects of the Types, you are taken to an intermediate screen that allows you to select the type of objects you want to assign permissions to.

Again, the Add button and the means for adding objects are fairly consistent for all permissions. What varies is the object types available for selection. For example, at the server level, the types of objects available to assign permissions are scoped at the server level. Figure 11.12 shows the Select Object Types window displayed when you choose the

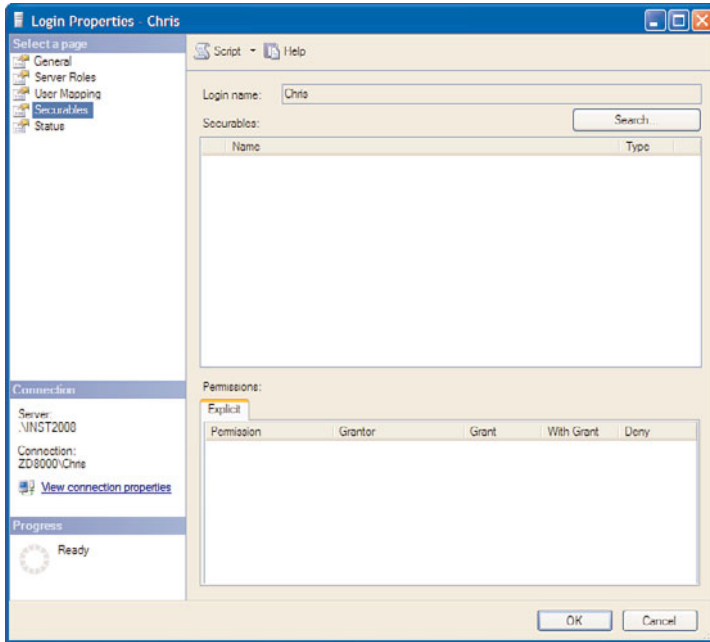

FIGURE 11.10 Server-level permissions.

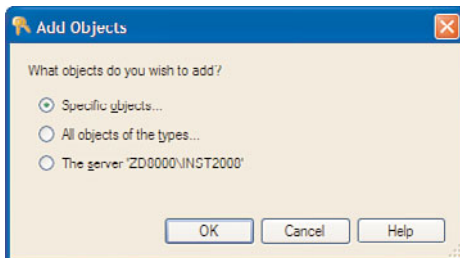

FIGURE 11.11 The Add Objects window.

All Objects of the Types option at the server level. You can see that the available objects are all scoped at the server level.

If the endpoints objects are selected, the securables grid is populated with all the available endpoints that have permissions to manage. Figure 11.13 shows the Login Properties window with the endpoints securables populated. The TSQL Named Pipes securable is selected, which allows you to specify the explicit permissions for the securable in the bottom grid. In this example, the Grant and With Grant check boxes have been selected for the control permission. This gives the login named Chris the right to control the Named Pipes endpoint and also allows him to grant this control right (because With Grant is selected) to other logins.

The examples we just walked through are related to the assignment of explicit permission on a specific instance of a securable. You can also apply server permissions at a higher

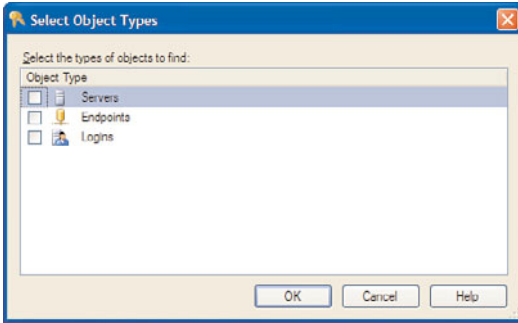

FIGURE 11.12 Server-level object types.

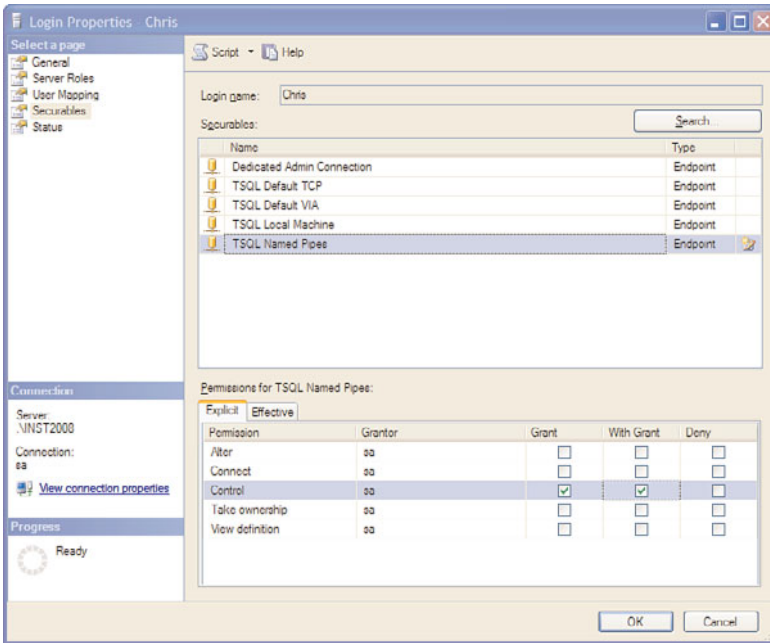

FIGURE 11.13 Server-level securables.

level. For example, you might want to specify permissions for a login to allow that login to control all server endpoints instead of specific endpoints. You can accomplish this in several ways. One way to do it is to select the **Server** object from the list of object types when adding permissions for a specific login. Another way is to right-click the server name in the Object Explorer and select **Properties**. The **Server Properties** window that appears has a **Permissions** page that lists all the logins for the server, along with the macro-level permissions scoped for the server. Figure 11.14 shows the **Server Properties** window with the login **Chris** selected. The explicit permissions listed in this case are at a higher level and are not just for one instance. The example shown in Figure 11.14 allows

the login Chris to alter any database or any endpoint on the server. This is based on the Grant check boxes selected.

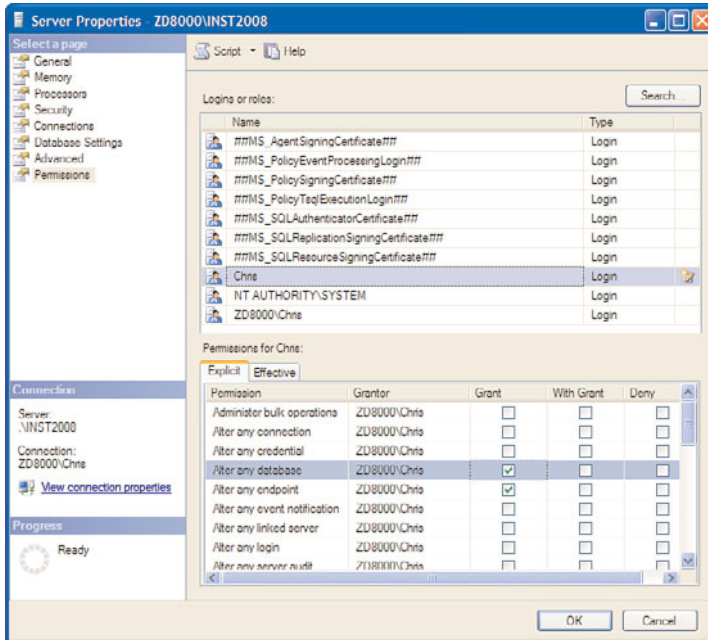

FIGURE 11.14 The Server Properties window's Permissions page.

Using SSMS to Manage Permissions at the Database Level

The same type of hierarchy exists with permissions at the database level as at the server level. You can apply permissions at a high level to affect many objects of a particular type, or you can apply them on a specific object. You can also manage the permissions at the database level on a specific database user, or you can manage them on the database across many users.

To demonstrate the differences between object types available at the database level, let's first look at managing permissions for a specific database user. As with logins, you can right-click a database user and select Properties. On the Properties window that appears, you select the Securables page, and you get a screen to assign permissions that is very similar to the login permissions screen. The difference at the database level is in the object types available for selection. Figure 11.15 shows the object types available when you choose the All Objects of Types choice during the addition of securables for a database user.

When a low-level object type such as a table or stored procedure is selected, you are able to apply explicit permissions to a specific object instance. Figure 11.16 shows an example of low-level securables available when the Table object type is selected.

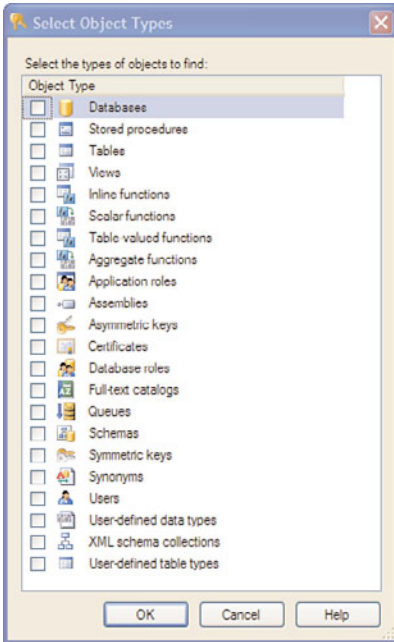

FIGURE 11.15 Database-level object types.

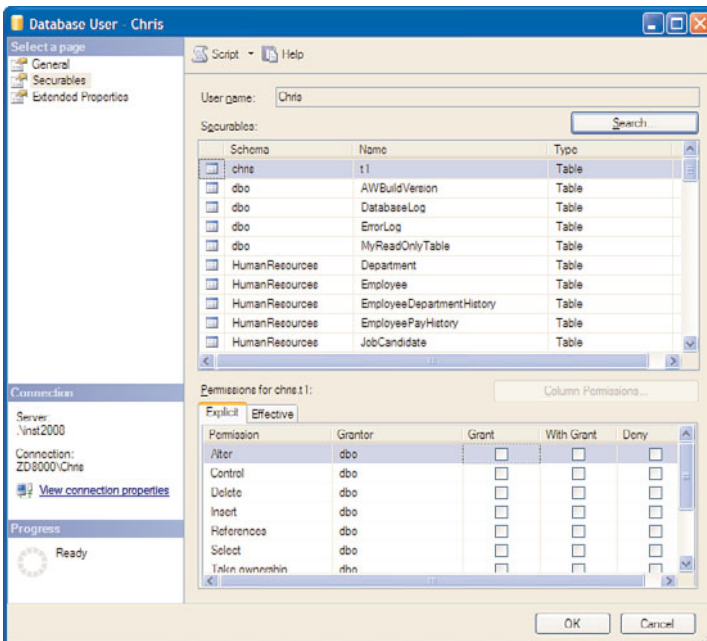

FIGURE 11.16 Low-level database securables.

To apply permissions at a higher level in the database, you choose the object type Databases. With this securable added to the permissions grid, you can apply permissions to a group of objects by selecting a single permission. Figure 11.17 shows the AdventureWorks2008 database selected as the securable and the related permissions available. In this example, the login Chris has been granted INSERT, SELECT, and UPDATE permissions to all the tables in the AdventureWorks2008 database.

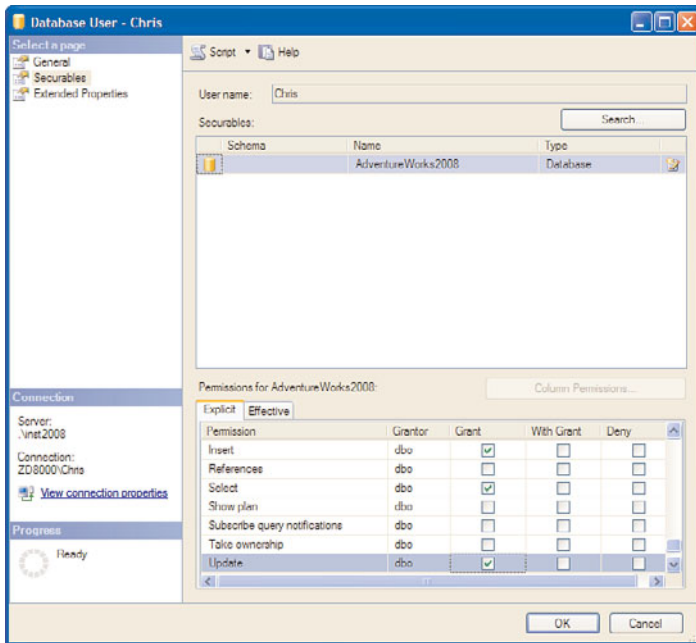

FIGURE 11.17 High-level database securables.

Using SSMS to Manage Permissions at the Object Level

The last permission assignment we look at is the object level. SSMS enables you to select a specific object instance in the Object Explorer and assign permissions to it. This method allows you to navigate to the object you want via the Object Explorer tree and assign permissions accordingly. Figure 11.18 shows the Object Explorer tree expanded to the Stored Procedures node. A specific stored procedure has been right-clicked, and the Properties option has been selected.

The Properties window has a page dedicated to permissions. You can select the Permissions page and then select the users or roles you want to add for the specific object, such as a stored procedure. Figure 11.19 shows the Permissions page with a user named Chris added to the Users or Roles window at the top of the page. The bottom portion of the page shows explicit permissions for the user Chris, which includes a DENY permission on the stored procedure selected.

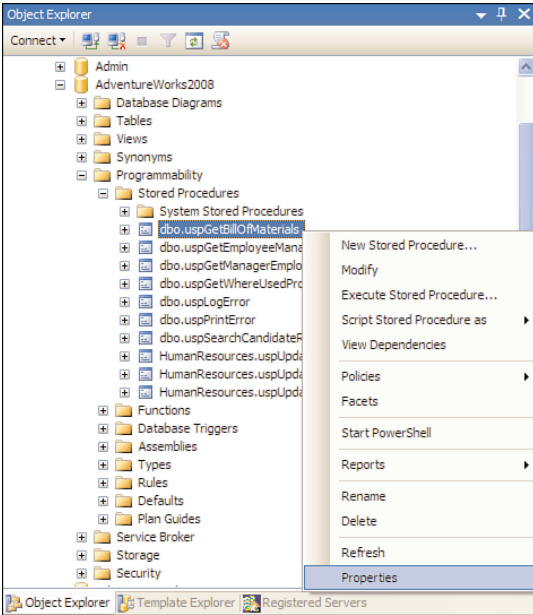

FIGURE 11.18 Object-level permissions selected via Object Explorer.

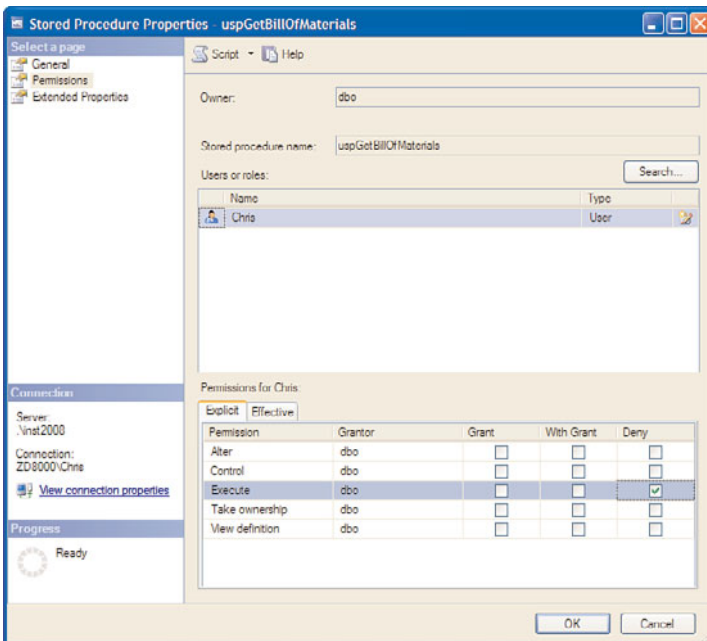

FIGURE 11.19 Object-level permissions.

NOTE

The methods described here for managing permissions in SSMS are by no means the only ways you can manage permissions in SSMS. You will find that the assignment of permissions pervades SSMS and that SSMS allows you to assign permissions in many different ways. The point to keep in mind is that database roles, application roles, schemas, and other objects in the security model all have similar methods for assigning permissions.

Using T-SQL to Manage Permissions

As you saw in the SSMS Permissions pages, three options exist for assigning every permission: GRANT, DENY, and REVOKE. Each option has its own T-SQL statements that can be used to manage permissions as well. The simplified syntax for the GRANT command is as follows:

```
GRANT { ALL [ PRIVILEGES ] }
    | permission [ ( column [ ,...n ] ) ] [ ,...n ]
    [ ON [ class :: ] securable ] TO principal [ ,...n ]
    [ WITH GRANT OPTION ] [ AS principal ]
```

This basic GRANT syntax is similar to that in SQL Server 2000, but the addition of many permissions and securables in SQL Server 2005 and SQL Server 2008 has expanded the scope of the command. SQL Server 2005 also introduced the WITH GRANT option which allows a permission to be granted to a principal and allows the principal to grant that permission to another principal. The WITH GRANT option has been carried forward to SQL Server 2008 and is a good way to delegate administrative functions to others.

The simplified syntax for the DENY and REVOKE commands is as follows:

```
DENY { ALL [ PRIVILEGES ] }
    | permission [ ( column [ ,...n ] ) ] [ ,...n ]
    [ ON [ class :: ] securable ] TO principal [ ,...n ]
    [ CASCADE] [ AS principal ]

REVOKE [ GRANT OPTION FOR ]
    {
        [ ALL [ PRIVILEGES ] ]
        |
            permission [ ( column [ ,...n ] ) ] [ ,...n ]
    }
    [ ON [ class :: ] securable ]
    { TO | FROM } principal [ ,...n ]
    [ CASCADE] [ AS principal ]
```

You can see that the simplified syntax for DENY and REVOKE is similar in structure to the GRANT statement. All the statements must identify the permission, securable, and principal that will receive the permission.

The ALL clause has been deprecated in SQL Server 2008. If ALL is specified, it does not affect all permissions on the object; it affects only a subset of the permissions related to the securable. The subset of permissions is dependent on the securable.

The following examples demonstrate several different types of permissions you can manage by using T-SQL commands:

```
--Grant permissions to create a table
-- to a user named Chris
GRANT CREATE TABLE TO Chris

--Grant ALL permissions on a stored procedure
-- to a database role named TestDBRole
GRANT ALL ON dbo.uspGetBillofMaterials TO TestDBRole

--DENY UPDATE permission on the Customer table
-- to user named Laura
DENY UPDATE ON OBJECT::sales.customer TO Laura

--REVOKE UPDATE permissions on the Customer table
-- to user named Laura.
REVOKE UPDATE ON OBJECT::sales.customer TO Laura
```

There are many different flavors of the GRANT, DENY, and REVOKE statements, depending on the securable they are affecting. Books Online outlines the syntax for each securable and the permissions that can be applied.

Remember that you can use the Script option to generate the T-SQL from SSMS. The Script button is available when you're managing permissions, and using it is a great way to familiarize yourself with the T-SQL that is used to effect changes. You can select the permissions you want to apply via the GUI screen and then click the Script button to generate the T-SQL.

The Execution Context

The execution context determines what permissions are checked when statements are executed or actions are performed on the database server. By default, the execution context is set to the principal connected to the server or database. If a user named Chris connects to the AdventureWorks2008 database, the permissions assigned to Chris are checked.

In SQL Server 2008, you can change the execution context so that permissions are checked for a principal other than that to which you are connected. You can make this change in execution context (called *context switching*) explicitly or implicitly.

Explicit Context Switching

With explicit context switching, you can use the EXECUTE AS statement to change the user or login used to check permissions. This is similar to the SET USER statement available in SQL Server 2000 and SQL Server 2005. It is extremely useful for administrators who are testing the permissions they have set for users or logins. The following example demonstrates the use of the explicit EXECUTE AS statement:

```
--Assume that you are connected as an administrator (DBO)
--and want to prevent members of the Public role from
--selecting from the Sales.Customer table
DENY SELECT ON sales.customer TO Public

--We can check that user Laura cannot select from the
-- Sales.Customer table using the EXECUTE AS statement
EXECUTE AS USER = 'laura'
SELECT TOP 1 * FROM sales.customer

-- Revert to the previous execution context.
REVERT
```

You can also do explicit context switching at the login level. You can use the EXECUTE AS statement to switch the execution context to another login instead of a user.

Context switching is linked to the IMPERSONATE permission. As an administrator, you can grant IMPERSONATE to a login or user to enable that user to execute as that user. For example, an administrator can temporarily enable another login to run in the same execution context by using the IMPERSONATE permission and EXECUTE AS statement. The following example demonstrates the assignment of the IMPERSONATE permission to a login named Laura:

```
--Chris grants the right to Laura to impersonate him
GRANT IMPERSONATE ON LOGIN::[chris] TO [laura]
GO

--Laura can then connect with her login and use
-- the EXECUTE AS command to run commands that
-- normally only Chris has permission to run
EXECUTE AS Login = 'Chris'
DBCC CHECKDB (AdventureWorks2008)
SELECT USER_NAME()
--Revert back to Laura's execution context
REVERT
SELECT USER_NAME()
```

Laura can now use EXECUTE as Chris, who is an administrator. This capability can be particularly useful when a user or login has many custom permissions that would take a lot of time to establish for another user or login.

Implicit Context Switching

With implicit context switching, the execution context is set within a module such as a stored procedure, trigger, or user-defined function. The `EXECUTE AS` clause is placed in the module and is set to the user that the module will be run as. The context switch is implicit because the user who runs the module does not have to explicitly specify the context before running the module. The context is set within the module.

The `EXECUTE AS` clause has several different options to establish the execution context. All modules are able to set the context to a specific user or login. Functions, stored procedures, and Data Manipulation Language (DML) triggers can also execute as `CALLER`, `SELF`, or `OWNER`. DDL triggers can run as `CALLER` or `SELF`. Queues can run as `SELF` or `OWNER`. The `CALLER` option is the default, and it runs the module in the context of the user who called the module. The `SELF` option causes the module to run in the context of the user or login that created the procedure. The `OWNER` option causes the module to run in the context of the current owner of the module.

The following example demonstrates the creation and execution of a stored procedure with the `EXECUTE AS` clause on a specific user named Chris:

```
CREATE PROCEDURE dbo.usp_TestExecutionContext
WITH EXECUTE AS 'chris'
AS SELECT USER_NAME() as 'User'

--Set the user to someone other than chris to test the
-- implicit EXECUTE AS
SETUSER 'DBO'
EXEC usp_TestExecutionContext

/*Results of the prior execution
User
-----
chris
*/
```

This example shows that the `USER_NAME` retrieved in the stored procedure is Chris, regardless of who executed the procedure.

Implicit execution context can be particularly useful in situations in which permissions cannot be granted to a user directly. For example, `TRUNCATE TABLE` permissions cannot be granted explicitly to a user, but a database owner can run this command. Instead of granting `dbo` rights to a user needing `TRUNCATE` permissions, you can create a stored procedure that does the truncation. You can create the stored procedure with the execution context of `dbo`, and you can grant the user rights to execute the stored procedure that does the truncation. When you use this method, the user can perform the truncation but does not have any of the other permissions related to a database owner.

Summary

SQL Server 2008 continues the trend of providing more security and more flexible security to the SQL Server database environment. Several new enhancements have been added to SQL Server 2008 that add to the slew of security changes added to SQL Server 2005. The granularity of the permissions and the other security-related features covered in this chapter allow you to keep your SQL Server environment safe.

Chapter 12, “Data Encryption,” looks at another aspect of SQL Server that helps secure your database environment. It covers encryption methods that can be implemented to further protect your data from unauthorized access.

CHAPTER 12

Data Encryption

With all the concern about identity theft these days, there has been increasingly more attention paid to how all the Personally Identifiable Information (PII) and other sensitive information stored in databases is being protected. It is necessary to secure and protect this data to avoid any potential liability should the PII or sensitive data fall into the wrong hands, and in some cases, doing so may even be required by law (for example, Health Insurance Portability and Accountability Act, or HIPAA, requirements).

Chapter 11, “Security and User Administration,” discusses methods to secure and control the access to your SQL Server data via login and user security. This type of security is usually sufficient to prevent access to the data by anyone other than properly authorized users. But what if you need to prevent authorized users, such as your database or server administrators, from viewing sensitive data? How can you protect sensitive data from hackers or in the event that a database backup is stolen?

One method is to encrypt the data. This chapter looks at two methods provided in SQL Server 2008 for encrypting data: column-level encryption and transparent data encryption (TDE). In addition to describing how to implement both methods, the chapter presents the features and limitations of each of these methods to help you decide which data encryption method may help you meet your data security needs.

IN THIS CHAPTER

- ▶ What's New in Data Encryption
- ▶ An Overview of Data Security
- ▶ An Overview of Data Encryption
- ▶ SQL Server Key Management
- ▶ Column-Level Encryption
- ▶ Transparent Data Encryption
- ▶ Column-Level Encryption Versus Transparent Data Encryption

What's New in Data Encryption

In SQL Server 2000 and earlier, if you wanted to encrypt data in your databases, you usually needed to implement some form of client-side encryption. SQL Server itself did not provide any means of encrypting data at the database level, so all the encryption and decryption occurred in the application itself. This required custom-written applications to encrypt and decrypt the data, and only those applications would be able to view the encrypted data.

SQL Server 2005 introduced the capability to perform column-level (sometimes called *cell-level*) encryption. This provided the capability to encrypt data within the database itself at the column level. However, this method is still not transparent to the applications and requires changes to the database schema as well as changes to your applications and T-SQL code to include the proper function calls to encrypt and decrypt the data as it is stored and retrieved.

SQL Server 2008 introduces a new form of database encryption: transparent data encryption. TDE allows you to encrypt an entire database without affecting client applications. The purpose of TDE is to prevent scenarios in which the physical media (such as database files or backups) containing sensitive data are stolen and then read by attaching the database files or restoring the backups.

NOTE

Both column-level and transparent data encryption are available only in the Enterprise and Developer Editions of SQL Server 2008 and SQL Server 2008 R2.

Another new feature in SQL Server 2008 is Extensible Key Management (EKM). EKM enables parts of the cryptographic key hierarchy to be managed by an external source such as Hardware Security Module (HSM), referred to as a *cryptographic provider*. Encryption and decryption operations using these keys are handled by the cryptographic provider. This allows for flexibility and choice in cryptographic providers as well as common key management.

An Overview of Data Security

Security is important for every product and every business. By following some simple security best practices, you can avoid many security vulnerabilities. This section discusses some security recommendations that you should consider for your SQL Server implementations. Securing SQL Server can be viewed as a series of steps, involving four areas: the platform, authentication, objects (including data), and applications that access the system.

The platform for SQL Server includes the physical hardware and networking systems connecting clients to the database servers. The first step in securing your SQL Server environment is to provide sufficient physical security by limiting access to the physical server and hardware components. To enhance the physical security of the SQL Server installation, you should consider placing the server in a room accessible only by authorized personnel, ideally a locked computer room with monitored flood detection and fire detection or suppression systems. In addition, you should physically secure your backup media by storing it at a secure offsite location.

Next, you need to ensure your system provides sufficient physical network security by keeping unauthorized users off the network by limiting access to the network to authorized users only. Make sure your database servers are installed in a secure zone of your company's intranet behind a firewall. Do not connect your SQL Servers directly to the Internet. Always make sure there is a firewall between your servers and the Internet and set it up to block all traffic except for that which is required.

Next, you need to ensure that you have secured your operating system and files. SQL Server uses operating system files for operation and data storage. Be sure to restrict access to these files to system administrators only. Use the NTFS file system because it is more stable and recoverable than FAT file systems. NTFS also enables security options such as file and directory Access Control Lists (ACLs) and Encrypting File System (EFS) file encryption.

For your installed SQL Server instances, you can enhance the security of the SQL Server installation by running your SQL Server services under service accounts granted the minimal permissions necessary for operation (do not run under the Windows Administrator account!). These accounts should be low-privileged Windows local user or domain user accounts.

Surface area reduction is also an important security measure. Surface area reduction helps improve security by providing fewer avenues for potential attacks on a system. In addition to running services under "least privilege" accounts, this measure also involves stopping or disabling unused components.

You should also enhance the security of the SQL Server instances through limiting the individuals, groups, and processes granted access to SQL Server and appropriately limiting access to the databases and objects the database contains. One way is to require Windows authentication for connections to SQL Server. If you are using SQL Server authentication as well, you should be sure to enforce password policies that require strong passwords and password expiration for all SQL Server logins. For more information on setting up SQL Server logins and managing database users and object permissions, see Chapter 11.

Even if you follow the recommendations presented here for securing your environment, you still can be vulnerable to access control problems. Encryption provides another way to enhance security by limiting data loss even in the rare occurrence that access controls are bypassed. For example, if a malicious user hacks into the database host computer and obtains sensitive data, such as credit card numbers, that stolen information might be useless if it is encrypted.

An Overview of Data Encryption

Encryption is the process of obfuscating data by the use of a key or password. This can make the data useless without the corresponding decryption key or password. Encryption does not solve access control problems. However, it enhances security by limiting data loss even if access controls are bypassed.

Encryption is actually the conversion of readable plaintext into ciphertext, which cannot be easily understood by unauthorized people. The concrete procedure of carrying out the encryption is called an *algorithm*. Decryption is the process of converting ciphertext back into its original form so it can be understood. Both encryption and decryption require a key, which must be kept secret because it enables the holder to carry out the decryption.

There are two primary methods of encryption: symmetric key encryption and asymmetric key encryption. Symmetric key encryption uses the same key for both encryption and decryption. Asymmetric key encryption, also called public-key encryption, uses two different keys for encryption and decryption, which together form a key pair. The key used for encryption is called a *public key*. The key used for decryption is referred to as a *private key*.

Symmetric key encryption is inherently less secure because it uses the same key for both encryption and decryption operations, and the exchange of data requires transfer of the key, which introduces a potential for its compromise. This can be avoided with an asymmetric key because individuals encrypting and decrypting data have their own, separate keys. However, asymmetric encryption is based on algorithms that are more complex, and its impact on performance is more significant, making it often unsuitable in scenarios involving larger amounts of data. However, it is possible to take advantage of the strengths of both methods by encrypting data with a symmetric key and then protecting the symmetric key with asymmetric encryption.

One solution to the dilemma of key distribution is to use digital certificates. A certificate is a digitally signed piece of software that associates a public key with the identity of the private key owner, assuring its authenticity. There is an inherent problem with this approach—namely, how to assure the identity of the certificate issuer. To resolve this issue, Microsoft provides a number of trusted certificate authorities (known as Trusted Root Certification Authorities) with the operating system. These certificate authorities are responsible for verifying that organizations requesting certificates are really what they claim to be.

Typically, the algorithms used for encryption are industry standard, such as the Advanced Encryption Standard (AES). The fact that the algorithms are published doesn't make them weaker, but rather helps ensure they are strong and robust. Because these algorithms have been reviewed by thousands of experts around the globe, they have stood the test of time. SQL Server 2008 allows administrators and developers to choose from among several algorithms, including DES, Triple DES, TRIPLE_DES_3KEY, RC2, RC4, 128-bit RC4, DESX, 128-bit AES, 192-bit AES, and 256-bit AES. No one algorithm is ideal for all situations, and a discussion on the merits of each is beyond the scope of this chapter. However, the following general principles apply:

- ▶ Strong encryption generally consumes more CPU resources than weak encryption.
- ▶ Long keys generally yield stronger encryption than short keys.
- ▶ Asymmetric encryption is stronger than symmetric encryption using the same key length, but it is slower.
- ▶ Long, complex passwords are stronger than short passwords.
- ▶ If you are encrypting lots of data, you should encrypt the data using a symmetric key and encrypt the symmetric key with an asymmetric key.

However, what really protects your data from third parties is not so much the algorithm but the encryption key, which you must keep secure. Keys must be stored securely and made available only on a need-to-know basis. Ideally, authorized people or systems should be able to use but not necessarily have a copy of the key. It's also a security best practice to implement key rotation, changing keys periodically in case a key has been compromised. For greater key security, you can also make use of Extensible Key Management, allowing keys to be managed by an external source such as Hardware Security Module.

SQL Server 2008 provides support for not only encryption of data, but also encryption of user network connections and stored procedures. The remainder of this chapter discusses the two methods of data encryption, column-level encryption and transparent data encryption. Client network encryption is covered in Chapter 10, "Client Installation and Configuration." Encryption of stored procedure code is discussed in Chapter 28, "Creating and Managing Stored Procedures."

NOTE

Although encryption is a valuable tool to help ensure security, it does incur overhead and can affect performance, and any use of encryption requires a maintenance strategy for your passwords, keys, and certificates.

Therefore, encryption should not be automatically considered for all data or connections. When you are deciding whether to implement encryption, consider how users access the data. If access is over a public network, data encryption may be required to increase data security. However, if all access is via a secure intranet configuration, encryption may not be required.

This chapter describes the encryption methods available in SQL Server 2008 and SQL Server 2008 R2 along with the pros and cons of implementing these encryption methods. This information should help you to determine whether using encryption is appropriate for implementing your data security solutions.

SQL Server Key Management

SQL Server 2008 provides rich support for various types of data encryption using symmetric and asymmetric keys and digital certificates. As an administrator, you probably need to manage at least the upper level of keys in the hierarchy shown in Figure 12.1. Each key

protects its child keys, which in turn protect their child keys, down through the tree. The one exception is when a password is used to protect a symmetric key or certificate. This is how SQL Server lets users manage their own keys and take responsibility for keeping the key secret.

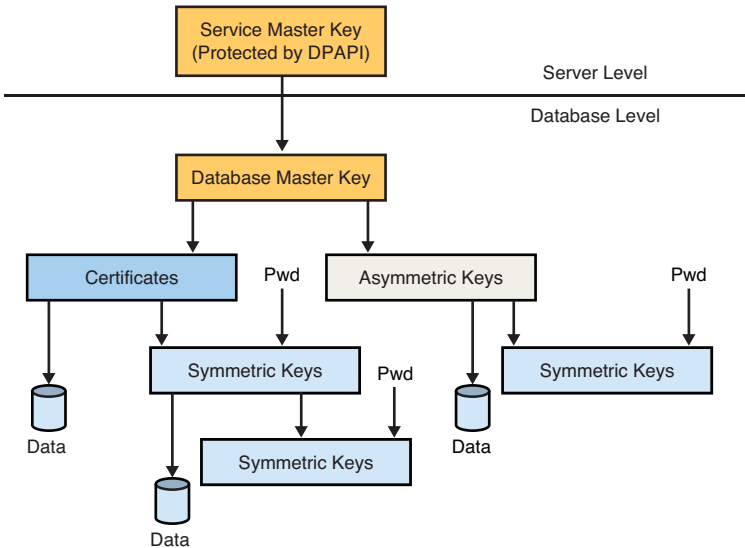

FIGURE 12.1 Key hierarchy in SQL Server 2008.

Each SQL Server instance has its *service master key*. The service master key is the one key that rules them all. It is a symmetric key created automatically during SQL Server installation and is encrypted and protected by the Data Protection API (DPAPI), which is provided by the underlying Windows OS, using the credentials of the SQL Server service account. Protection of this key is critical because if it is compromised, an attacker can eventually decipher every key in the server managed by SQL Server. SQL Server manages the service master key for you, although you can perform maintenance tasks on it to dump it to a file, regenerate it, and restore it from a file. However, most of the time you will not need or want to make any of these changes to the key, although administrators are advised to back up their service master keys in the event of key corruption.

The main purpose of the server master key is to secure system data, such as passwords used in instance-level settings such as linked servers or connection strings. The service master key is also used to secure each of the *database master keys*. Within each database, the database master key serves as the basis for creating certificates or asymmetric keys, which subsequently can be applied to protect data directly or to further extend the encryption hierarchy (for example, by creating symmetric keys). Creation, storage, and other certificate and key management tasks can be handled internally, without resorting to features of the operating system or third-party products.

Each database can have a single master key. You must create a database master key before using it by using the `CREATE MASTER KEY` Transact-SQL statement with a user-supplied password:

```
CREATE MASTER KEY ENCRYPTION BY PASSWORD = 'R@d0m!T3%t'
```

SQL Server encrypts the database master key using a triple DES key derived from the password as well as the service master key. The first copy is stored in the database, and the second is stored in the master database. Having the database master key protected by the server master key makes it possible for SQL Server to decrypt the database master key automatically when required. The application or user does not need to open the master key explicitly using the password. This is a major benefit of having the keys protected in the hierarchy.

NOTE

Detaching a database with an existing master key and moving it to another server can be an issue. The problem is that the new server's database master key is different from that of the old server. As a result, the server cannot automatically decrypt the database master key. This situation can be circumvented by opening the database master key with the password with which it is encrypted and using the `ALTER MASTER KEY` statement to encrypt it with the new database master key.

When the database master key exists, developers can use it to create any of three types of keys, depending on the type of encryption required:

- ▶ Asymmetric keys
- ▶ Symmetric keys
- ▶ Certificates

TIP

Microsoft recommends against using certificates or asymmetric keys for encrypting data directly. Asymmetric key encryption is many times slower, and the amount of data that you can protect using this mechanism is limited, depending on the key modulus. It is recommended that you protect certificates and asymmetric keys using a password instead of by the database master key.

Extensible Key Management

Another new feature in SQL Server 2008 that provides greater key security is Extensible Key Management. EKM enables you to manage your encryption keys via an external provider. This allows for flexibility and choice in encryption providers as well as common key management across your enterprise.

With the growing demand for regulatory compliance and concern for data privacy, organizations are taking advantage of encryption as a way to provide a “defense in depth” solution. As organizations increasingly use encryption and keys to secure their data, key management becomes more complex. Some high security databases use thousands of keys, and you must employ a system to store, retire, and regenerate these keys. This approach is often impractical using only database encryption management tools. As a solution, various hardware vendors provide products to store encryption keys on hardware or software modules. These products also provide a more secure key management solution because the encryption keys do not reside with encryption data. They also move the key management workload from SQL Server to a dedicated key management system.

Extensible key management in SQL Server 2008 also supports the use of Hardware Security Module, which enables the encryption keys used to protect your data to be stored in an off-box device such as a smartcard, USB device, or EKM/HSM module, providing a physical separation of keys from data. SQL Server 2008 Extensible Key Management enables third-party EKM/HSM vendors to register their modules in SQL Server. When registered, SQL Server users can use the encryption keys stored on EKM modules. This enables SQL Server to access the advanced encryption features these modules support such as bulk encryption and decryption, and key management functions such as key aging and key rotation.

SQL Server 2008 Extensible Key Management also provides data protection from database administrators. Data can be encrypted by using encryption keys that only the database user has access to on the external EKM/HSM module.

To summarize, SQL Server 2008 Extensible Key Management provides the following benefits:

- ▶ An additional authorization check that enables separation of duties between database administration and key management
- ▶ Improved performance through hardware-based encryption/decryption rather than software-based encryption/decryption
- ▶ External encryption key generation
- ▶ Physical separation of data and keys
- ▶ Encryption key retrieval
- ▶ External encryption key retention and encryption key rotation
- ▶ Easier encryption key recovery
- ▶ Manageable encryption key distribution
- ▶ Secure encryption key disposal

When possible, it is highly recommended that you use EKM with both database- and column-level encryption for more comprehensive key management and hardware-based cryptography.

Column-Level Encryption

Column-level encryption (sometimes referred to as cell-level encryption) was introduced in Microsoft SQL Server 2005 and is still fully supported in SQL Server 2008 R2. Column-level encryption offers a more granular level of encryption than TDE, allowing you to encrypt specific data columns in the context of specific users.

Column-level encryption is implemented as a series of built-in functions and a key management hierarchy. Implementing column-level encryption is a manual process that requires a re-architecture of the application to call the encryption and decryption functions explicitly when storing or retrieving data. In addition, the tables must be modified to store the encrypted data as varbinary. The data is then recast back to the appropriate data type when it is read.

Column-level encryption and decryption are provided by pairs of functions that complement each other:

- ▶ **EncryptByCert()** and **DecryptByCert()**—Encrypts and decrypts data using the public key of a certificate to generate a private asymmetric key
- ▶ **EncryptByAsymKey()** and **DecryptByAsymKey()**—Encrypts and decrypts data using an asymmetric key
- ▶ **EncryptByKey()** and **DecryptByKey()**—Encrypts and decrypts data by using a symmetric key
- ▶ **EncryptByPassphrase()** and **DecryptByPassphrase()**—Encrypts and decrypts data by using a passphrase to generate a symmetric key

Before you can begin generating keys to encrypt columns, you must first make sure a database master key has been created:

```
USE AdventureWorks2008R2;
GO

--If there is no master key, create one now.
IF NOT EXISTS
    (SELECT * FROM sys.symmetric_keys
     WHERE symmetric_key_id = 101)
CREATE MASTER KEY ENCRYPTION
    BY PASSWORD = 'Th15i$aS7riN&ofR@nD0m!T3%t'
GO
```

NOTE

The examples in this chapter make use of the AdventureWorks2008R2 database but can be run in the AdventureWorks2008 database as well; however, there may be differences in the data values returned. For more information on downloading and installing the AdventureWorks databases, see the Introduction.

Encrypting Columns Using a Passphrase

As our first example, let's keep things simple and look at how to encrypt a column using a passphrase. To do so, let's look at the `Sales.CreditCard` table, which currently stores card numbers in cleartext:

```
select top 5 * from Sales.CreditCard
go
```

CreditCardID	CardType	CardNumber	ExpMonth	ExpYear	ModifiedDate
1	SuperiorCard	33332664695310	11	2006	2007-08-30
2	Distinguish	55552127249722	8	2005	2008-01-06
3	ColonialVoice	77778344838353	7	2005	2008-02-15
4	ColonialVoice	77774915718248	7	2006	2007-06-21
5	Vista	11114404600042	4	2005	2007-03-05

Credit card numbers really should not be stored in their cleartext form in the database, so to fix this, first create a copy of the `Sales.CreditCard` table and define the `CardNumber_encrypt` column as a `varbinary(256)` so you can store the encrypted credit card numbers in the column (encrypted columns in SQL Server 2008 can be stored only as `varbinary` values):

```
USE AdventureWorks2008R2;
GO

select CreditCardID,
       CardType,
       CardNumber_encrypt = CONVERT(varbinary(256), CardNumber),
       ExpMonth,
       ExpYear,
       ModifiedDate
into Sales.CreditCard_encrypt
from Sales.CreditCard
where 1 = 2
```

Now, you can populate the `CreditCard_encrypt` table with rows from the original `CreditCard` table using the `EncryptByPassPhrase` function to encrypt the credit card numbers as the rows are copied over:

```
declare @passphrase varchar(128)
set @passphrase = 'unencrypted credit card numbers are bad, um-kay'
insert Sales.CreditCard_encrypt (
    CardType,
    CardNumber_encrypt,
    ExpMonth,
    ExpYear,
```

```

        ModifiedDate
    )
select top 5
    CardType,
    CardNumber_encrypt = EncryptByPassPhrase(@passphrase, CardNumber),
    ExpMonth,
    ExpYear,
    ModifiedDate
from Sales.CreditCard

```

Now, try a query against the `CreditCard_encrypt` table without decrypting the data and see what it returns (note, for display purposes, the values in the `CardNumber_encrypt` column have been truncated):

```

select * from Sales.CreditCard_encrypt
go

```

CreditCardID	CardType	CardNumber_encrypt	ExpMonth	ExpYear	ModifiedDate
1	SuperiorCard	0x010000007C65089E...	11	2006	2007-08-30
2	Distinguish	0x010000000C624987...	8	2005	2008-01-06
3	ColonialVoice	0x01000000AA8761A0...	7	2005	2008-02-15
4	ColonialVoice	0x010000002C2857CC...	7	2006	2007-06-21
5	Vista	0x0100000095F6730D...	4	2005	2007-03-05

In the preceding results, you can see that the credit card numbers have been encrypted as a varbinary value, and no meaningful information can be obtained from this. To view the data in its unencrypted form, you need to use the `DecryptByPassPhrase` function and convert the value back to an `nvarchar(25)`:

```

declare @passphrase varchar(128)
set @passphrase = 'unencrypted credit card numbers are bad, um-kay'
select CreditCardID,
    CardType,
    CardNumber = convert(nvarchar(25), DecryptByPassPhrase(@passphrase,
    CardNumber_encrypt)),
    ExpMonth,
    ExpYear,
    ModifiedDate
from Sales.CreditCard_encrypt
GO

```

CreditCardID	CardType	CardNumber	ExpMonth	ExpYear	ModifiedDate
1	SuperiorCard	33332664695310	11	2006	2007-08-30
2	Distinguish	55552127249722	8	2005	2008-01-06
3	ColonialVoice	77778344838353	7	2005	2008-02-15
4	ColonialVoice	77774915718248	7	2006	2007-06-21
5	Vista	11114404600042	4	2005	2007-03-05

So that's a simple example showing how to encrypt a column. You may be thinking, however, using a passphrase like this probably isn't very secure. The passphrase used to encrypt the column would have to be shared with all users and applications that need to store or retrieve data in the `CreditCard_encrypt` table. A shared passphrase like this can be easily compromised, and then the data is visible to anyone who can gain access to the database. It is usually more secure to encrypt data using a symmetric key or certificate.

Encrypting Columns Using a Certificate

One solution to the problem of encrypting using a shared passphrase is to encrypt the data using a certificate. A primary benefit of certificates is that they relieve hosts of the need to maintain a set of passwords for individual subjects. Instead, the host merely establishes trust in a certificate issuer, which may then sign an unlimited number of certificates.

Certificates can be created within SQL Server 2008 using the `CREATE CERTIFICATE` command. The certificate created is a database-level securable that follows the X.509 standard and supports X.509 V1 fields. The `CREATE CERTIFICATE` command can load a certificate from a file or assembly, or it can also generate a key pair and create a self-signed certificate. The `ENCRYPTION BY PASSWORD` option is not required; the private key of the certificate is encrypted using the database master key. When the private key is encrypted using the database master key, you do not have to specify a decryption password when retrieving the data using the certificate.

The first step is to create the certificate with the `CREATE CERTIFICATE` command:

```
USE AdventureWorks2008R2;
CREATE CERTIFICATE BillingDept01
    WITH SUBJECT = 'Credit Card Billing'
GO
```

After you create the certificate, the next step is to create a symmetric key that will be encrypted by the certificate. You can use many different algorithms for encrypting keys. The supported encryption algorithms for the symmetric key are `DES`, `TRIPLE_DES`, `RC2`, `RC4`, `RC4_128`, `DESX`, `AES_128`, `AES_192`, and `AES_256`. The following code creates a symmetric key using the `AES_256` encryption algorithm and encrypts it using the `BillingDept01` certificate:

```
USE AdventureWorks2008R2;
CREATE SYMMETRIC KEY BillingKey2010 WITH ALGORITHM = AES_256
    ENCRYPTION BY CERTIFICATE BillingDept01;
GO
```

Now you empty out the rows inserted previously in the `CreditCard_encrypt` table using the `PassPhrase` encryption method by truncating it:

```
USE AdventureWorks2008R2;
Truncate table Sales.CreditCard_encrypt
```

Next reinsert rows from the `CreditCard` table, this time using the symmetric key associated with the certificate to encrypt the data using the `EncryptByKey` function. The `EncryptByKey` function requires the GUID of the symmetric key as the first parameter. You can look up this identifier by running a query against the `sys.symmetric_keys` table or simply use the `KEY_GUID()` function, as in this example:

```
USE AdventureWorks2008R2;
-- First, decrypt the key using the BillingDept01 certificate
OPEN SYMMETRIC KEY BillingKey2010
    DECRYPTION BY CERTIFICATE BillingDept01
-- Now, insert the rows using the symmetric key
-- encrypted by the certificate
insert Sales.CreditCard_encrypt (
    CardType,
    CardNumber_encrypt,
    ExpMonth,
    ExpYear,
    ModifiedDate
)
select top 5
    CardType,
    CardNumber_encrypt = EncryptByKey(KEY_GUID('BillingKey2010'),
        CardNumber),
    ExpMonth,
    ExpYear,
    ModifiedDate
from Sales.CreditCard
```

If you examine the contents of the `CreditCard_encrypt` table, you can see that they have been encrypted:

```
select * from Sales.CreditCard_encrypt
go
```

CreditCardID	CardType	CardNumber_encrypt	ExpMonth	ExpYear	ModifiedDate
1	SuperiorCard	0x0046C380E7A27749...	11	2006	2007-08-30
2	Distinguish	0x0046C380E7A27749...	8	2005	2008-01-06

```

3          ColonialVoice 0x0046C380E7A27749... 7          2005    2008-02-15
4          ColonialVoice 0x0046C380E7A27749... 7          2006    2007-06-21
5          Vista          0x0046C380E7A27749... 4          2005    2007-03-05

```

Now, an authorized user that specifies the appropriate certificate can retrieve the data by using DecryptByKey function:

```

USE AdventureWorks2008R2;
OPEN SYMMETRIC KEY BillingKey2010
    DECRYPTION BY CERTIFICATE BillingDept01
select CardType,
       CardNumber = convert(nvarchar(25), DecryptByKey(CardNumber_encrypt)),
       ExpMonth,
       ExpYear,
       ModifiedDate
from Sales.CreditCard_encrypt
go

```

CreditCardID	CardType	CardNumber	ExpMonth	ExpYear	ModifiedDate
1	SuperiorCard	33332664695310	11	2006	2007-08-30
2	Distinguish	55552127249722	8	2005	2008-01-06
3	ColonialVoice	77778344838353	7	2005	2008-02-15
4	ColonialVoice	77774915718248	7	2006	2007-06-21
5	Vista	11114404600042	4	2005	2007-03-05

When you are done using a key, it is good practice to close the key using the CLOSE SYMMETRIC KEY statement:

```
CLOSE SYMMETRIC KEY BillingKey2010
```

The keys defined in a database can be viewed through the system catalog table, sys.symmetric_keys:

```

select name,
       pvt_key_encryption_type,
       issuer_name,
       subject,
       expiry_date = CAST(expiry_date as DATE),
       start_date = CAST(start_date as DATE)
from sys.certificates
go

```

name	pvt_key_encryption_type	issuer_name	subject	expiry_date	start_date
.....

```
BillingDept01 MK                Credit Card Billing
Credit Card Billing 2011-05-01  2010-05-01
```

The certificates defined in a database can be viewed through the system catalog tables, `sys.certificates`:

```
select name,
       key_length,
       key_algorithm,
       algorithm_desc,
       create_date = CAST(create_date as DATE),
       modify_date = CAST(modify_date as DATE),
       key_guid
from sys.symmetric_keys
go
```

```
name                key_length  key_algorithm  algorithm_desc
create_date  modify_date  key_guid
-----
##MS_DatabaseMasterKey## 128          D3             TRIPLE_DES
2010-04-30  2010-04-30  A3550B00-6BAE-41E2-A1BC-D784DC35779E
BillingKey2010          256          A3             AES_256
2010-04-30  2010-04-30  10C5C800-0B4C-44C2-9F71-5415007C2E81
```

If the usage of the key and certificate are no longer needed, they should be dropped from the database:

```
DROP SYMMETRIC KEY BillingKey2010
DROP CERTIFICATE BillingDept01
```

NOTE

There is a lot more information about column-level encryption and key management that could be discussed at this point, but such discussion would be beyond the scope of this chapter; our intent here is to merely introduce the concepts of data encryption. For more information on column-level encryption, refer to *SQL Server 2008 Books Online*.

Transparent Data Encryption

As mentioned previously, transparent data encryption (TDE) is a new feature introduced in SQL Server 2008 that allows an entire database to be encrypted. Unlike column-level encryption, in TDE the encryption and decryption of data is performed automatically by the Database Engine, and this is fully transparent to the end user and applications. No changes to the database or applications are needed. Consequently, TDE is the simpler choice when bulk encryption of data is required to meet regulatory compliance or corporate data security standards.

The encryption of a database using TDE helps prevent the unauthorized access of data in the scenario in which physical media or backups have been lost or stolen. Transparent data encryption uses a database encryption key (DEK) for encrypting the database. The DEK is stored in the database boot record and is secured by a certificate stored in the master database. The database master key is protected by the service master key, which is in turn protected by the Data Protection API. When TDE is enabled on a database, attaching data files to another SQL Server instance or the restoring of a backup to another SQL Server instance is not permitted until the certificate that was used to secure the DEK is available.

NOTE

Optionally, the DEK can be secured by an asymmetric key that resides in a Hardware Security Module with the support of Extensible Key Management. The private key of the certificate is encrypted with the database master key that is a symmetric key, which is usually protected with a strong password.

For example, if a hard drive that contains database files is stolen, without TDE, those database files can be attached in another SQL Server instance, thus allowing access to the nonencrypted data in those files. With TDE, the data and log files are automatically encrypted, and the data within these files cannot be accessed without an encryption key. Additionally, backups of databases that have TDE enabled are also encrypted automatically. We're all familiar with stories about how backup tapes containing sensitive information have been lost or stolen. With TDE, the data in the backup files is completely useless without also having access to the key used to encrypt that data.

The encryption and decryption of data with TDE are performed at the page level as data moves between the buffer pool and disk. Data residing in the buffer pools is not encrypted. TDE's specific purpose is to protect data at rest by encrypting the physical files of the database, rather than the data itself. These physical files include the database file (.mdf), transaction log file (.ldf), and backup files (.bak). Data pages are encrypted as they are written from the buffer pool to the database files on disk. Conversely, the data is decrypted at the page level when the data is read in from the files on disk into the buffer pool. The encryption and decryption are done using a background process transparent to the database user. Although additional CPU resources are required to implement TDE, overall, this approach offers much better performance than column-level encryption. According to Microsoft, the performance hit averages only about 3–5%.

TDE supports several different encryption options, such as AES with 128-bit, 192-bit, or 256-bit keys or 3 Key Triple DES. You make your choice when implementing TDE.

Implementing Transparent Data Encryption

Like many encryption scenarios, TDE is dependent on an encryption key. The TDE database encryption key is a symmetric key that secures the encrypted database. The DEK is protected using a certificate stored in the master database of the SQL Server instance where the encrypted database is installed.

Implementing TDE for a specific database is accomplished by following these steps:

- ▶ Create a master key.
- ▶ Create or obtain a certificate protected by the master key.
- ▶ Create a database encryption key and protect it by the certificate.
- ▶ Configure the database to use encryption.

Listing 12.1 demonstrates the commands needed to encrypt the AdventureWorks2008R2 database, including the creation of a master key, certificate, and DEK protected by the certificate.

LISTING 12.1 Encrypting the AdventureWorks2008R2 Database

```
USE master;
GO

--Create the master key which is stored in the master database
CREATE MASTER KEY ENCRYPTION BY PASSWORD = 'mystrongpassword$$';
GO

-- Create a certificate that is also stored in the master
-- database. This certificate will be used to encrypt a user database
CREATE CERTIFICATE MyCertificate
  with SUBJECT = 'Certificate stored in Master Db'
GO

-- Create a Database Encryption Key (DEK) that is based
-- on the previously created certificate
-- The DEK is stored in the user database
USE AdventureWorks2008R2
GO
CREATE DATABASE ENCRYPTION KEY
WITH ALGORITHM = AES_256
ENCRYPTION BY SERVER CERTIFICATE MyCertificate
GO
```

```
-- Turn the encryption on for the AdventureWorks2008R2
ALTER DATABASE AdventureWorks2008R2
SET ENCRYPTION ON
GO
```

After you enable TDE, you might want to monitor the progress of the encryption. This can be done by running the following query:

```
SELECT DBName = DB_NAME(database_id), encryption_state
FROM sys.dm_database_encryption_keys ;
GO
```

DBName	encryption_state
tempdb	3
AdventureWorks2008R2	3

This query returns the database encryption state. A database encryption state of 2 means that encryption has begun, and an encryption state of 3 indicates that encryption has completed. When the tempdb database and user database you are encrypting reach a state of 3, the entire user database and tempdb database are encrypted.

When TDE is enabled for a given database, encryption is applied to a variety of files related to the database, including the following:

- ▶ **Database Data Files**—All data files that contain the database data are encrypted. These files typically have the extension .mdf or .ndf.
- ▶ **Database Log Files**—The transaction log files are encrypted so that no clear text is visible in the files. These files typically have the extension .ldf.
- ▶ **Database Backups**—All database backups, including full, differential, and log, are encrypted.
- ▶ **Tempdb**—If any databases on a server are encrypted with TDE, the tempdb database is also encrypted.

In addition to these files, you can also manually enable TDE on the distribution and subscriber database involved in replication. This encrypts a portion of data involved in replication, but there are still some unencrypted files. Snapshots from snapshot replication as well as the initial distribution of data for transactional and merge replication are not encrypted.

Managing TDE in SSMS

You can also view and manage transparent data encryption in SQL Server Management Studio. To do so, right-click on the database in the Object Explorer for which you want to configure TDE and select Tasks; then select Manage Database Encryption. If you are setting up the initial configuration for TDE in a database, you see a dialog like that shown in Figure 12.2.

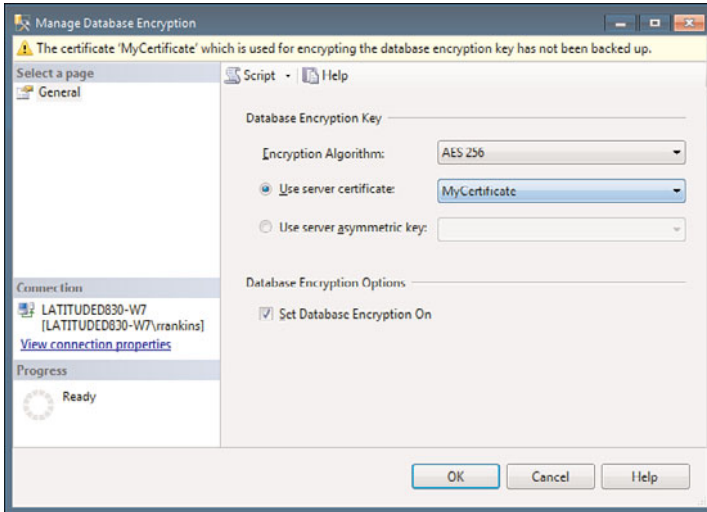

FIGURE 12.2 Enabling TDE in SSMS.

The options available in this dialog correspond to commands shown in Listing 12.1. You specify the encryption algorithm to be used and the server certificate used to protect the database encryption key. When you are ready to enable TDE for the database, put a check mark in the Set Database Encryption On check box.

If TDE is already enabled for a database, the dialog changes to provide you with options to re-encrypt the database encryption key and to regenerate the DEK using a different encryption algorithm. You can also enable/disable database encryption (see Figure 12.3). A second page displays the current TDE properties and encryption state of the database (see Figure 12.4).

Backing Up TDE Certificates and Keys

The most important issue to consider when using TDE is that you must back up and retain the certificate and private key associated with the encryption. If these things are lost or unavailable, you are not able to restore or attach the encrypted database files on another server. The following warning message displayed after creating a certificate drives home this point:

Warning: The certificate used for encrypting the database encryption key has not been backed up. You should immediately back up the certificate and the private key associated with the certificate. If the certificate ever becomes unavailable or if you must restore or attach the database on another server, you must have backups of both the certificate and the private key or you will not be able to open the database.

Backup up the certificate and private key

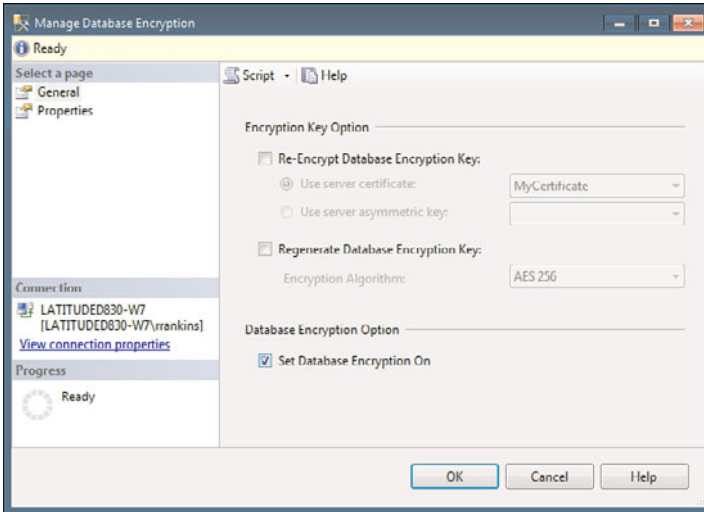

FIGURE 12.3 Modifying TDE properties in SSMS.

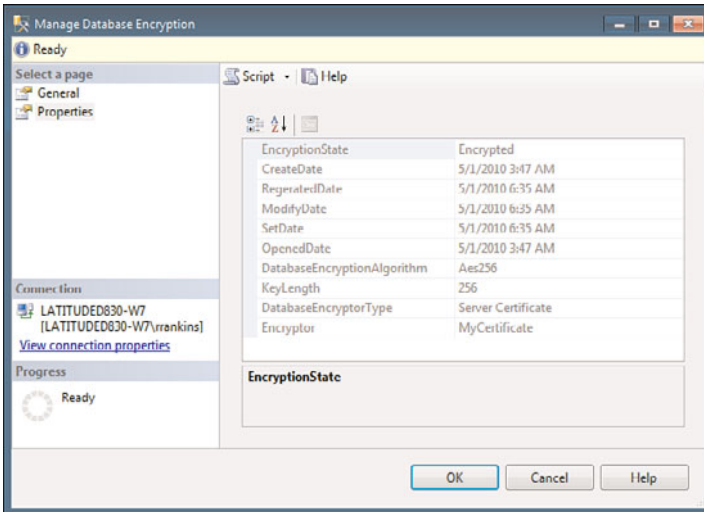

FIGURE 12.4 Viewing TDE properties in SSMS.

Backing up the certificate, private key, and master key for the server is relatively straightforward. An example of backing up the master key is shown in the following SQL statement:

```
BACKUP MASTER KEY TO FILE = 'c:\mssql12008\backup\masterkey'
    ENCRYPTION BY PASSWORD = 'somekeybackuppasword$$'
```

Backing up the certificate and associated private key also uses the `BACKUP` command. The following example backs up the certificate created in Listing 12.1:

```
BACKUP CERTIFICATE MyCertificate TO FILE = 'c:\mssql2008\backup\MyCertificate'
WITH PRIVATE KEY ( FILE = 'c:\mssql2008\backup\MyCertificatePrivateKey' ,
  ENCRYPTION BY PASSWORD = 'somecertbackuppasword$$' )
```

If you want to restore a database backup on another server instance, a master key for the server must exist. If one does not exist, you can create one by using the `CREATE MASTER KEY ENCRYPTION` syntax. After creating the master key, you are able to create the TDE certificate from a backup of the certificate from the original SQL Server instance, as shown in the following example:

```
CREATE CERTIFICATE MyCertificate
FROM FILE = 'c:\mssql2008\backup\MyCertificate'
WITH PRIVATE KEY (FILE = 'c:\mssql2008\backup\MyCertificatePrivateKey',
  DECRYPTION BY PASSWORD = 'somecertbackuppasword$$')
```

After the certificate is restored on the other server instance, you can restore the encrypted database backup. At this point, the restore can be performed just as you would restore any unencrypted database backup. The restored database is also encrypted and behaves like the original TDE database.

TDE is a relatively simple and effective way to encrypt and protect your data. Other encryption methods that exist with SQL Server can protect different elements of your database. Encryption can be applied to columns of data, an entire table, as well as the communication that occurs between databases and the clients that access them. The level of encryption and need to use it depend on the type of data you are securing.

Limitations of TDE

Although TDE offers many benefits over column-level encryption, it has some of its own limitations, which are important to consider. They include

- ▶ TDE is not granular like column-level encryption. The entire database is encrypted, but only on disk. Sensitive data such as Social Security numbers or credit card numbers can be seen by anyone who has permission to access those columns. TDE also does not prevent DBAs from viewing any data in the database.
- ▶ TDE does not protect communications between client applications and SQL Server. Network encryption methods should be used to protect sensitive data flowing over the network.
- ▶ `FILESTREAM` data is not encrypted.
- ▶ When any one database on a SQL Server instance has TDE enabled, the `tempdb` database is also automatically encrypted. This can affect performance for both encrypted and nonencrypted databases running on the same instance.

- Databases encrypted with TDE can't take advantage of SQL Server 2008's new backup compression. If you want to take advantage of both backup compression and encryption, you have to use a third-party application, such as Idera's SQL Safe Backup or Redgate's SQL Backup, which both have the capability to both compress and encrypt backups.

Column-Level Encryption Versus Transparent Data Encryption

So is column-level encryption or transparent data encryption the right solution for your systems? Both column-level encryption and transparent data encryption provide a means of obfuscating sensitive data to protect it from unauthorized access. However, they do so in different ways.

TDE prevents the unauthorized access of the contents of the database files and backups, but does not protect sensitive data within the database from being viewed by authorized users or database administrators. Column-level encryption provides more granular control over the data being encrypted but is not transparent to your applications.

Table 12.1 lists the similarities and differences between column-level encryption and TDE.

TABLE 12.1 Comparison of Column-Level Encryption and Transparent Data Encryption

Features/Limitations	Column-Level Encryption	Transparent Data Encryption
Data is encrypted on disk and backups	Yes	Yes
Supports HSMs	Yes	Yes
Data level of encryption	Granular, at the column level	Encrypts the entire database only
User level of encryption	Encrypted data can be restricted at the user level on a need-to-know basis	Any user with sufficient database permissions can view encrypted data
Impact on applications	Database applications need to be modified	Completely transparent to applications and end users
Indexing of encrypted data	Encrypted columns cannot be indexed	No restrictions on indexes
Performance impact	May be significant depending on the type of encryption key used	Small impact on performance (3–5%)

For some organizations, you might want to consider implementing both column-level encryption along with TDE for a database. Although this combination is more complex to set up and administer, it offers greater security and encryption granularity than does either method used alone. TDE protects the database files and backups from unauthorized

access, whereas column-level encryption protects sensitive data within the database from being accessed by authorized users, including DBAs. Implementing TDE in conjunction with cell-level encryption provides a layered approach to data security, which enhances its effectiveness.

The main disadvantage to implementing column-level encryption is that it isn't transparent to the end-user applications. In addition to requiring changes to the database schema, it also requires changes in the applications to include the proper function calls to encrypt and decrypt the data as it is stored and retrieved. Another issue with column-level encryption is that you cannot index encrypted columns, nor can you generate statistics on the encrypted columns. This can affect query performance because search arguments that reference encrypted columns cannot be optimized. For this reason, typically only the most sensitive columns of a table that do not need to be indexed are encrypted.

Summary

Chapter 11, "Security and User Administration," discusses methods to secure and control the access to your SQL Server data via login and user security to prevent unauthorized users from accessing your SQL Server instances and databases. Column-level encryption, as discussed here, takes these protections a step further by preventing authorized users, such as your database or server administrators, from viewing sensitive data within a database. Transparent data encryption protects all your data from being accessed by unauthorized users in the event that your database files or backups are lost or stolen.

Chapter 13, "Security and Compliance," discusses security methods available in SQL Server and how they can be implemented to meet your security compliance requirements. It also covers the new data auditing methods you can use to track changes to your data and database objects.

CHAPTER 13

Security and Compliance

As you complete what you think is your best database design and application on the planet, you stop yourself dead in your tracks and say, with hesitation, “What about the security and compliance implications?” Now is not the time to start thinking about these aspects. In fact, as we show you in this chapter, you should start considering these issues from the beginning of the development life cycle.

With the growth of software and database development in the world, there is a rise in the demand for security best practices to achieve the goals of creating secure software. Best practices must start from the glass and reach through the application, to the database layer, and even to the operating system and the physical file levels. Best practices are also meant to be scrutinized for overall results on the basis of the level of security, efficiency, and complexity they provide. How much and which best practice to use can also be considered on the basis of confidentiality, integrity, and availability (which is known as *CIA*). Software security must be considered at many layers and is additive in nature—each layer providing the necessary security and compliance of one part of the bigger puzzle. To get it right, you must “design in” security from the beginning.

In this chapter we discuss security aspects in conjunction with a traditional development life cycle; this includes aspects such as vulnerability assessments, threat modeling, and identity management. You can take many steps to prevent *SQL injection*, for example, and other vulnerabilities. We also talk about compliance aspects in regards to global and regional regulations such as the Health Insurance Portability and Accountability Act (also known as HIPAA),

IN THIS CHAPTER

- ▶ Exposure and Risk
- ▶ Across the Life Cycle
- ▶ The Security Big Picture
- ▶ Identity Access Management Components
- ▶ Compliance and SQL Server
- ▶ SQL Server Auditing
- ▶ Setting Up Auditing via T-SQL
- ▶ SQL Injection Is Easy to Do

the Payment Card Industry (PCI) standards, and data privacy regulations such as Personally Identifiable Information (PII).

We also provide a simple example of using the SQL Server Auditing feature that can be extremely useful in identifying and monitoring compliance of access and usage at the SQL Server database or object levels. And lastly, we show you how to do some malicious damage with SQL injection. We show you how to do this so that you can learn how to prevent it. But first, let's try to better understand what exposure and risk are all about.

Exposure and Risk

You must understand that security is really “risk management” or “risk mitigation.” It can be very difficult to completely secure an application or environment. However, you are able to control or limit damage by following certain practices. Your data and applications have different levels of security requirements depending on the exposure endpoints (an *exposure endpoint* is defined by who is using the application and data). Figure 13.1 shows a simple matrix of data and application sensitivity versus the exposure endpoints of that application. By definition, the more external facing your application is (such as to the Internet) and the higher the sensitivity of the data involved, the higher risk precautions you have to take.

		Exposure End Points	
		Limited Exposure (Internal/Intranet Only)	Exposable (External Internet)
Data/Application	Low Sensitivity (Public)	Low Risk	Medium Risk
	Medium Sensitivity (Confidential)	Medium Risk	High Risk
	High Sensitivity (Highly Confidential)	High Risk	High Risk

FIGURE 13.1 The exposure endpoints “risk” by category of data/application sensitivity.

Let's say you have an internal company SQL Server–based application that has only very low sensitivity data (public-facing data such as benefits data). You freely share this type of data with whoever wants to see it. The types of controls or rigor are likely very small for this type of application—perhaps as simple as an integrated Active Directory with your SQL Server and read-only access for all user roles.

On the other side of the spectrum, you may have applications generating financial transactions with credit card data that must have zero vulnerabilities, encrypt data across the network, encrypt data at rest within SQL Server, and use the new SQL auditing feature for database-level monitoring of all data accesses.

A big part of the risk management aspect is understanding what the impact of this risk would be if your system is compromised. It is always best to identify this aspect up front in some type of risk “cost” or “impact.” Many financially strong companies have gone out of business as a result of security breaches they had not anticipated or considered. It is better to plan for such risk from the beginning.

Another aspect to consider is staying compliant with data you use in nonproduction environments. Often, companies needlessly put their entire livelihood at risk by using live data values in nonproduction environments. If PII or other company-sensitive data is available in your nonproduction environments (such as in Development, Test, and Quality Assurance platforms), you are violating laws and regulations around the globe and putting your company and your customers at risk. You can easily employ data subsetting and masking to your nonproduction data. Putting this practice in place is a great idea.

Across the Life Cycle

We introduce formal development life-cycle concepts in other chapters. In those chapters, such as Chapter 41, “A Performance and Tuning Methodology,” the emphasis is on designing in performance from the beginning. A part of good design is how you have complied with laws and regulations, how you have protected the data you access or store, how you have secured your application and data, and how you have verified all this. For these reasons, we provide some details and describe what must be done across the development life cycle to properly address security and compliance. We term this process the “risk mitigation” of what you build.

Figure 13.2 shows a formal waterfall development life cycle with key security and compliance items identified at each relevant phase. Getting into the risk mitigation business starts by giving security and compliance the full commitment and recognition they deserve.

This step starts with a clear statement of security and compliance objectives as you are sizing up your application in the assessment phase. These objectives often take the form of stating how you will address the rules, laws, data sensitivities, access considerations, and eventual end users (and the countries they reside in).

Next, you focus on the clear identification and specification of all security and scope of compliance. You look at the details of exactly where the compliance or security lines need to be, determine how you must fully address them, and clearly identify which must be adhered to for your application. Often, organizations have security information analysts and data privacy groups that contribute to this part of your development efforts. They, in turn, bring others to the table, such as legal, auditing, and even corporate communications folks.

As you go into the design phase, you must complete the full analysis and design of every security and compliance element for your application. As part of this analysis and design phase, you should start enumeration test plans that must be completely verified before your application can be delivered to its users.

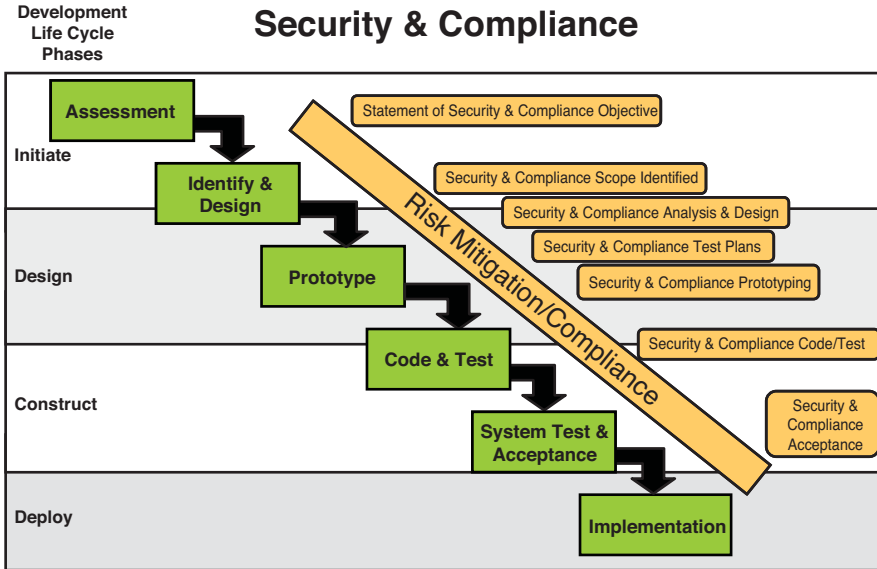

FIGURE 13.2 Security and compliance across the development life cycle.

In the prototyping phase, you have a chance to start demonstrating how security, access, privacy, and compliance will be addressed. This phase is very important because of all the complications, rules, laws, and issues that are at stake and must be verified. We have not run a development effort without extensive prototyping of as many security and compliance tests as are humanly possible. It is this risk that must be fully addressed early and never as an afterthought!

As you fully code and test your database and application, you must never skip the security testing and validation. It is best to put these tests *first* in your overall test plans. As your application completely takes shape, a complete application scan for vulnerabilities can be performed. Popular tools such as AppScan are essential tools of the trade for performing this task.

Finally, as you near deployment, you should make sure all the security and compliance acceptance tests are met. You need to capture these results fully because the successful completion of this part of acceptance testing can be shown in SOX compliance auditing.

The Security Big Picture

Now, let's turn to the bigger security and compliance picture that shows many of the layers involved in a broader security enforcement approach. Figure 13.3 shows many of these layers, starting at the top with solid guidelines, policies, and compliance-reporting capabilities. You must start with these components to guarantee that you are aware of what must be done and have a way to show you are doing what the policies outline.

Next, you must define and create other aspects of security and compliance, such as security event management, alerting and monitoring, complete threat models, and vulnerability

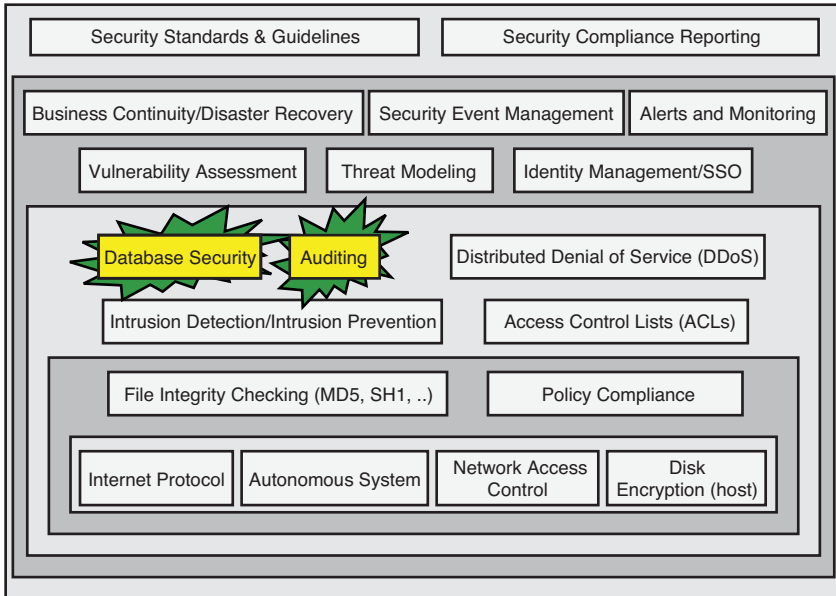

FIGURE 13.3 Security enforcement layers and components.

assessment objectives. These types of components must also reach into and be enforceable across major events such as disaster recovery (to ensure business continuity) and continue to support what you have deployed around identity management and single sign-on.

The next inner layer is where your database security is defined, along with any database-level or database instance-level auditing you put into place. It is also this layer where messy things such as SQL injection can occur and Denial of Service often surfaces. Getting some type of intrusion detection and prevention scheme into place is essential. Clear access controls are also essential. Later in this chapter, we describe some basic SQL Server-based auditing at the database level. Chapters 11, “Security and User Administration,” and 12, “Data Security,” also describe much of what you must do around overall security administration and database-level security. Figure 13.3 highlights these two critical areas.

Moving further down the layers of security, you find file integrity checking, secure Internet protocols, disk-level encryption, and other security-enhancing items. They all work together to bring you what should be a more secure (and compliant) place to deploy your applications within.

With SQL Server 2008 R2, you are essentially out-of-the-box ready to do absolutely *nothing*. In other words, Microsoft has taken the policy to “allow nothing,” and any access, execution, or other action must be explicitly granted. Believe it or not, this is the right thing to do. This approach ensures that all objects and accesses are explicitly declared and, by definition, are fulfilling security and many compliance regulations.

The Open Web Application Security Project (OWASP; www.owasp.org) lists its recent top 10 application vulnerabilities as follows:

- ▶ SQL Injection
- ▶ Cross-Site Scripting
- ▶ Broken Authentication and Session Management
- ▶ Insecure Direct Object References
- ▶ Cross-Site Request Forgery
- ▶ Security Misconfiguration
- ▶ Failure to Restrict URLs
- ▶ Unvalidated Redirects and Forwards
- ▶ Insecure Cryptographic Storage
- ▶ Insufficient Transport Layer Protection

Identity Access Management Components

One of the key areas identified in the security big picture (as you can see looking back at Figure 13.3) is identity management. It is key in the sense that well-managed identities are essential to well-managed security. There is a quite a bit to consider when talking about identities. Figure 13.4 shows a common “identity universe” for a company that has both internal- and external-facing applications. In other words, identities are both customers that interact with the business and internal identities such as employees and other work-force identities (contractors, temps, partners, and so on). Both sets of identities must be managed well, and often there are overlapping identities that require accesses (and identity management) in both areas (internal and external).

Often, companies use one internal-facing LDAP directory such as Microsoft’s Active Directory for managing their internal identities and then another LDAP directory such as Sun One LDAP for managing all external-facing identities (for forums, eStore, and so on). Then they create triggers or synchronization jobs that do a “search before create” type of processing when new identities are created within either LDAP directory. Because overlap is rare, not much extra “create” overhead occurs, but when they do overlap, only one identity (such as a partner identity that might be in that company’s internal and external LDAP directories) gets created. This is effectively “mastering” the user identities. It is recommended that you consider both sources of identities at all times. You should also establish strict access roles for all identities with the least rights going to anonymous identities.

More and more companies are also now moving to concepts such as Open ID, where a company can utilize the authentication and identification established by third-party Open ID providers and grant trust to these identities with very high confidence. The industry is moving this way fast. Figure 13.5 shows the logical components of identity access management.

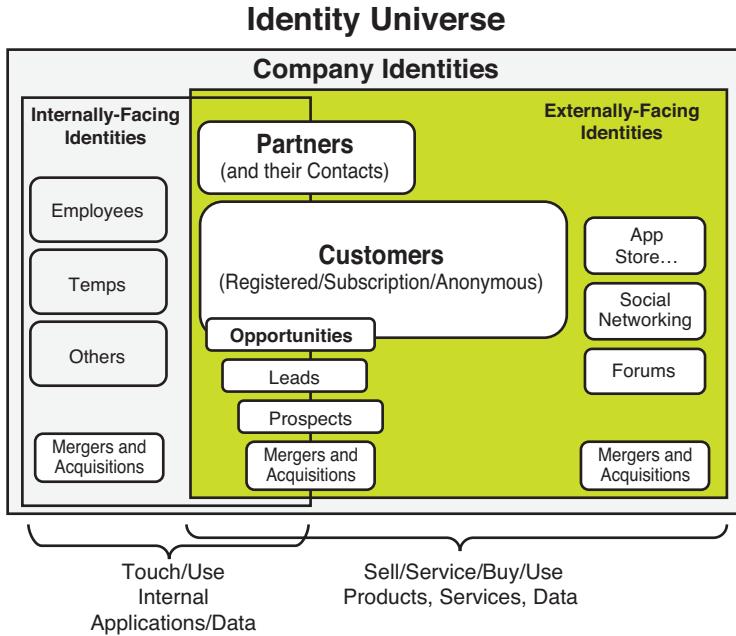

FIGURE 13.4 Identity universes (internal and external-facing applications).

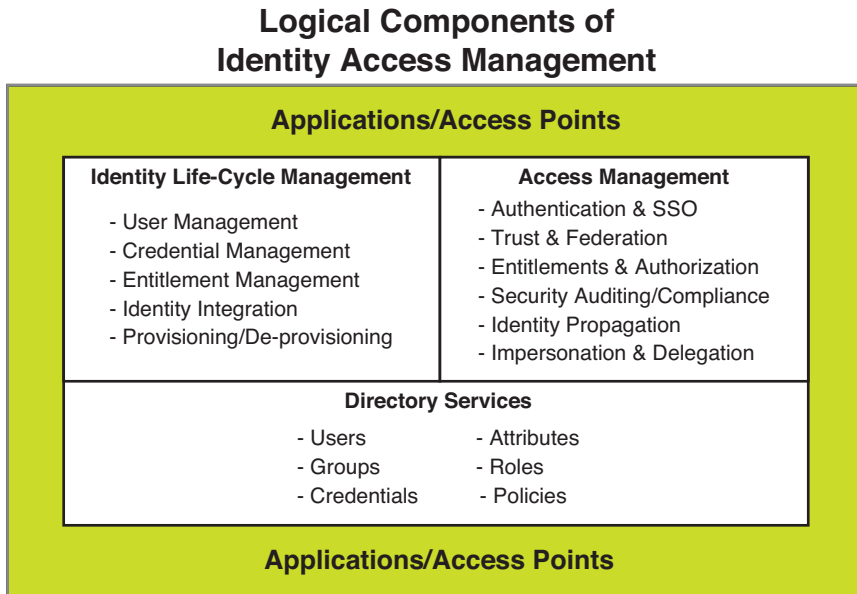

FIGURE 13.5 Logical components of identity access management.

This figure shows that you must carefully address full identity life-cycle management, which includes user ID management, credential management, entitlement management, identity integration (between multiple LDAPs), and provisioning *and* deprovisioning identities. Access management is all about authentication, single sign-on, authorization, and impersonation and delegation rules. And, the directory services themselves define the users, groups, all attributes (or elements) of a user or group, roles, policies to enforce, and credentials to be used. All applications and access points must be plugged in to this identity access management framework. All risk is minimized by a sound identity access management foundation.

Compliance and SQL Server

On the global level, hundreds of compliance laws are in place that affect almost every aspect of data access, data protection, data movement, and even data storage. Countries such as Germany now have some of the most severe data compliance rules on the planet, such as strict control of how certain personal data is stored and what personal data can be stored; these rules even prohibit personal data from being transmitted (or moved) across German borders. If you are planning to create applications and databases that will span countries or contain sensitive or private data, you must “design in” the rules and enforcements from the beginning (as we have been stressing throughout this chapter).

Let’s address the most common “sensitive” data: Personal Identifiable Information (or PII for short). PII data is at the center of most global data privacy laws and regulations. As you can see from a subset of the PII data model in Figure 13.6, PII data is any personal information that identifies an individual, such as name; address; driver’s license number; other government-issued identification (such as passport number); and even gender, ethnicity, and age.

If you have any databases or applications that have this type of data in it, you are bound by local and/or regional laws and regulations whether you like it or not. It is the law. You must then protect this data in accordance with those regulations and laws; otherwise, you become liable for fines, lawsuits, or worse (risk exposure of that data could put you out of business). As you can also see in Figure 13.6, there are different sensitivity levels around PII data. Something like a person’s name is considered low sensitivity, whereas an employee ID is considered medium sensitivity. And marital status, gender, Social Security number, bank account number, driver’s license number, and passport number are considered high sensitivity and often must be treated with special care and feeding with capabilities such as encryption in transit and at rest (while stored in a table).

Following is a list of some of the many laws and regulations that have been put into effect and that you will likely have to address in your application:

- ▶ The Health Insurance Portability and Accountability Act (also known as HIPAA) was introduced in 1996 to protect critical health and patient information. HIPAA forces companies to strictly control data identified under its jurisdiction.

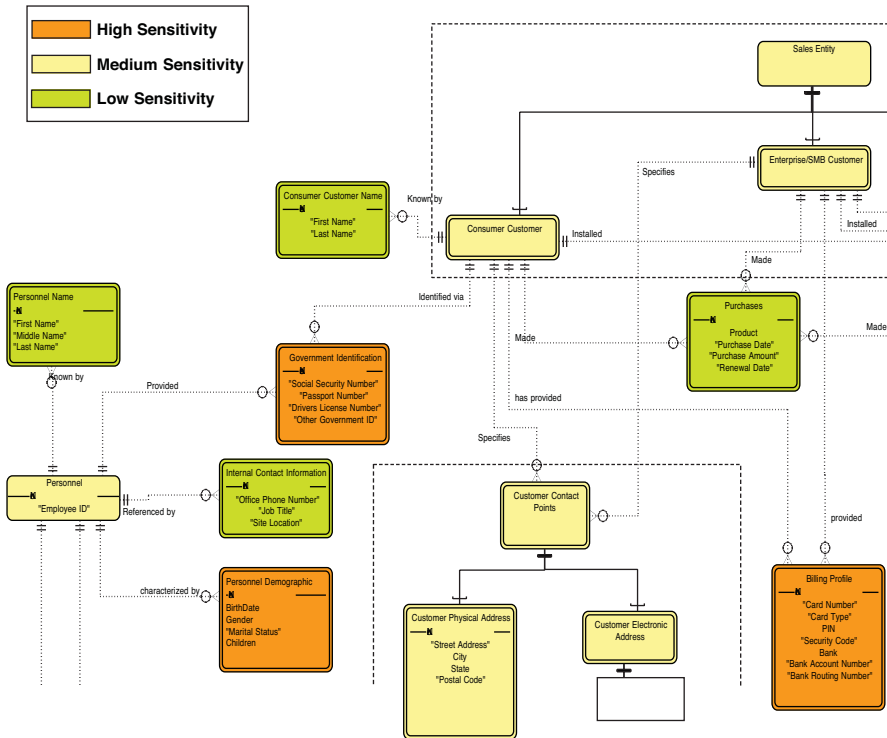

FIGURE 13.6 Personally Identifiable Information (PII).

- ▶ The Sarbanes-Oxley Act (known as SOX), put into place in 2002, requires auditors to assess and report on the effectiveness of a company's internal controls on information and extend into the authorization of access and updates to data.
- ▶ The Gramm-Leach-Bliley Act (GLBA) of 1999 further defines steps that must be taken by financial institutions to protect, secure, and prevent access of core financial data.
- ▶ California's Information Practices Act of 2005 details strict controls around PII data, what needs to be encrypted, and laws surrounding breaches of controlled data.
- ▶ The Children's Online Privacy Protection Act, passed in 1998, focuses on the procedures to protect the confidentiality, security, and integrity of personal information collected from children.

Other industry-oriented laws and regulations have emerged, such as the Payment Card Industry data security standard (PCI standard). It is focused on what must be done to ensure credit card information is secure from the moment a customer makes a purchase until the merchant disposes of the credit card transactions.

Two great books on security and compliance are *Cryptography in the Database* by Kevin Kenan (2006, Addison-Wesley) and *The Executive Guide to Information Security* by Mark Egan (2005, Addison-Wesley). These books will make great focused additions to your technology library.

SQL Server Auditing

Introduced with SQL Server 2008 is the SQL Server Audit feature. This long-overdue feature now adds a great native auditing functionality into the SQL Server Database Engine.

NOTE

The SQL Server Audit feature is available only in the SQL Server 2008 Enterprise and Developer Editions.

An *audit* is the combination of several elements into a single package for a specific group of server actions or database actions. The components of SQL Server Audit combine to produce an output that is called an *audit*.

The SQL Server Audit feature in SQL Server 2008 is intended to replace SQL Trace as the preferred auditing solution. SQL Server Audit is meant to provide full auditing capabilities, and only auditing capabilities, unlike SQL Trace, which also serves for performance debugging. The SQL Server Audit feature is built on top of Extended Events, a new high-performance eventing infrastructure introduced in SQL Server 2008. SQL Server Audit leverages the performance benefits of Extended Events, which provides both asynchronous and synchronous write capabilities (by default, SQL Server Audit uses the asynchronous eventing model).

NOTE

By default, the audit events are written to the audit target in an asynchronous fashion for performance reasons. When tighter guarantees of audit records being written to the audit log are required, you can select synchronous write, with the understanding that some amount of performance degradation should be expected. The choice of asynchronous or synchronous is controlled by the `QUEUE_DELAY` option of the `CREATE AUDIT DDL`.

SQL Server Audit is also tightly integrated with the Windows operating systems and can push (write) its audits to the Windows Application or Security Event Log. With SQL Server Auditing, you can set up auditing of just about any event or execution within SQL Server, and it can be as granular as you need (right down to a table and operation level). This capability is important because not only can you track all these events, but you can use this auditing capability to fulfill application and database audit compliance and look for patterns of misuse, or even specific “hot” objects that contain the most sensitive data in your database.

As you can see in Figure 13.7, a branch under each database called `Security` contains several of the common security-related nodes that you’ve seen before (`Users`, `Roles`, `Schemas`, and so on). But now, there is a `Database Audit Specifications` branch from which you can set up and view the database audit specifications you have defined. You

can have as many specifications as you want, and again, they can be at varying levels of granularity.

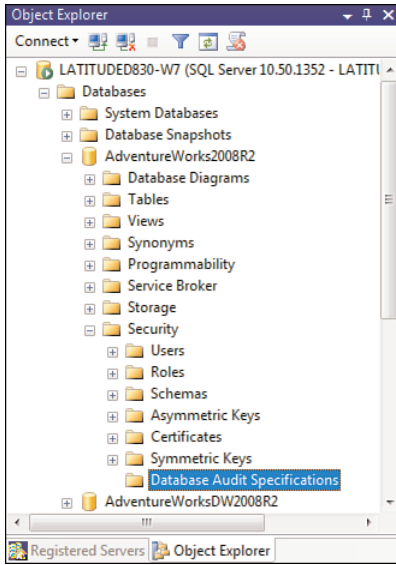

FIGURE 13.7 The new Database Audit Specifications item in the SQL Server Management Studio (SSMS) Object Explorer.

Before you can set up a Database Audit Specification, however, you must first set up a SQL Server Audit object. To do this, you must use a couple of new entries in the Object Explorer under the Security folder at the SQL Server instance level: Audits and Server Audit Specifications.

Essentially, three main objects describe audits in SQL Server 2008:

- ▶ **The Server Audit object**—Used to describe the target for audit data, plus some top-level configuration settings. This destination can be a file, the Windows Application log, or the Windows Security log. The Server Audit object contains no information about what is being audited—just *where* the audit data is going. Multiple Server Audit objects can be defined with each object independent from one another (that is, they can each specify a different destination).
- ▶ **The Server Audit Specification object**—Used to describe what to audit at a server instance-wide level. A server audit specification must be associated with a Server Audit object to define where the audit data is written. There is a one-to-one relationship between the Server Audit Specification object and the Server Audit object.
- ▶ **The Database Audit Specification**—Used to describe *what* to audit at a specific database level. Where the audit data is written is determined by the Server Audit object it is associated with. Each database audit specification can be associated with

only one server audit. A server audit can be associated with audit specifications for multiple databases, but only one database audit specification per database.

To create a new Server Audit object, right-click on the Audits item in Object Explorer and select New Audit (see Figure 13.8).

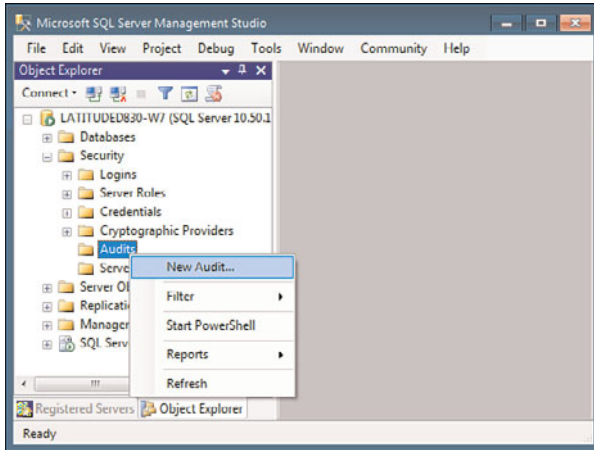

FIGURE 13.8 Creating a new Server Audit object in Object Explorer at the Server instance level.

When you set up a Server Audit object, you specify where the audit information will be written to. In Figure 13.9, you can see that we are creating a server audit named `NEW_SQL_Server_Audit` and are defining it to use the Application log at the Windows operating system level as the audit destination. You can also choose to write to the Windows Security log or to a text file. Events written to the Application or Security Event log can be accessed with Event Viewer or with specialized Event log management software, such as Microsoft Systems Center Operations Manager.

NOTE

Depending on the volume of audit targets being monitored, better performance may be achieved by using a file as the audit target rather than the Windows Event log. Also, when written to a file, the audit data is accessible through a built-in table-valued function (`fn_get_audit_file`), which allows the use of regular `SELECT` syntax to query the audit trail.

NOTE

You can also configure the Audit object to shut down the SQL Server instance if, for whatever reason, SQL Server Audit is unable to write its audit events to the audit target. Although shutting down the server instance may seem drastic, doing so may be necessary for certain scenarios, to ensure that the server cannot operate without its activity being audited.

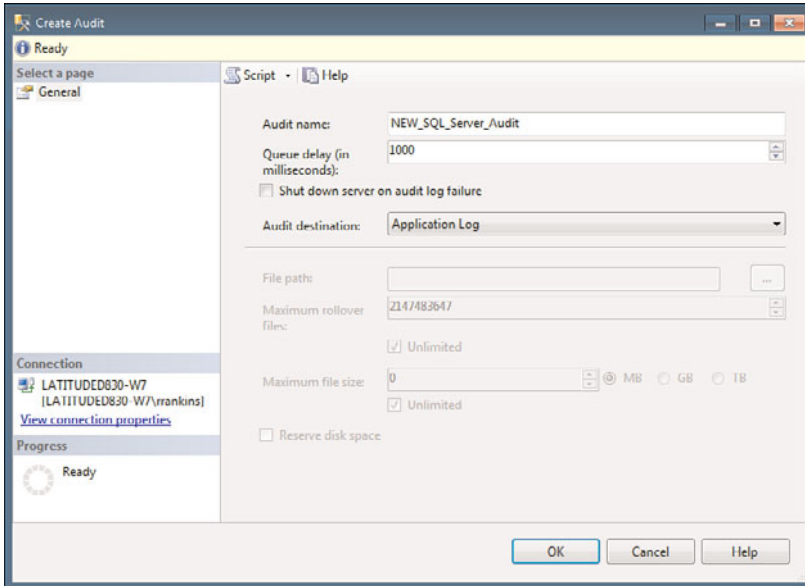

FIGURE 13.9 The Create Audit dialog.

After you set up the Server Audit object, the next step is to go to the Database Audit Specifications folder, as shown in Figure 13.7, in the database for which you want to set up auditing. Right-click this folder and select *New Database Audit Specification* to bring up the dialog shown in Figure 13.10. This is where you define your database-level audits.

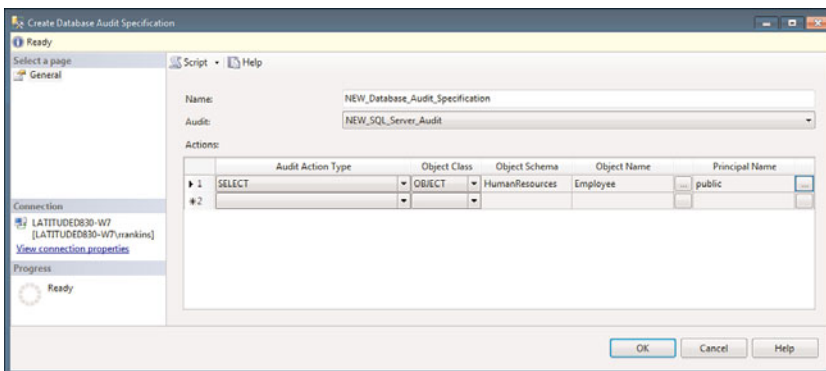

FIGURE 13.10 The Create Database Audit Specification dialog.

In the Create Database Audit Specification dialog, you specify the name of the Database Audit object and the Server Audit object it will be running under. In this example, the Database Audit name is `NEW_Database_Audit_Specification`, and it will be running under

the `NEW_SQL_Server_Audit` Audit object defined in Figure 13.9. In this example, the database audit is being set up to audit any `SELECT` statements (reads) run against the `Employee` table (which, of course, contains company-sensitive employee data) by any user (public).

At this point you have created a Server Audit object and database audit specification associated with the server audit. However, neither of these audits is enabled. You can enable them by right-clicking on each and selecting `Enable`. As soon as the Server Audit object is enabled, it begins auditing and writing audit records to the specified destination (in this example, the Windows Application log).

NOTE

If your SQL Server login is configured for a default database other than master, enabling the SQL Server Audit object via SSMS fails with the following message:

Cannot alter a server audit from a user database. This operation must be performed in the master database.

If you receive this error, you need to enable/disable the server audit via T-SQL, as shown in Listing 13.1.

You can review the details by right-clicking on the Server Audit and selecting `View Audit Logs` or, if you are auditing to the Windows Application or Security Event Log, by opening the Windows Event Viewer directly. One of the advantages of opening the Audit log from within SSMS is that it automatically filters the log to show only SQL Server Audit events. In Figure 13.11, you can see that we've opened the Log File Viewer and selected to view the Application log (where we directed our SQL Server Audit to go). A few `SELECT` statements were run against the `Employee` table and, sure enough, the audit information of the `SELECT` statements shows up in the Application log.

Within the Log File Viewer, you can filter your audit results or search them to look for patterns, specific violations, and so on. From the Log File Viewer, you also have the option of exporting the audit logs to a text file or to a comma-separated values (CSV) file. With a CSV file, you could import the audit logs into a database for further analysis and correlation. It's up to your security and audit team to decide how these audits are to be used.

In addition to database-level auditing of actions at the database level, you can also set up auditing of server-level events, such as management changes and logon and logoff operations. These are set up in the SSMS Object Explorer through the Server Audit Specifications item in the Security folder for the SQL Server instance (refer to Figure 13.8).

Setting Up Auditing via T-SQL

Alternatively, you can set up auditing with T-SQL statements and also switch the audit off and on using the `ALTER SERVER AUDIT` command by using `WITH (STATE=ON)` or `WITH (STATE=OFF)`, as shown in Listing 13.1.

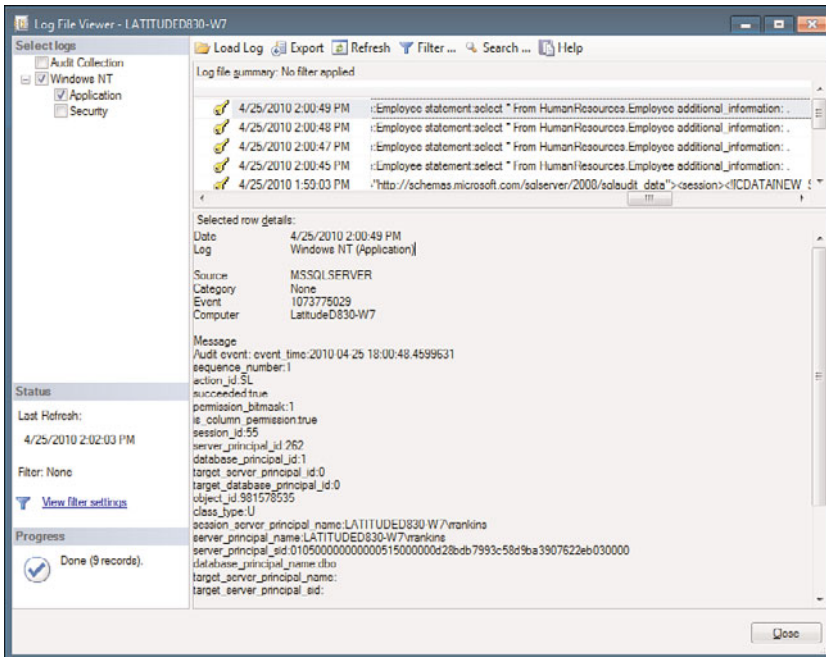

FIGURE 13.11 Log File Viewer showing the audit events of a SQL Server Audit object.

LISTING 13.1 Setting Up Auditing with T-SQL

```

/* Create the SQL Server Audit object, and send the results to the
   Windows Application event log. */
USE master;
GO
CREATE SERVER AUDIT NEW_SQL_Server_Audit
    TO APPLICATION_LOG
    WITH ( QUEUE_DELAY = 1000,  ON_FAILURE = CONTINUE);
GO

/* Create the Database Audit Specification object using an Audit event */
USE AdventureWorks2008R2;
GO
CREATE DATABASE AUDIT SPECIFICATION NEW_Database_Audit_Specification
FOR SERVER AUDIT NEW_SQL_Server_Audit
    ADD (SELECT
            ON OBJECT::[HumanResources].[Employee]
            BY [public])
    WITH (STATE = ON);
GO

```

```

/* Enable the audit. */
USE master;
go
ALTER SERVER AUDIT NEW_SQL_Server_Audit
WITH (STATE = ON);

/* Test the audit is working */
USE AdventureWorks2008R2;
GO
SELECT * from HumanResources.Employee;
GO

/* Disable the audit. */
USE master;
GO
ALTER SERVER AUDIT NEW_SQL_Server_Audit
WITH (STATE = OFF);
GO

```

It is recommended that you create your audit specifications with scripts so that you can easily manage them and not have to re-create them via SSMS dialogs.

SQL Injection Is Easy to Do

As we previously stated, SQL injection is the number-one security vulnerability globally as reported and tracked by the Open Web Application Security Project (OWASP; www.owasp.org). Because of this continued vulnerability, we decided to show you how to do SQL injection. However, keep in mind that we are showing you how to do it so that you can prevent this situation from happening to you. You need to make sure you include the vulnerability checks as a part of your coding and design reviews. Then this will never happen to you.

If you have a typical .NET forms application that prompts users to provide filter criteria to locate information, this is often a perfect place for hackers to add their own malicious code to do damage. Even your own employees might be hackers or want to cause harm. We call these folks “Evil SQL’ers.”

The most common way SQL injection occurs is with the direct insertion of code into a variable that is part of a SQL statement. In other words, a user-defined variable is concatenated with a partially defined SQL statement and then subsequently executed as part of the application. The hacker adds a terminating character to the first part of the input and then follows it up with his or her own destructive SQL statement.

Let’s consider the following simple Contact Name search application as an example. A .NET forms application might define a variable called `ContactFirstName` and then prompt the end user for a value to search for any contact’s first name that begins with a set of

characters such as “Don.” Such an operation might result in finding “Don,” “Donald,” and “Donny” matching rows. The code might look like this:

```
var ContactFirstName;
ContactFirstName = Request.form ("ContactFirstName");
var sql = "SELECT * FROM [AdventureWorks].[Person].[Contact]
          WHERE [FirstName] like ' ' + ContactFirstName + '%'";
```

The subsequent SQL code that would be submitted to SQL Server for execution would be as follows:

```
SELECT * FROM [AdventureWorks].[Person].[Contact]
WHERE [FirstName] Like 'Don%';
```

This code works perfectly.

To test this code as if you are an “Evil SQL’er,” create a table named `XtraContactsTable` that you can pretend is your primary contacts table where all your company’s contacts are stored. Go ahead and create this empty table for this evil test. The simple `CREATE` statement could be

```
CREATE TABLE [dbo].[XtraContactsTable]
([ContactFirstName] [nvarchar](10) NULL) ON [PRIMARY];
```

To be really evil, attempt to drop this table and cause severe damage to this company using the SQL injection method. Now, at the applications prompt for a contact first name, you, acting as the evil SQL’er, can instead type the following:

```
Don'; drop table [dbo].[XtraContactsTable] --
```

The subsequent SQL code that is sent to SQL Server for execution is

```
SELECT * FROM [AdventureWorks].[Person].[Contact]
WHERE [FirstName] Like 'Don%';
drop table [dbo].[XtraContactsTable] --
```

The first part of the query is executed, followed by the `DROP TABLE` statement. Try this with the table you just created. After you execute the entire “valid” SQL statement, you see rows returned from the first part of the query, and the drop of the `XtraContactsTable` is also executed. If the evil code had simply used the `Employee` table name or the `Contact` table name, all your company’s most sacred data would be gone in a flash.

That is SQL injection! It is easier to do than you think. And now you know how to do it, which means you must also prevent this and other SQL injection vulnerabilities from the beginning. In this case, you should write code to reject quotation marks, specific delimiters (such as `;`), and comment characters such as `--` and `/*...*/`. We have included this SQL code example on the CD with this book as well.

Another popular method by Evil SQL’ers is to put a nasty piece of code into text or char data that will be stored as data in a table. When (or if) the data is ever used as part of a

SQL statement (and concatenated to SQL code as just demonstrated), the code in the data is executed. Pretty tricky! Sort of like a time bomb waiting to explode.

NOTE

For additional examples of SQL injection and SQL coding tips to help prevent SQL injection attacks, see Chapter 43, “Transact-SQL Programming Guidelines, Tips, and Tricks.”

Summary

As stated earlier, best practices for security and compliance must start from the glass and reach through the application, to the database layer, and even to the operating system and the physical file levels. This chapter describes an orderly process to follow as you develop applications that include security and compliance reviews and add testing all along the way. You should never wait until your application is done to start checking for security vulnerabilities; verify adherence to compliance rules or regulations; or determine what data needs to be protected, encrypted, or perhaps not even stored.

Taking advantage of the new SQL Server Auditing feature can be extremely useful in identifying and monitoring compliance of access and usage at the SQL Server database or object levels. Now you know how to do a little damage via SQL injection. You should also know how to prevent this type of damage. Remember, software security is really risk management. It is this risk that must be analyzed thoroughly. After you analyze it, responding in a known situation is always easier. Risks can appear due to architectural problems or with holes in applications (such as with SQL injection). The main aim of software security is to just fall safely and carefully and to limit the damage. We don't want to read about your failing in the newspaper or on Twitter.

In the next chapter, you learn about database backup and restores. To fix damage caused by security issues like those described in this chapter, you may have to restore your database to its state before the attack occurred. We hope that this never happens to you.

CHAPTER 14

Database Backup and Restore

You need to perform database backups to protect your investment in data. Making backups may seem mundane, but consider Murphy's Law ("If anything can go wrong, it will") when you are considering your backup plan. For example, if you forget to add a new database to your backup plan, that database will crash. If you neglect to run a test restore of your backups, those backups will not restore properly. This type of thinking may seem a bit defeatist, but it can help you create a robust backup solution that allows you to sleep comfortably knowing you have a good plan.

Fortunately, SQL Server comes with many different backup and restore options you can use to develop a robust backup plan and avoid those worst-case scenarios. This chapter covers the key considerations in developing a backup and restore plan and then covers the options available with SQL Server to implement that plan.

What's New in Database Backup and Restore

The majority of the backup and restore features that existed in SQL Server 2005 still exist in SQL Server 2008. A few options, however, have been eliminated or deprecated. For example, the backup options used to truncate the transaction log in prior versions are no longer supported.

Specifically, the `NO_LOG` and `TRUNCATE_ONLY` options have been eliminated. The alternative for performing this kind of operation is to set the database recovery model to simple.

Several other deprecated features are still available in SQL Server 2008 but will be removed in a future version of SQL

IN THIS CHAPTER

- ▶ What's New in Database Backup and Restore

- ▶ Types of Backups
- ▶ Recovery Models
- ▶ Backup Devices
- ▶ Backing Up a Database
- ▶ Backing Up the Transaction Log
- ▶ Backup Scenarios
- ▶ Restoring Databases and Transaction Logs
- ▶ Restore Scenarios
- ▶ Additional Backup Considerations

Server. The Tape backup option is one example. The option to set a password on a backup or media-set will be removed in the next version of SQL Server. The protection provided by these passwords is weak, which is the reason they are being removed.

The biggest enhancement in backup and restore is the ability to create a compressed backup. Compressed backups use less space and can be created in less time than conventional backups. The creation of compressed backups can be established server-wide or can be enabled on a single backup using the `COMPRESSION` option. This feature is available only in SQL Server 2008 Enterprise and Developer Editions.

Developing a Backup and Restore Plan

Developing a solid backup and restore plan for SQL Server is one of the most critical tasks an administrator performs. Simply put, if you are a database administrator (DBA) and have a significant loss of data in a database you are responsible for, your job may be on the line. You need to carefully examine the backup needs of your organization, document those needs, and deliver a plan that defines how your backup and restore plan will meet those needs.

The best place to start in identifying the backup requirements is to ask the right questions. The following questions can help drive out the answers you need:

- ▶ How much data loss is acceptable? For example, if you choose to do only full database backups each night, would it be acceptable to lose all the data added to the database during the next day? This could happen if you had a failure and had to restore to the last full backup.
- ▶ What is the nature of the database? For example, is the database used for a data warehouse, or is it used for a high-volume transaction processing system?
- ▶ How often does the data in the database change? Some databases may change very little or not at all during the day but sustain heavy batch updates during the evening.
- ▶ What is the acceptable recovery time in the event a database must be restored from previous backups? This question is directly related to the amount of downtime acceptable for the applications using the database.
- ▶ Is there a maintenance window for the application/database? The maintenance window is typically a period of time when the database or server can be taken offline. What are the exact times of the maintenance windows?
- ▶ What is the size of the database(s) you need to back up?
- ▶ What media is available for backup, and where is the media located?
- ▶ What is the budget for database backup and recovery? If no budget has been established, the answers to some of the preceding questions drive the cost of the solution.

Some of the questions that need to be asked to come up with a good backup and restore plan may raise some eyebrows. For example, you may find that the answer you get for the question “How much data loss is acceptable?” is “None!” Don’t panic. There are sensible

responses for these types of answers. The reality is that you can deliver a solution that virtually eliminates the possibility of data loss—but that comes at a cost. The cost may come in the form of real dollars as well as other costs, such as performance or disk space. As with many other technical solutions, you need to consider trade-offs to come up with the right plan.

NOTE

Many of the questions that relate to database backup and restore are related to system backups as well. System-wide backups, which happen independently of SQL Server backups, capture all or most of the files on a server and write them to appropriate media. These server backups are often performed by DBAs, system administrators, and the like. You should consider having the person or persons responsible for the system backups present when asking the database backup and restore questions. This will help with the coordination and timing of the backups.

When you have the answers to these questions, you need to document them, along with your recommended solution. You should identify any assumptions and make sure to outline any portion of the plan that has not met the requirements.

The good news is that the implementation of the plan is often less difficult than coming up with the plan itself. Microsoft provides a myriad of tools to create database backups that can meet the needs of your organization. The remainder of this chapter focuses on the details required to finalize a solid backup and recovery plan.

Types of Backups

SQL Server offers several different types of backups you can use to restore a database to a former state. Each of these backups uses a file or set of files to capture the database state. The files are found outside the SQL Server database and can be stored on media such as tape or hard disk.

As described in the following sections, these backup types are available with SQL Server 2008:

- ▶ Full database backups
- ▶ Differential database backups
- ▶ Partial backups
- ▶ Differential partial backups
- ▶ File and filegroup backups
- ▶ Copy-only backups
- ▶ Transaction log backups

Full Database Backups

A full database backup is an all-inclusive backup that captures an entire database in one operation. This full backup can be used to restore a database to the state it was in when the database backup completed. The backup is transactionally consistent, contains the entire database structure, and contains the related data stored in these structures.

As with many other backups, SQL Server allows for updates to the database while a full backup is running. It keeps track of the changes occurring during the backup by capturing a portion of the transaction log in the database backup. The backup also records the log sequence number (LSN) when the database backup is started, as well as the LSN when the database backup completes. The LSN is a unique sequential number you can use to determine the order in which updates occur in the database. The LSNs recorded in the backup are used in the restore process to recover the database to a point in time that has transactional consistency.

A full database backup is often used in conjunction with other backup types; it establishes a base for these other types if a restore operation is needed. The other backup types are discussed in the following sections, but it is important not to forget about the full backup that must be restored first in order to utilize other backup types. For example, let's say you are making hourly transaction log backups. If the database is to be recovered using those transaction log backups, the last full database backup must be restored first, and then the subsequent log backups can be applied.

Differential Database Backups

Differential database backups capture changes to any data extent that happened since the last full database backup. The last full database backup is referred to as the *differential base* and is required to make the differential backup useful. Each data extent that is monitored consists of eight physically contiguous data pages. As changes are made to the pages in an extent, a flag is set to indicate that a change has been made to the extent. When the differential database backup is executed, only those extents that have had pages modified are written to the backup.

Differential database backups can save backup space and improve the overall speed of recovery. The savings in space and time are directly related to the amount of change that occurs in the database. The amount of change in the database depends on the amount of time between differential backups. When the number of database changes since the last backup is relatively small, you achieve the best results. If, however, a significant number of changes occur to the data between differential backups, the value of this type of backup is diminished.

Ultimately the number of data pages that are affected by the changes determine the number of pages that must be included in the differential backup. The number of pages is affected by the indexing structure as well as the nature of the updates. If for example,

there are many rows that are changed but those rows are all clustered on a limited number of data pages then the differential backup will not be that large.

Partial Backups

Partial backups provide a means for eliminating read-only data from a backup. In some implementations, a portion of the data in a database may not change and is strictly used for inquiry. If this data is placed on a read-only filegroup, you can use partial backups to back up everything except the read-only data. This technique reduces the size of your backup and reduces the time it takes to complete the backup. The read-only filegroups should still be backed up, but this needs to occur only after the read-only data is loaded.

Differential Partial Backups

Differential partial backups work like differential database backups but are focused on the same type of data as partial backups. The extents that have changed in filegroups that are not read-only are captured in this type of backup. This includes the primary filegroup and any read/write filegroups defined at the time of the backup. Like differential database backups, these backups also require a differential base, but it must be a single differential base. In other words, multiple base backups that have been taken at different times for different database files will not work. You must use a single base backup that encompasses all of the database files.

File and Filegroup Backups

File and filegroup backups are targeted at databases that contain more than one filegroup. In these situations, the filegroup or files in the filegroups can be backed up independently. If a filegroup is backed up, all the files defined in the filegroup are backed up.

File and filegroup backups are often used for larger databases where the creation time for a full database backup takes too long or the resulting backup is too large. In these situations, you can stagger the backups of the files or filegroups and write them to different locations.

The main disadvantage of this type of backup is the increase in administrative overhead. Each of the files in the database must be backed up, and a complete set of these files must be retained to restore the database. For a full recovery model, the transaction log backups must also be retained.

NOTE

SQL Server 2008 supports file and filegroup backups for all recovery models, including simple recovery. The catch with simple recovery is that the files and filegroups are limited to read-only secondary filegroups. SQL Server 2000 did not allow these types of backups with simple recovery.

Copy-Only Backups

Copy-only backups allow a backup of any type to be taken without affecting any other backups. Normally, a database backup is recorded in the database itself and is identified as part of a chain that can be used for restore. For example, if a full database backup is taken, any subsequent differential database backups use this full database backup as their base. A restore process utilizing the differential database backups would have a reference to the full database backup, and that backup would have to be available.

Copy-only backups do not affect the restore chain. They are useful in situations in which you simply want to get a copy of the database for testing purposes or things of this nature. Microsoft has made it easier to make this kind of backup by adding the Copy Only Backup check box when performing a backup using SQL Server Management Studio (SSMS). In SQL Server 2005, the Copy Only Backup had to be performed via the Transact-SQL (T-SQL) `BACKUP` command. An example of the copy-only backup is provided later in this chapter, in the section “Backing Up a Database.”

Transaction Log Backups

Transaction log backups capture records written to the transaction log file(s) defined for a database. The full and bulk-logged recovery models are the only models that support transaction log backups. These models cause transaction events to be retained in the transaction log so that they can be backed up. Simple recovery mode causes the transaction log to be truncated periodically and thus invalidates the usefulness of the transaction log backups.

The transaction log backups and their strong ties to the recovery model are discussed in more detail in the next section.

Recovery Models

Each database has a recovery model that determines how transactions will be written to the transaction log. The recovery model you choose has a direct impact on your ability to recover from a media failure. These following three recovery models are available with SQL Server 2008:

- ▶ Full recovery
- ▶ Bulk-logged
- ▶ Simple

You set the recovery model via T-SQL or the Database Properties window in SSMS. The following example shows the T-SQL command you can use to change the AdventureWorks2008 database to the bulk-logged model:

```
ALTER DATABASE [AdventureWorks2008] SET RECOVERY BULK_LOGGED WITH NO_WAIT
```

Figure 14.1 shows the Options page on the Database Properties window, which also allows you to select a recovery model.

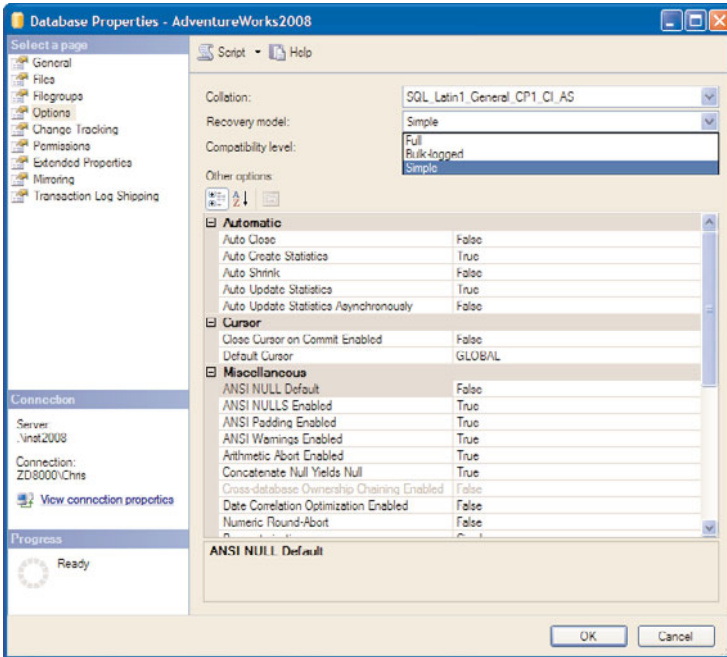

FIGURE 14.1 Setting the recovery model in SSMS.

Full Recovery

The full recovery model gives you the most protection against data loss. A database set to full recovery will have all database operations written to the transactions log. These operations include insertions, updates, and deletions, as well as any other statements that change the database. In addition, the full recovery model captures any database inserts that are the result of a BCP command or BULK INSERT statement.

In the event of a media failure, a database that is in full recovery can be restored to the point in time at which the failure occurred. Your ability to restore to a point in time is dependent on your database backup plan. If a full database backup is available, along with the transaction log backups that occurred after the full database backup, you can recover to the point of the last transaction log backup. In addition, if your current transaction log is available, you can restore up to the point of the last committed transaction in the transaction log.

This recovery model is the most comprehensive, but in some respects, it is the most expensive. It is expensive in terms of the transaction log space needed to capture all the database operations. The space can be significant with databases that have a lot of update activity or with databases that have large bulk load operations. It is also expensive in

terms of server overhead because every transaction is captured and retained in the transaction log so that they can be recovered in the event of a failure.

TIP

A common problem in SQL Server environments involves a database that is set to full recovery but whose transaction log is never backed up. In this scenario, the transaction log can grow to the point that it fills up the drive on which the transaction log is located. You need to ensure that you have regularly scheduled backups of the transaction log if you have set your database to full recovery. The transaction log backups allow you to recover from a media failure and also remove the inactive portion of the transaction log so that it does not need to grow.

Bulk-Logged Recovery

The bulk-logged recovery model is similar to full recovery, but it differs in the way that bulk operations are captured in the transaction log. With full recovery mode, SQL Server writes every row to the transaction log that is inserted with BCP or BULK INSERT. Bulk-logged recovery keeps track of the extents that have been modified by a bulk load operation but does not write each row to the transaction log. This reduces the overall size of the transaction log during bulk load operations and still allows the database to recover after a bulk load operation has occurred.

The biggest downside to setting a database to bulk-logged recovery is that the log backups for the databases can be large. The log backups are large because SQL Server copies all the data extents that have been affected by bulk load operations since the last backup of the transaction log. Remember that data extents consist of eight data pages each, and each page is 8KB in size. This may not seem like much by today's standards, but it can be significant when you're bulk loading a large table. For example, consider a table occupying 1GB of space that is truncated each week and reloaded with a bulk insert. The bulk insert operation goes relatively fast because the rows are not being written to the transaction log, but the backup of the transaction log is much larger.

NOTE

In testing we did on a table with approximately 2.4 million rows (that occupied 500MB of space), the log file grew over 2GB during a bulk insert operation that reloaded all rows in a full recovery mode database. In contrast, the same bulk insert operation on the database with bulk-logged recovery grew the log by only 9MB. However, the backup of the 9MB transaction log was approximately 500MB. This is much larger than the actual log itself because the bulk operation caused all the modified extents from the bulk insert operation to be stored in the log backup as well.

The other downside to bulk-logged recovery is that with it, you may sacrifice the ability to restore to the most recent point in time. This situation occurs if a bulk insert operation

has occurred since the last database backup and a media failure occurs. In this case, the restores can occur for any backups that were taken that do not contain a bulk insert operation, but any outstanding changes that were retained in the transaction log cannot be applied. The reason is that bulk operations are not written to the log directly in this model and cannot be recovered. Only bulk operations captured in a backup can be restored.

If transactions have occurred in a database since the last backup, and no bulk insert operations have occurred, you can recover those pending transactions as long as the media containing the transaction log is still available. The tail of the transaction log can be backed up and applied during a restore operation. The tail of the log and other restore scenarios are discussed in the “Restore Scenarios” section, later in this chapter.

Simple Recovery

The simple recovery model is the easiest to administer, but it is the option that has the greatest possibility for data loss. In this mode, your transactions log is truncated automatically based on a checkpoint in the database. These checkpoints happen often, and they cause the data in the transaction log to be truncated frequently.

NOTE

Prior to SQL Server 2000, the `trunc. log on checkpoint database` option was used to truncate the log on a checkpoint and produce the same type of behavior as simple recovery. This database option and the equivalent backup options `NO_LOG` and `TRUNCATE_ONLY` are no longer supported. The only supported method for truncating the transaction log in SQL Server 2008 is to switch the database to use the simple recovery model.

The most important point to remember about the simple recovery model is that with it, you cannot back up the transaction log that captures changes to your database. If a media failure occurs, you are not able to recover the database activity that has occurred since the last database backup. This is a major exposure, so simple recovery is not recommended for production databases. However, it can be a good option for development databases where the loss of some transactions is acceptable. In these types of environments, simple recovery can equate to saved disk space because the transaction log is constantly truncated. The administration in these environments is reduced as well because the transaction log backups are not an option and thus do not need to be managed.

For a more detailed discussion of the transaction log, see Chapter 31, “Transaction Management and the Transaction Log.”

Backup Devices

A backup device is used to provide a storage destination for the database backups created with SQL Server. Backups can be written to logical or physical devices. A logical device is essentially an alias to the physical device and makes it easier to refer to the device when

performing database backups. The physical backup devices that SQL Server can write to include files on local disks, tape, and network shares.

Disk Devices

A disk device is generally stored in a folder on a local hard drive. This should not be the same hard drive where your data is stored! Disk devices have several advantages, including speed and reliability. If you have ever had a backup fail because you forgot to load a tape, you can appreciate the advantage of disk backups. On the other hand, if backups are stored on a local disk and the server is destroyed, you lose your backups as well.

NOTE

Disks have become increasingly popular media as the prices have fallen. Storage area networks (SANs) and other large-scale disk solutions have entered mainstream usage and offer a large amount of storage at a relatively inexpensive price. They also offer redundancy and provide fault tolerance to mitigate the chance of losing data on a disk. Finally, increased network bandwidth across LANs and WANs has allowed for the movement of backups created on disk to alternate locations. This is a simple way to achieve additional fault tolerance.

Tape Devices

Tape devices are used to back up to tape. Tape devices must be directly connected to the server, and parallel backups to multiple drives are supported to increase throughput. Tape backups have the advantage of being scalable, portable, and secure. Scalability is important as a database grows; available disk space often precludes the use of disk backups for large databases. Because tapes are removable media, they can easily be transported offsite, where they can be secured against theft and damage.

SQL Server supports the Microsoft Tape Format (MTF) for backup devices, which means that SQL Server backups and operating system backups can share the same tape. This capability is convenient for small sites with shared use servers and only one tape drive. You can schedule your SQL Server backups and file backups without having to be onsite to change the tape.

Network Shares

SQL Server 2008 allows the use of both mapped network drives and Universal Naming Convention (UNC) paths in the backup device filename. A mapped network drive must be mapped as a network drive in the session in which SQL Server is running. This is prone to error and generally not recommended. UNC paths are much simpler to administer. With UNC backup devices, the SQL Server service account must be able to see the UNC path on the network. This is accomplished by granting the service account full control permission on the share or by making the service account a member of the Administrators group on the remote computer.

Keep in mind that backups performed on a network share should be done on a dedicated or high-speed network connection, and the backup should be verified to avoid potential

corruption introduced by network error. The time it takes a backup to complete over the network depends on network traffic, so you need to take this factor into consideration when planning your backups.

Media Sets and Families

When you're backing up to multiple devices, the terms *media set* and *media family* are used to describe the components of the backup. A *media set* is the target destination of the database backup and comprises several individual media. All media in a media set must be of the same type (for example, all tape or all disk). A *media family* is the collection of media associated with an individual backup device. For example, a media family could be a collection of five tapes contained in a single tape device.

The first tape in the media family is referred to as the *initial* media, and the subsequent tapes are referred to as *continuation* media. All the media families combined are referred to as the *media set*. If, for example, a backup is written to 3 backup devices (each with 4 tapes), the media set would contain 3 media families and consist of a total of 12 tapes. It is recommended to use the `MEDIA_NAME` parameter of the `BACKUP` command to specify a name for the media set. This parameter associates the multiple devices as members of the media set. The `MEDIA_NAME` parameter can then be referenced in future backup operations.

Creating Backup Devices

You can create logical backup devices by using T-SQL or SSMS. The T-SQL command for creating these logical backup devices is `sp_addumpdevice`, which has the following syntax:

```
sp_addumpdevice [ @devtype = ] 'device_type'
                , [ @logicalname = ] 'logical_name'
                , [ @physicalname = ] 'physical_name'
                [ , { [ @cntrltype = ] controller_type |
                    [ @devstatus = ] 'device_status' }
                ]
```

The following sample script demonstrates the creation of the different types of backup devices:

```
-- Local Disk
EXEC sp_addumpdevice 'disk', 'diskdev1',
    'c:\mssql12008\backup\AdventureWorks2008.bak'
-- Network Disk
EXEC sp_addumpdevice 'disk', 'networkdev1',
    '\\myserver\myshare\AdventureWorks2008.bak'
-- Tape
EXEC sp_addumpdevice 'tape', 'tapedev1', '\\.\tape0'
```

To create backup devices with SSMS, you navigate to the `Server Objects` node in the Object Explorer and right-click `Backup Devices` and then `New Backup Device`; the Backup

Device screen appears. This screen includes a text box for the device name, along with a section to select the destination for the device. This is the physical location, and you can select either Tape or File.

Backing Up a Database

Now that you know the types of backups, the recovery models they relate to, and the devices you can write to, you are ready to back up your database. You can create backups with SQL Server 2008 by using either the SSMS or T-SQL. Some backups are supported only through T-SQL, but the vast majority can be accomplished with either tool.

Creating Database Backups with SSMS

The backup options in SSMS are accessible through the Object Explorer. For example, you can right-click the AdventureWorks2008 database in the SSMS Object Explorer, select Tasks and Backup, and a backup window like the one shown in Figure 14.2 appears.

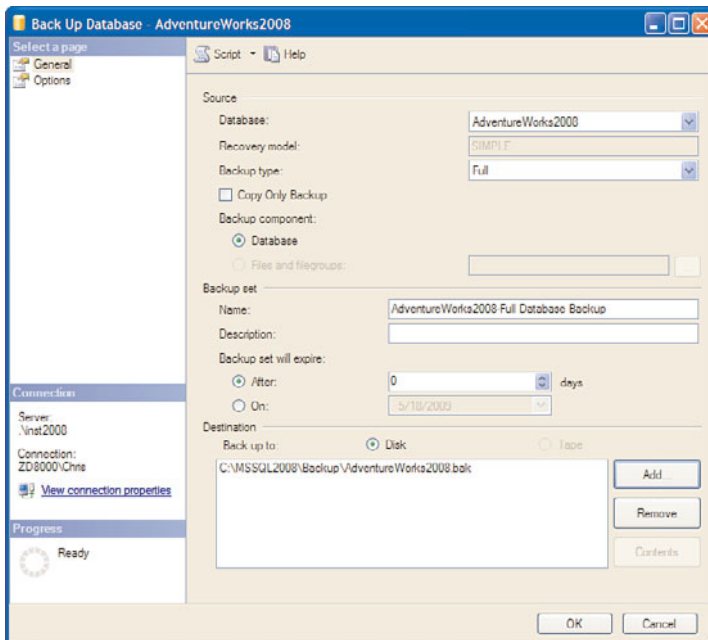

FIGURE 14.2 The Back Up Database window in SSMS.

The Source section on the Back Up Database window contains information relative to the database that will be backed up. The target database is displayed in the first drop-down, along with the recovery model set for the database. The backup types available in the drop-down are dependent on the recovery model. For simple recovery, only full and differ-

ential backup types are available. For full recovery and bulk-logged recovery models, all backup types are available in the drop-down.

The Backup Set section allows you to give the backup a meaningful name and specify when the backup set will expire. When the backup set expires, the backup can be overwritten and is no longer retained. If the backup is set to expire after 0 days, it will never expire.

The Destination section identifies the disk or tape media that will contain the backup. You can specify multiple destinations in this section by clicking the Add button. For disk media, you can specify a maximum of 64 disk devices. The same limit applies to tape media. If multiple devices are specified, the backup information is spread across those devices. All the devices must be present for you to be able to restore the database. If no tape devices are attached to the database server, the Tape option is disabled.

You can select several different types of options for a database backup. Figure 14.3 shows the options page available when you back up a database by using SSMS.

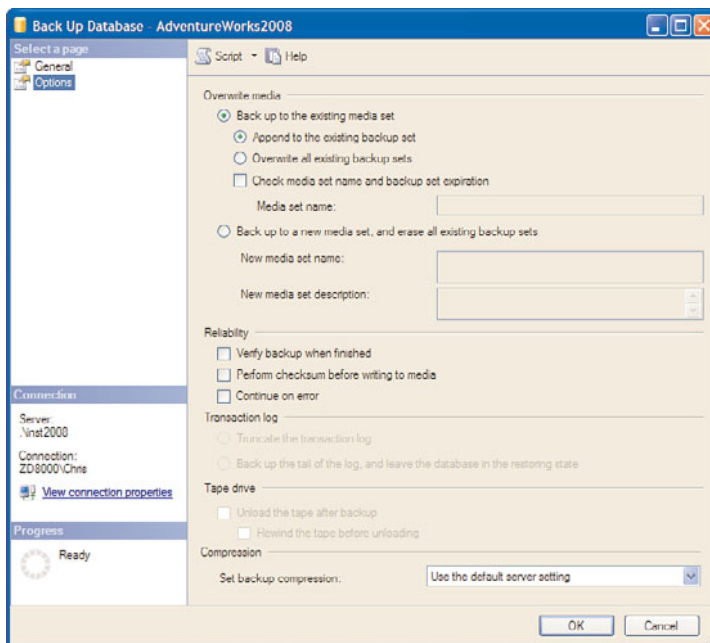

FIGURE 14.3 The Back Up Database Options page in SSMS.

The Overwrite Media section allows you to specify options relative to the destination media for the backup. Keep in mind that a given media set can contain more than one backup. This can occur if the Append to the Existing Backup Set options is selected. With this option, any prior backups contained on the media set are preserved, and the new backup is added to it. With the Overwrite All Existing Backup Sets option, the media set contains only the latest backup, and no prior backups are retained.

You can use the options in the Reliability section to ensure that the backup that has been created can be used reliably in a restore situation. Verifying the backup when finished is highly recommended, but doing so causes the backup time to be extended during the verification. Similarly, the Perform Checksum Before Writing to Media option helps ensure that you have a sound backup, but again, it causes the database backup to run longer.

The options in the Transaction Log section are available for databases in the full recovery or bulk-logged model. These options are disabled in the simple recovery model. The Truncate the Transaction Log option causes any inactive portion of the transaction log to be removed after the database backup is complete. The inactive portion of the log and other detail of the transaction log are discussed in more detail in Chapter 30 “Transaction Management and the transaction log”. This option, the default, helps keep the size of the transaction log manageable. The Back Up the Tail of the Log option is related to point-in-time restores and is discussed in more detail in the “Restore Scenarios” section later in this chapter.

The set of options in the Tape Drive section are enabled only when tape has been selected for the destination media. Selecting the Unload the Tape After Backup option causes the media tape to be ejected when the backup completes. This option can help identify the end of a backup and prevent the tape from being overwritten the next time the backup runs. The Rewind the Tape Before Unloading option is self-explanatory; it causes the tape to be released and rewound before you unload the tape. The last set of options relate to compressed database backups. The options for compressed backups are discussed in detail in the Compressed Backup section later in this chapter.

NOTE

Keep in mind that all backups can be performed while the database is in use. SQL Server is able to keep track of the changes occurring during the backup and can maintain transactional consistency as of the end of the backup. You need to consider some performance overhead during the actual backup, but the backup can occur during active database hours. However, it is still a good idea to schedule your database backups during off-hours, when database activity is at a minimum.

Creating Database Backups with T-SQL

The T-SQL `BACKUP` command offers a myriad of options to perform all the backup operations available in SSMS. However, SSMS does not support some backup operations that can be performed only with T-SQL.

The `BACKUP` command comes in three different flavors. The first flavor involves the backup of a database. The command syntax starts with `BACKUP DATABASE`, followed by the relevant parameters and options. The second flavor involves the backup of a file or filegroup that is part of the database. The command syntax for this type of backup also utilizes the `BACKUP`

DATABASE command, but a file or filegroup is specified after the database name to identify which parts of the database should be backed up. The last flavor involves the backup of the database's transaction log. The syntax for backing up the transaction log starts with BACKUP LOG. Each flavor shares many of the same options. The basic syntax for backing up a database follows:

```
BACKUP DATABASE { database_name | @database_name_var }
TO < backup_device > [ ,...n ]
[ [ MIRROR TO < backup_device > [ ,...n ] ] [ ...next-mirror ] ]
[ WITH
    [ BLOCKSIZE = { blocksize | @blocksize_variable } ]
    [ [ , ] { CHECKSUM | NO_CHECKSUM } ]
    [ [ , ] COMPRESSION | NO_COMPRESSION ]
    [ [ , ] COPY_ONLY ]
    [ [ , ] { STOP_ON_ERROR | CONTINUE_AFTER_ERROR } ]
    [ [ , ] DESCRIPTION = { 'text' | @text_variable } ]
    [ [ , ] DIFFERENTIAL ]
    [ [ , ] EXPIREDATE = { date | @date_var }
    | RETAINDAYS = { days | @days_var } ]
    [ [ , ] PASSWORD = { password | @password_variable } ]
    [ [ , ] { FORMAT | NOFORMAT } ]
    [ [ , ] { INIT | NOINIT } ]
    [ [ , ] { NOSKIP | SKIP } ]
    [ [ , ] MEDIADescription = { 'text' | @text_variable } ]
    [ [ , ] MEDIANAME = { media_name | @media_name_variable } ]
    [ [ , ] MEDIAPASSWORD = { mediapassword | @mediapassword_variable } ]
    [ [ , ] NAME = { backup_set_name | @backup_set_name_var } ]
    [ [ , ] { NOREWIND | REWIND } ]
    [ [ , ] { NOUNLOAD | UNLOAD } ]
    [ [ , ] RESTART ]
    [ [ , ] STATS [ = percentage
] ]
]
```

The number of options is extensive, but many of them are optional. A BACKUP DATABASE command can be as simple as the following example:

```
BACKUP DATABASE [AdventureWorks2008]
TO DISK = N'C:\mssql12008\backup\AdventureWorks2008_COPY.bak'
```

The first part of the BACKUP command is related to the database you want to back up (*database_name*), followed by the location to which you want to write the backup (*backup_device*). The remainder of the syntax relates to the options that can be specified following the WITH clause. These options determine how your backup will be created and the properties of the resulting backup. Table 14.1 outlines these options.

TABLE 14.1 **BACKUP DATABASE** Options

Option	Description
BLOCKSIZE	The physical block size that will be used to create the backup. The default is 64KB.
CHECKSUM NO_CHECKSUM	When CHECKSUM is specified, a checksum is calculated before the backup is written to validate that the backup is not corrupt. The default is NO_CHECKSUM.
COMPRESSION NO_COMPRESSION	This new option in SQL Server 2008, available only with the Enterprise or Developer Edition, causes the backup file to be compressed. The default is NO_COMPRESSION.
STOP_ON_ERROR CONTINUE_AFTER_ERROR	This option is used in conjunction with the CHECKSUM option. The STOP_ON_ERROR option, which is the default, causes the backup to fail if the checksum cannot be validated.
DESCRIPTION	This is a 255-character description of the backup set.
DIFFERENTIAL	This option causes a differential backup to occur, which captures changes only since the last backup.
EXPIREDATE	This option specifies the date on which the backup set will expire and be overwritten.
RETAINDAYS	This option specifies the number of elapsed days before the backup set can be overwritten.
PASSWORD	This is a password that must be specified when restoring the backup set.
FORMAT NOFORMAT	FORMAT causes the existing media header and backup set to be overwritten. The default is NOFORMAT.
INIT NOINIT	The INIT option causes a backup set to be overwritten. The backup set is not overwritten if the backup set has not expired or if it does not match the media name specified with the NAME option. NOINIT, which is the default, causes the backup set to be appended to the existing media.
NOSKIP SKIP	NOSKIP, which is the default, allows backup sets to be overwritten if they have expired. The SKIP option skips expiration and media name checks and is used to prevent the overwriting of backup sets.
MEDIADescription	This is a 255-character description for the entire backup media containing the backup sets.

TABLE 14.1 **BACKUP DATABASE** Options

Option	Description
MEDIA_NAME	This is a 128-character name for the backup media. If it is specified, the target media must match this name.
MEDIA_PASSWORD	This is a password for the media set. When media is created with this password, the password must be supplied to be able to create a backup set on that media or to restore from that media.
NAME	This is a 128-character name for the backup set.
NOREWIND REWIND	This option is used for tape operations. REWIND, which is the default, causes the tape to be released and rewound after it fills.
NOUNLOAD UNLOAD	This option is used for tape operations. NOUNLOAD, which is the default, causes the tape to remain in the tape drive after a backup completes. UNLOAD causes the tape to be rewound and unloaded when the backup completes.
RESTART	This option has no effect and is in place only for backward compatibility.
STATS	This option causes completion statistics to be displayed at the specified interval to assess progress.
COPY_ONLY	This option allows a backup to be made without affecting the normal sequence of backups.

The “Backup Scenarios” section, later in this chapter, provides some examples of how to use these options.

Backing Up the Transaction Log

As discussed, the full and bulk-logged recovery models cause transactions to be written to the database’s transaction log. These transactions should be backed up periodically for two main reasons. First, the transaction log backups can be used in case of a media failure to restore work completed in the database. These backups limit your exposure to data loss and enable you to reapply changes that have occurred.

The second reason for backing up the transaction log is to keep the size of the log manageable. Keep in mind that SQL Server is a write-ahead database management system (DBMS) and thus writes most changes to the transaction log first, before it updates the actual data files. This type of DBMS is great for recovery purposes, but it can be a real headache if you do not periodically clear those transactions from the log. Without a

backup or manual truncation, the log can fill to a point where it will use up all the space on your disk.

Creating Transaction Log Backups with SSMS

The same backup screen utilized for database backups in SSMS can also be used for transaction log backups. Figure 14.4 shows the Back Up Database window with Transaction Log selected as the backup type. A device must be selected to write the backup to, and some additional options on the Options page that relate to the transaction log are enabled.

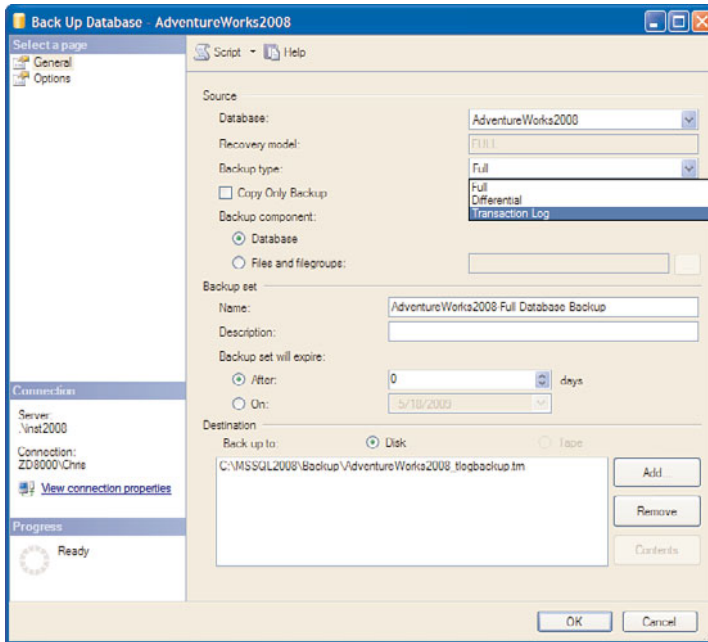

FIGURE 14.4 Backing up the transaction log in SSMS.

Creating Transaction Log Backups with T-SQL

When you back up a transaction log by using T-SQL, you use the `BACKUP LOG` command, which includes all the previously listed options except the `DIFFERENTIAL` option.

(Differential backups do not apply to transaction logs.) Several additional options are available for transaction log backups. The following abbreviated syntax for the `BACKUP LOG` command shows the options used exclusively for backing up transaction logs:

```
BACKUP LOG { database_name | @database_name_var }
TO < backup_device > [ ,...n ]
[ [ MIRROR TO < backup_device > [ ,...n ] ] [ ...next-mirror ] ]
[ WITH
```

```
....  
[ [ , ] NO_TRUNCATE ]  
[ [ , ] { NORECOVERY | STANDBY = undo_file_name } ]
```

The options specific to BACKUP LOG are discussed in detail in the following sections.

The NO_TRUNCATE Option

You use the NO_TRUNCATE option when the log is available, but the database is not. This option prevents the truncation of the transaction log after a backup occurs. Under normal circumstances, the BACKUP LOG command not only writes to the transaction log, but also signals a checkpoint for the database to flush any dirty buffers from memory to the database files. This behavior becomes a problem when the media containing the database is unavailable and you must capture the current contents of a log to a backup file for recovery. If you last did a log backup four hours ago, this would mean the loss of all the input since then. If your log is on a separate disk that is not damaged, you have those four hours of transactions available to you, but BACKUP LOG fails because it can't run a checkpoint on the data files. You run BACKUP LOG with the NO_TRUNCATE option, and the log is backed up, but the checkpoint is not run because the log is not actually cleared. You now have this new log backup to restore as well, enabling recovery to the time of failure. The only transactions lost are those that were not yet committed.

The NORECOVERY | STANDBY=*undo_file_name* Options

The NORECOVERY option causes the tail of the log to be backed up and leaves the database in a RESTORING state, which allows additional transaction logs to be applied, if necessary. The tail of the log is the active portion of the log that contains transactions not yet backed up. This "tail" is critical in restore situations in which all committed transactions are reapplied. Typically, the NORECOVERY option is used with the NO_TRUNCATE option to retain the contents of the log.

The STANDBY option also backs up the tail of the log, but it leaves the database in a read-only/standby state. The read-only state allows inquiry on the database and allows additional transaction logs to be applied to the database as well. *undo_file_name* must be supplied with the STANDBY command so that transactions not committed and rolled back at the time of the backup can be reapplied if additional transaction logs are applied to the database. This STANDBY option produces the same results as executing BACKUP LOG WITH NORECOVERY followed by a RESTORE WITH STANDBY command.

NOTE

As mentioned earlier, Microsoft has removed the NO_LOG and TRUNCATE_ONLY options available with earlier versions of SQL Server, including SQL Server 2005. Setting a database to use the simple recovery model is the alternative to these options.

Backup Scenarios

Typically, several different types of backups are used in a comprehensive backup plan. These backups are often combined to produce maximum recoverability while balancing the load on the system and amount of time to recover the database. The following backup scenarios outline some of the ways SQL Server backups are used.

NOTE

Many of the examples that follow utilize a backup directory named `c:\mssql12008\backup`. If you are interested in running some of these examples on your own system, you need to create this directory on the database server first before running the scripts that reference this directory. You can use backup and data directories different from the default directory to simplify the directory structure for the SQL Server files. Typically, these directories should not be on the C: drive, but the C: drive is used here for simplicity.

Full Database Backups Only

A full database backup, without the use of other database backups, is often found in nonproduction environments where the loss of transactional data is relatively unimportant. Some development environments are good examples of this. In these environments, a nightly full backup is sufficient to ensure that recent Data Definition Language (DDL) changes and the related development data for the day are captured. If a catastrophic failure occurs during the day and causes a restore to occur, the database can be restored from the prior night's backup. The following example shows a full backup of the `AdventureWorks2008` database:

```
--Full Database Backup to a single disk device
BACKUP DATABASE [AdventureWorks2008]
  TO DISK = N'C:\mssql12008\backup\AdventureWorks2008.bak'
  WITH NOFORMAT, INIT, NAME = N'AdventureWorks2008-Full Database Backup',
  SKIP, NOREWIND, NOUNLOAD, STATS = 10
```

The sole use of daily full database backups needs to be carefully considered. The benefits of limited administration and limited backup space requirements have to be weighed against the costs of losing an entire day's transactions.

Full Database Backups with Transaction Log Backups

Compared to making a full database backup only, a more comprehensive approach to database backups includes the use of transaction log backups to augment the recoverability of full database backups. Transaction log backups that are taken periodically capture incremental database activity that can be applied to a full database backup during database restore.

You need to measure the frequency of the transaction log backup against the tolerance for data loss. For example, if the requirement is to prevent no more than one hour's worth of

work, the transaction log backups should be taken hourly. If the media on which the backup is stored is accessible, you should lose no more than one hour's worth of data.

As mentioned earlier, the database must be placed in full or bulk-logged recovery mode to capture transaction log backups. Listing 14.1 shows the commands necessary to place the AdventureWorks2008 database in full recovery mode, the required backup to establish a base, followed by the command to perform the actual transaction log backup.

LISTING 14.1 Full Backups with Transaction Logs

```
--First need to change the recovery model from simple to full
--so that the tlogs are available for backup
ALTER DATABASE [AdventureWorks2008] SET RECOVERY FULL WITH NO_WAIT

--*** A Full database backup must be taken after the
--*** recovery mode has been changed
--*** in order to set a base for future tlog backups.
--*** If the full backup is not taken
--*** then tlog backups will fail.
--The Following full backup utilizes two devices on the same drive.
--Often times multiple devices are backed up to different drives.
--Backing up to different drives
-- can speed up the overall backup
time and help when you are running low on space on a drive
-- where your backups are written.

BACKUP DATABASE [AdventureWorks2008]
  TO DISK = N'C:\mssql12008\backup\AdventureWorks2008_Full_Dev1.bak',
  DISK = N'C:\mssql12008\backup\AdventureWorks2008_Full_Dev2.bak'
  WITH NOFORMAT, NOINIT, SKIP, NOREWIND, NOUNLOAD, STATS = 10

--Transaction log backups can be taken now that a base has been established
--The following tlog backup is written to a single file
BACKUP LOG [AdventureWorks2008]
  TO DISK = N'C:\mssql12008\backup\log\AdventureWorks2008_FirstAfterFull.trn'
  WITH NOFORMAT, INIT, NAME = N'AdventureWorks2008-Transaction Log Backup',
  SKIP, NOREWIND, NOUNLOAD, STATS = 10, CHECKSUM
```

Differential Backups

Differential backups can be used to reduce the amount of time required to restore a database and can be particularly useful in environments where the amount of data that changes is limited. Differential backups capture only the database extents that have changed since the last database backup—typically, a full database backup.

The addition of differential backups to a plan that includes full database backups and transaction log backups can significantly improve the overall recovery time. The differential database backup eliminates the need to apply any transaction log backups that have occurred from the time of the last full backup up until the completion of the differential backup. Figure 14.5 depicts a backup plan that includes full database backups, transaction log backups, and differential backups. The differential backups are executed on a daily basis between the full backups.

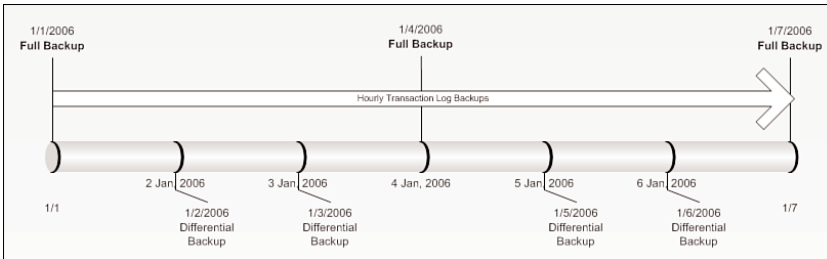

FIGURE 14.5 A backup plan that includes differential backup.

It is important to remember that differential backups are cumulative and contain all changes since the last differential base. There is no need to apply previous differential backups if the new differential base has not been established. For example, in the backup plan shown in Figure 14.5, if a media failure occurred in the middle of the day on January 3, the differential backup that would be used is the one taken at the beginning of the day on January 3; the differential backup that occurred on January 2 would not be needed. The full backup from January 1, the differential from January 3, and any transaction log backups that had occurred since the differential on January 3 would be used to restore the database.

You can create differential backups by using SSMS or T-SQL. The following example demonstrates the creation of a differential backup for the AdventureWorks2008 database using T-SQL:

```
BACKUP DATABASE [AdventureWorks2008]
TO DISK = N'C:\mssql12008\backup\AdventureWorks2008_Diff2.bak'
WITH DIFFERENTIAL , NOFORMAT, INIT,
NAME = N'AdventureWorks2008-Differential Database Backup',
SKIP, NOREWIND, NOUNLOAD, STATS = 10
```

Partial Backups

Partial backups are useful when read-only files or filegroups are part of a database. Listing 14.2 contains the commands necessary to add a read-only filegroup to the AdventureWorks2008 database. The commands in Listing 14.2 do not perform a partial

backup, but they do modify a sample database so that a partial database would make sense.

LISTING 14.2 Adding a Read-Only Filegroup to a Database

```
--Need to add a read only filegroup first to demonstrate
ALTER DATABASE AdventureWorks2008
ADD FILEGROUP ReadOnlyFG1
GO
-- Add a file to the Filegroup
ALTER DATABASE AdventureWorks2008
ADD FILE
(
    NAME = AdventureWorks2008_ReadOnlyData,
    FILENAME = 'C:\mssql12008\data\AdventureWorks2008_ReadOnlyData.ndf',
    SIZE = 5MB,
    MAXSIZE = 100MB,
    FILEGROWTH = 5MB) TO FILEGROUP ReadOnlyFG1
go
--Create a table on the ReadOnly filegroup
CREATE TABLE AdventureWorks2008.dbo.MyReadOnlyTable
(
    FirstName varchar(50),
    LastName varchar(50),
    EMailAddress char(1000) )
ON ReadOnlyFG1

--Insert some data into the new read only Filegroup
insert AdventureWorks2008.dbo.MyReadOnlyTable
select LastName, FirstName, 'xxx'
from AdventureWorks2008.person. person

--Make the filegroup readonly
ALTER DATABASE [AdventureWorks2008] MODIFY FILEGROUP [ReadOnlyFG1] READONLY
```

When you have a filegroup that contains read-only data, a partial backup can be valuable. The partial backup by default excludes any read-only filegroups and backs up only the read/write data that could have changed.

Listing 14.3 contains three separate backup commands that relate to the partial backup. The first backup command is not a partial backup but instead backs up the read-only filegroup. If the read-only filegroup is not backed up prior to the partial backup, the read-only filegroup is backed up, as is part of the partial backup. The second backup command creates the actual partial backup. The key parameter in this backup is `READ_WRITE_FILEGROUPS`, which causes the backup to skip the read-only data. The third backup command in Listing 14.3 shows that it is possible to perform a partial backup that includes the read-only data as well. This command includes a specific reference to the read-only filegroup, which causes it to be backed up as well.

LISTING 14.3 Making a Partial Backup

```
--Need to backup the readonly filegroup that was created
-- or it will be included in the partial backup
BACKUP DATABASE [AdventureWorks2008]
FILEGROUP = N'ReadOnlyFG1'
TO DISK = N'C:\mssql2008\backup\AdventureWorks2008_ReadOnlyFG.bak'
WITH NOFORMAT, NOINIT, NAME = N'AdventureWorks2008-Full Filegroup Backup',
SKIP, NOREWIND, NOUNLOAD, STATS = 10

--Create the Partial Database Backup
--It will not contain the data from readonly filegroup
--The partial database backup can be restored without affecting
-- the data in the readonly filegroup
BACKUP DATABASE [AdventureWorks2008] READ_WRITE_FILEGROUPS
TO DISK = N'C:\mssql2008\backup\AdventureWorks2008_Partial.bak'
WITH NOFORMAT, INIT, NAME = N'AdventureWorks2008-Partial Database Backup',
SKIP, NOREWIND, NOUNLOAD, STATS = 10

--It is possible to backup the readonly filegroup(s) as well
--by listing the readonly filegroups in the backup command as shown in the
--following backup command
BACKUP DATABASE [AdventureWorks2008] FILEGROUP = 'ReadOnlyFG1',
READ_WRITE_FILEGROUPS
TO DISK = N'C:\mssql2008\backup\AdventureWorks2008_Partial_WithReadOnly.bak'
WITH NOFORMAT, INIT, NAME = N'AdventureWorks2008-Partial Database Backup',
SKIP, NOREWIND, NOUNLOAD, STATS = 10
```

File/Filegroup Backups

Much of our discussion thus far has focused on backing up an entire database, but it is possible to back up only particular files or a group of files in a filegroup. A SQL Server database, by default, has only two files: the data file (with the file extension `.mdf`) and the log file (with the extension `.ldf`). You can add additional files and filegroups that contain these files to extend the database beyond the original two files. These additional files are often data files added to larger databases that require additional space. With very large databases, performing a full backup that contains all the database files can take too much time. In such a case, the individual files or filegroups can be backed up separately, enabling you to spread out the backup.

Listing 14.4 shows the T-SQL command that can be used to back up the read-only file you added to the AdventureWorks2008 database in Listing 14.3.

LISTING 14.4 Creating a File Backup

```

BACKUP DATABASE [AdventureWorks2008] FILE = 'AdventureWorks2008_ReadOnlyData'
  TO DISK = N'C:\mssql12008\backup\AdventureWorks2008_ReadOnlyData.bak'
  WITH NOFORMAT, INIT, NAME = N'AdventureWorks2008-ReadOnly File Backup',
  SKIP, NOREWIND, NOUNLOAD, STATS = 10

```

There is some additional administrative overhead associated with file and filegroup backups. Unlike a full database backup that produces one file that contains the entire database, the file backups do not stand by themselves and require other backups to be able to create the entire database. You need to keep the following points in mind when performing file and filegroup backups:

- ▶ A file or filegroup backup does not back up any portion of the transaction log. To restore a file or filegroup backup, you must have the transaction log backups since the last file or filegroup backup, including the tail of the log, for the database system to ensure transactional consistency. This also implies that the database must be in full or bulk-logged recovery because these are the only models that support transaction log backups.
- ▶ Individual file or filegroup backups can be restored from a full database backup.
- ▶ Point-in-time recovery is not permitted with file or filegroup backups.
- ▶ Differential backups can be combined with file or filegroup backups. These differential backups capture only those extents that have changed since the file or filegroup backup was made.

File and filegroup backups can be very powerful options for very large databases, but you need to ensure that the relevant backups can be accounted for. In all backup situations, the key to a successful plan is testing your backup strategy; this is particularly true with file and filegroup backups.

Mirrored Backups

The use of mirrored backups can help diminish the possibility of losing a database backup. Database backups can be your lifeline to recovery, and you do not want to lose them. Mirrored backups simultaneously write the backup information to more than one media set. You can mirror the backup to two, three, or four different media sets. Listing 14.5 gives an example of a mirrored backup that writes two different media sets.

LISTING 14.5 Creating a Mirrored Backup

```

BACKUP DATABASE AdventureWorks2008
  TO disk = 'C:\mssql12008\backup\AdventureWorks2008_Mirror1a.bak',

```

```

    disk = 'C:\mssql12008\backup\AdventureWorks2008_Mirror1b.bak'
MIRROR TO disk = 'c:\mssql12008\backup\AdventureWorks2008_Mirror2a.bak',
    disk = 'C:\mssql12008\backup\AdventureWorks2008_Mirror2b.bak'
WITH FORMAT,
    MEDIANAME = 'AdventureWorks2008MirrorSet'

```

The example in Listing 14.5 is simplistic and demonstrates only the backup's capability to write to two different locations. At the end of the backup example, four files will exist. Each pair of files can be used to restore the database. In the real world, a backup like that in Listing 14.5 would write to two different disk or tape drives. Storing the media on the same drive is very risky and does not give you all the advantages a mirror can afford.

Copy-Only Backups

If you want a backup that will not affect future or past backups, copy-only backups are for you. The copy-only backup allows you to make a database or log backup without identifying the backup as one that should be included in a restore sequence.

Contrast this with a full database backup: If a full database backup is taken, the information related to this backup is captured in the system tables. This backup can form the base for other backups, such as transaction log backups or differential backups, and must be retained to be able to restore the backups that depend on the base.

The following example shows a copy-only backup; the `COPY_ONLY` parameter is the key to creating this kind of backup:

```

BACKUP DATABASE [AdventureWorks2008]
  TO DISK = N'C:\mssql12008\backup\AdventureWorks2008_COPY.bak'
  WITH COPY_ONLY

```

Compressed Backups

How would you like to create a backup file that is smaller and takes less time to create? Sign me up. This has got to be an option that the average database user would love to use. Compressed backups are smaller in size than uncompressed backups. The reduced size of a compressed backup typically requires less device I/O and can therefore reduce backup times significantly.

You must be aware that there are some trade-offs, however. First, this feature is available only with Enterprise Edition or Developer Edition. Second, the creation of a compressed backup can impact on the performance of concurrent operations on your database server while the backup is being created. Specifically, CPU usage increases during the backup. This may or may not be an issue for you. Consider that many full database backups are taken during off-hours, so there are more CPU cycles available during this time. Either way, you should monitor the CPU usage using compression versus not using compression to evaluate the impact. Another option is to create low-priority compressed backups in a

session whose CPU usage is limited by the Resource Governor. (For more information on using the Resource Governor, see Chapter 40, “Managing Workloads with the Resource Governor.”)

When you get past these hurdles, the creation of a compressed backup is straightforward. One option is to set a server option so that all backups are created as compressed files by default. You can use the `sp_configure` stored procedure to set the backup compression default. If this is set to `true`, future backups will be created in a compressed format unless the backup is specifically created with the `NO_COMPRESS` option.

You also have the option of creating a compressed backup regardless of the server option. This is done using the new `COMPRESSION` option available with the T-SQL `BACKUP` command. The following example shows how to create an `AdventureWorks2008` backup in the compressed format:

```
BACKUP DATABASE [AdventureWorks2008]
TO DISK = N'C:\MSSQL2008\Backup\AdventureWorks2008_compressed.bak'
WITH NOFORMAT, NOINIT,
    NAME = N'AdventureWorks2008-Full Database Backup',
SKIP, NOREWIND, NOUNLOAD, COMPRESSION, STATS = 10
```

The compression is quite impressive. In some simple tests performed on the `AdventureWorks2008` database, the compressed backup was one fourth the size of a noncompressed backup. The compression ratio varies depending on the type of data in the database that you are backing up but can be as good as or better than 4:1.

System Database Backups

The system databases are the `master`, `model`, `msdb`, `resource`, `tempdb`, and `distribution` databases. SQL Server uses these databases as part of its internal workings. All these databases should be part of your backup plan, except for `resource` and `tempdb`. You can find detailed descriptions of these databases in Chapter 7, “SQL Server System and Database Administration.” The important point to remember about all these databases is that they contain key information about your SQL Server environment. The `msdb` database contains information about backups and scheduled jobs. The `master` database contains information about all the user databases stored on the server. This information can change over time.

To ensure that you do not lose the information the system databases contain, you should back up these databases as well. Typically, nightly full database backups of these databases suffice. You can use the same backup T-SQL syntax or SSMS screens that you use for a user databases to accomplish this task.

Restoring Databases and Transaction Logs

A database restore allows a database or part of a database to be recovered to a state that it was in previously. This state includes the physical structure of the database, configuration options, and data contained in the database. The options you have for recovery are heavily dependent on the backup plan you have in place and way you have configured

your database. Databases that are set to simple recovery mode have limited options for database restore. Databases that are in full recovery mode and have frequent backups have many more restore options. Following are the basic options for restore:

- ▶ Restore an entire database.
- ▶ Perform a partial restore.
- ▶ Restore a file or page from a backup.
- ▶ Restore a transaction log.
- ▶ Restore a database to a point in time by using a database snapshot.

The following sections delve further into the restore options listed here. They focus on the means for accomplishing these restores and some of the common restore scenarios you might encounter.

Restores with T-SQL

The command to restore a database in SQL Server is aptly named RESTORE. The RESTORE command is similar to the BACKUP command in that it can be used to restore a database, part of a database, or a transaction log. You restore an entire database or part of a database by using the RESTORE DATABASE syntax. You do transaction log restores by using the RESTORE TRANSACTION syntax.

Database Restores with T-SQL

Listing 14.6 shows the full syntax for RESTORE DATABASE.

LISTING 14.6 RESTORE DATABASE Syntax

```
--To Restore an Entire Database from a Full database backup (a Complete Restore):
RESTORE DATABASE { database_name | @database_name_var }
[ FROM <backup_device> [ ,...n ] ]
[ WITH
  [ { CHECKSUM | NO_CHECKSUM } ]
  [ [ , ] { CONTINUE_AFTER_ERROR | STOP_ON_ERROR } ]
  [ [ , ] ENABLE_BROKER ]
  [ [ , ] ERROR_BROKER_CONVERSATIONS ]
  [ [ , ] FILE = { file_number | @file_number } ]
  [ [ , ] KEEP_REPLICATION ]
  [ [ , ] MEDIANAME = { media_name | @media_name_variable } ]
  [ [ , ] MEDIAPASSWORD = { mediapassword |
    @mediapassword_variable } ]
  [ [ , ] MOVE 'logical_file_name' TO 'operating_system_file_name' ]
    [ ,...n ]
  [ [ , ] NEW_BROKER ]
  [ [ , ] PARTIAL ]
  [ [ , ] PASSWORD = { password | @password_variable } ]
  [ [ , ] { RECOVERY | NORECOVERY | STANDBY =
```

```

        {standby_file_name | @standby_file_name_var }
    } ]
    [ [ , ] REPLACE ]
    [ [ , ] RESTART ]
    [ [ , ] RESTRICTED_USER ]
    [ [ , ] { REWIND | NOREWIND } ]
    [ [ , ] STATS [ = percentage ] ]
    [ [ , ] { STOPAT = { date_time | @date_time_var }
    | STOPATMARK = { 'mark_name' | 'lsn:lsn_number' }
        [ AFTER datetime ]
    | STOPBEFOREMARK = { 'mark_name' | 'lsn:lsn_number' }
        [ AFTER datetime ]
    } ]
    [ [ , ] { UNLOAD | NOUNLOAD } ]
]

```

Once again, there are many available options for restoring a database, but a simple restore is fairly straightforward. The following example demonstrates a full restore of the AdventureWorks2008 database:

```

RESTORE DATABASE [AdventureWorks2008]
FROM DISK = N'C:\mssql12008\backup\AdventureWorks2008_FullRecovery.bak'
WITH FILE = 1, NOUNLOAD, REPLACE, STATS = 10

```

For more sophisticated restores, you can specify options following the WITH clause. Table 14.2 briefly describes these options. Many of the options are the same as for the BACKUP command and provide similar functionality.

TABLE 14.2 **RESTORE DATABASE** Options

Option	Description
CHECKSUM NO_CHECKSUM	When CHECKSUM is specified, a checksum is calculated before the backup is restored. If the checksum validation fails, the restore fails as well. The default is NO_CHECKSUM.
STOP_ON_ERROR CONTINUE_AFTER_ERROR	The STOP_ON_ERROR option, which is the default, causes the backup to fail if an error is encountered. CONTINUE_AFTER_ERROR allows the restore to continue if an error is encountered.
ENABLE_BROKER	This option starts the Service Broker so that messages can be received.

TABLE 14.2 **RESTORE DATABASE** Options

Option	Description
ERROR_BROKER_CONVERSATIONS	Service Broker conversations with the database being restored are ended, with an error stating that the database is attached or restored.
FILE = { <i>file_number</i> @ <i>file_number</i> }	This option identifies the backup set number to be restored from the backup media. The default is 1, which indicates the latest backup set.
KEEP_REPLICATION	This option prevents replication settings from being removed during a restore operation. This is important when setting up replication to work with log shipping.
MEDIA_NAME	This is a 128-character name for the backup media. If it is specified, the target media must match this name.
MEDIA_PASSWORD	This is a password for the media set. If the media was created with a password, the password must be supplied to restore from that media.
MOVE	This option causes the specified <i>logical_file_name</i> to be moved from its original file location to another location.
NEW_BROKER	This option creates a new <i>service_broker_guid</i> .
PARTIAL	This option causes a partial restore to occur that includes the primary filegroup and any specified secondary filegroup(s).
PASSWORD	This password is specific to the backup set. If a password was used when creating the backup set, a password must be used to restore from the media set.
RECOVERY NORECOVERY STANDBY	The RECOVERY option, which is the default, restores the database so that it is ready for use. NORECOVERY renders the database inaccessible but able to restore additional transaction logs. The STANDBY option allows additional transaction logs to be applied but the database to be read. These options are discussed in more detail later in this section.

TABLE 14.2 **RESTORE DATABASE** Options

Option	Description
REPLACE	This option causes the database to be created with the restore, even if the database already exists.
RESTART	This option allows a previously interrupted restore to restart where it was stopped.
RESTRICTED_USER	This option restricts access to the database after it has been restored. Only members of the db_owner, dbcreator, or sysadmin role can access it.
REWIND NOREWIND	This option is used for tape operations. REWIND, which is the default, causes the tape to be released and rewound.
STATS	This option causes completion statistics to be displayed at the specified interval to assess progress.
STOPAT STOPATMARK STOPBEFOREMARK	This option causes a restore to recover to a specified date/time or to recover to a point defined by a specific transaction. The STOPAT option restores the database to the state it was in at the date and time. The STOPATMARK and STOPBEFOREMARK options restore based on the specified marked transaction or LSN.
UNLOAD NOUNLOAD	This option is used for tape operations. NOUNLOAD cause the tape to remain in the tape drive after a restore completes. UNLOAD, which is the default, causes the tape to be rewound and unloaded when the restore completes.

Various options are utilized in the “Restore Scenarios” section, later in this chapter. Those restore scenarios provide a frame of reference for the options and further meaning about what they can accomplish.

Transaction Log Restores with T-SQL

The syntax details and options for restoring a transaction log backup are similar to those for RESTORE BACKUP. The options not available with RESTORE LOG include ENABLE_BROKER, ERROR_BROKER_CONVERSATIONS, NEW_BROKER, and PARTIAL.

The RECOVERY | NORECOVERY | STANDBY options are particularly important when performing transaction log restores and also when restoring a database that will have transaction

logs applied. If these options are used incorrectly, you can render your database inaccessible or unable to restore subsequent transaction log backups. With the `RECOVERY` option, any uncommitted transactions are rolled back, and the database is made available for use. When a restore (of either a database or transaction log) is run with this option, no further transaction logs can be applied. The `NORECOVERY` and `STANDBY` options do allow subsequent transaction logs to be applied. When the `NORECOVERY` option is specified, the database is completely unavailable after the restore and is left in a restoring state. In this state, you cannot read the database, update the database, or obtain information about the database, but you can restore transaction logs.

With the `STANDBY` option, the database is left in a read-only state that allows some database access. `standby_file_name` must be specified with the `STANDBY` option. The standby file contains uncommitted transactions rolled back to place the database in a consistent state for read operations. If subsequent transaction log backups are applied to the `STANDBY` database, the uncommitted transactions in the standby file are reapplied to the database.

CAUTION

Take note of the `standby_file_name` name used when restoring with the `STANDBY` option and make sure the file is secure. If another restore operation is performed and the same `standby_file_name` is used, the previous standby file is overwritten. The database cannot be fully recovered without the standby file, so you have to perform all the restore operations again.

We speak from personal experience on this one. During a data recovery drill, for a large database (approximately 1TB), we spent hours restoring the transaction logs on a set of log-shipped databases. We manually restored the last log to be applied to place the database in `STANDBY` mode. Another database also in the data recovery drill was also placed in `STANDBY`, and unfortunately, the same standby file was used on this database. This caused more than one person a very long night. Be careful!

Some of the other options of the `RESTORE DATABASE` command are covered in the “Restore Scenarios” section, later in this chapter. Once again, many of these options are not required for most types of restores. For example, the following command uses basic options to restore a transaction log backup to the `AdventureWorks2008` database:

```
RESTORE LOG [AdventureWorks2008] FROM
DISK =
N'C:\mssql12008\backup\AdventureWorks2008\AdventureWorks2008_backup_200906091215.trn'
WITH FILE = 1, NOUNLOAD, STATS = 10, NORECOVERY
```

Typically, the individual restore commands you will use are along the lines of the preceding example. The restores become more complicated when many restores of different types are involved in a recovery option. Fortunately, SSMS can help ease this pain.

Restoring by Using SSMS

The restore capabilities in SSMS are comprehensive and can reduce the amount of time needed to perform a restore and limit the number of errors. This is partly due to the fact that SSMS keeps track of the backups that have occurred on a server. When a restore operation is requested for a database, SQL Server reads from its own system tables and presents a list of backups that it knows about that can be restored. In situations in which many files need to be restored, SSMS can be an invaluable tool.

You access the restore functions in SSMS by right-clicking the database in the Object Explorer and selecting Tasks and then Restore. The options available for restore include Database, File and Filegroups, and Transaction Log. Which restore options are enabled depends on the state of the database being restored. The Transaction Log option is disabled for databases that were restored with the `RECOVERY` option or are set to simple recovery mode. Figure 14.6 shows an example of the restore screen that is displayed when you select a database restore for the AdventureWorks2008 database.

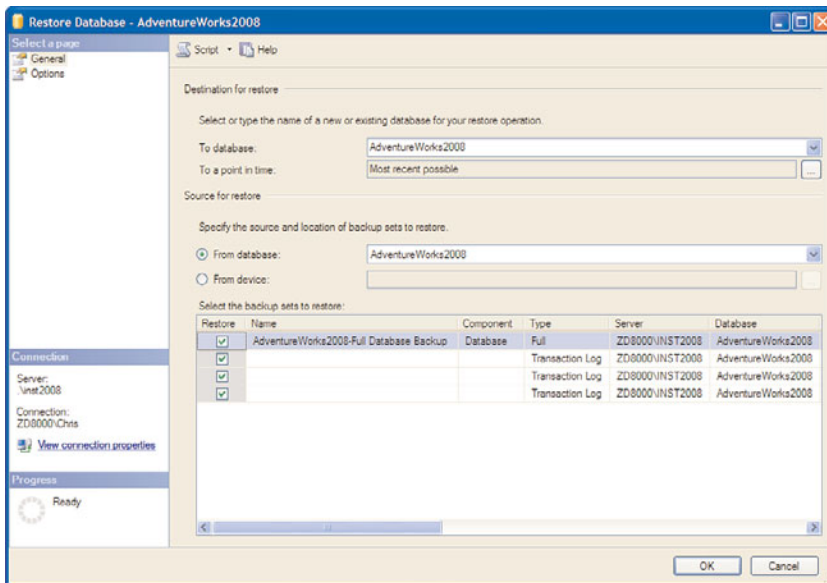

FIGURE 14.6 A database restore with SSMS.

The Restore Database window can show more than one type of backup, depending on what is available. The first backup shown in Figure 14.6 is a full backup, followed by a series of transaction log backups. The beauty of this screen is that the backups are shown in the order in which they should be applied. This order is very important with restores

because they must be applied in the order in which they occurred. You can choose to apply all the backups or selectively choose the backups you want to apply. If you uncheck the first full database backup, all subsequent log backups are unchecked as well. If you recheck the full database backup and click one of the transaction log backups toward the bottom of the list, all the required backups that happened prior to the selected backups are also selected.

Figure 14.7 shows an example of the Options page of the Restore Database window for the AdventureWorks2008 database. The Options page allows you to specify many of the T-SQL RESTORE options reviewed previously. The Overwrite the Existing Database option is equivalent to the REPLACE parameter and forces a replacement of the restored database if it exists already. The Preserve the Replication Settings option is equivalent to KEEP_REPLICATION. The Restrict Access to the Restored Database option is the same as using the RESTRICTED_USER option with the T-SQL RESTORE command. The Prompt Before Restoring Each Backup option does not have a T-SQL equivalent; it displays a prompt before restoring each backup set to ask whether you want to restore it.

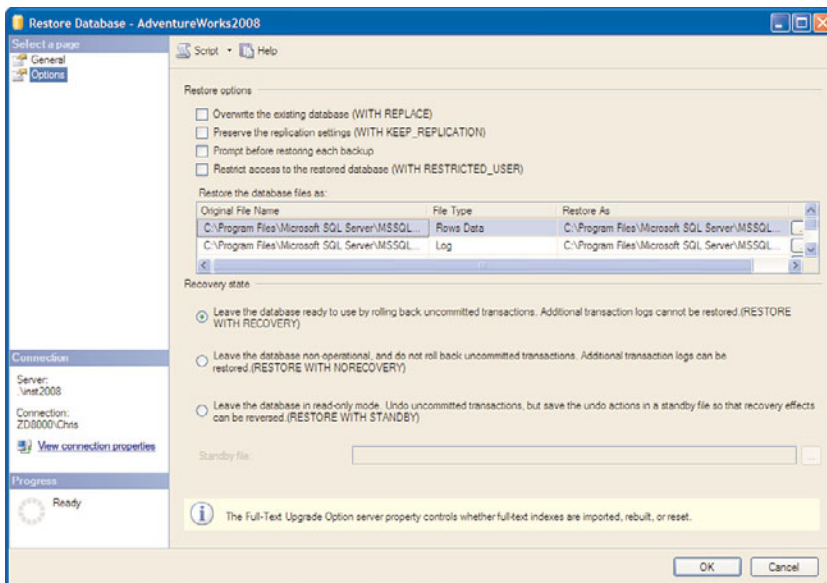

FIGURE 14.7 Restore options with SSMS.

The last three options on the Options page relate the recovery state of the last backup set restored. The first option is synonymous with the RECOVERY option, the second option is the same as NORECOVERY, and the last option is equivalent to the STANDBY option. The standby filename must be supplied with the STANDBY option and defaults to the default backup directory for the server. By default, the name of the file contains the name of the database being restored.

TIP

You should click the Script button available on the Restore Database window if you want to see what is going on under the hood of the SSMS restores or want to run a restore later. You can learn a lot about the T-SQL options and how they work by scripting out the commands.

Restore Information

Backup files and system tables contain a wealth of information about what can be restored or already has been restored. You can retrieve information from the backup files by using variations of the RESTORE command. These variations do not actually perform the restore operation but provide information about the backups that can be restored. The RESTORE commands and some useful system tables are detailed in the following sections.

The RESTORE FILELISTONLY Command

The RESTORE FILELISTONLY command returns a result set that contains a list of the database and log files contained in the backup. An example of this command follows:

```
RESTORE FILELISTONLY
FROM DISK = 'C:\mssql12008\backup\AdventureWorks2008_Partial.bak'
```

The results from this type of restore include the logical and physical filenames, the type of each file, and the size of each file.

The RESTORE HEADERONLY Command

The RESTORE HEADERONLY command returns a result set that contains the backup header data for all backup sets on the specified backup device. This command is useful when multiple backup sets are written to the same device. An example of this command follows:

```
RESTORE HEADERONLY
FROM DISK = 'C:\mssql12008\backup\AdventureWorks2008_Partial.bak'
```

More than 50 columns are returned in the result set. Some particularly useful pieces of information include the start and finish time for the backup, recovery mode when the backup was taken, type of backup, and name of the computer from which the backup was performed.

The RESTORE VERIFYONLY Command

The RESTORE VERIFYONLY command verifies that a backup set is complete and readable. The restore does not attempt to verify the structure of the data in the backups, but it has been enhanced to run additional checks on the data. The checks are designed to increase the probability of detecting errors. An example of this command follows:

```
RESTORE VERIFYONLY
FROM DISK = 'C:\mssql12008\backup\AdventureWorks2008_Partial.bak'

/*Result from the prior RESTORE VERIFYONLY command
The backup set on file 1 is valid.
*/
```

The results from the prior example show that the `RESTORE VERIFYONLY` command does not contain much output, but the value of this command is in helping ensure that the backups are sound.

Backup and Restore System Tables

The system tables for backups and restores are found in the `msdb` system database. These system tables are used to keep historical information about the backups and restores that have occurred on the server. These system tables are listed in Table 14.3.

TABLE 14.3 Backing Up and Restoring System Tables

<code>msdb</code> System Table	Description
<code>backupfile</code>	Contains one row for each data or log file of a database.
<code>backupfilegroup</code>	Contains one row for each filegroup in a database at the time of backup.
<code>backupmediafamily</code>	Contains a row for each media family.
<code>backupmediafile</code>	Contains one row for each backup media set.
<code>backupset</code>	Contains a row for each backup set.
<code>logmarkhistory</code>	Contains one row for each marked transaction that has been committed.
<code>restorefile</code>	Contains one row for each restored file. These include files restored indirectly, by filegroup name.
<code>restorefilegroup</code>	Contains one row for each restored filegroup.
<code>restorehistory</code>	Contains one row for each restore operation.
<code>suspect_pages</code>	Contains one row per page that failed with an 824 error (with a limit of 1,000 rows).
<code>sysopentapes</code>	Contains one row for each currently open tape device.

Refer to “Backup and Restore Tables” in the “System Tables” section of SQL Server Books Online for a detailed description of each table, including each column that can be retrieved.

You are able to query these tables to obtain a variety of information related to backups and restores. You can tailor these queries to look at a specific database or a specific time frame. The following example retrieves restore information for the AdventureWorks2008 database:

```
select destination_database_name 'database', h.restore_date, restore_type,
       cast((backup_size/1024)/1024 as numeric(8,0)) 'backup_size MB',
       f.physical_device_name
from msdb..restorehistory h (NOLOCK)
     LEFT JOIN msdb..backupset b (NOLOCK)
       ON h.backup_set_id = b.backup_set_id
     LEFT JOIN msdb..backupmediafamily f (NOLOCK)
       ON b.media_set_id = f.media_set_id
where h.restore_date > getdate() - 5
     and UPPER(h.destination_database_name) = 'AdventureWorks2008'
order by UPPER(h.destination_database_name), h.restore_date desc
```

This example displays information related to restores that have been executed in the past five days for the AdventureWorks2008 database. The restore date, type of restore, size of the backup, and physical location of the file used for the restore are displayed when you run this query.

CAUTION

Queries against system tables are acceptable and can provide a wealth of information, but you need to exercise caution whenever you are dealing with a system table. SQL Server uses these tables, and problems can occur if the values in them are changed or their physical structure is altered.

Backup and Restore Report

A set of standard reports that come with SQL Server 2008 provide a variety of information about your databases, including recent restores and backups. You can access these reports by right-clicking on a database in the SSMS Object Explorer, then Reports, and then Standard Reports. You see over a dozen reports ready for you to run.

A report particularly useful for obtaining restore and backup information is named Backup and Restore Events. This report details the latest backup and restore events that have occurred on a particular database. An example of this report is shown in Figure 14.8.

The interactive report allows you to drill down into each backup or restore event to obtain more information. For example, the restore information shown in Figure 14.8 was obtained by clicking on the plus button next to the Successful Restore Operations label. You can then drill down into an individual restore to obtain more information, including the physical files involved in the operation.

Date-Time	Destination	Restore Type	Mode	Recovery Option	User	Backup Name
5/25/2009 10:24:45 AM	AdventureWorks2008	Log	No replace	Recovery	ZD8000\Chris	
Destination Physical Files						
C:\Program Files\Microsoft SQL Server\MSSQL10.INST2008\MSSQL\DATA\AdventureWorks2008_Log.ldf						
5/25/2009 10:24:45 AM	AdventureWorks2008	Log	No replace	No recovery	ZD8000\Chris	
5/25/2009 10:24:44 AM	AdventureWorks2008	Log	No replace	No recovery	ZD8000\Chris	
5/25/2009 10:24:44 AM	AdventureWorks2008	Log	No replace	No recovery	ZD8000\Chris	
5/25/2009 10:24:43 AM	AdventureWorks2008	Log	No replace	No recovery	ZD8000\Chris	

FIGURE 14.8 Backup and Restore Events report.

Restore Scenarios

Restore scenarios are as varied as the backup scenarios that drive them. The number of scenarios is directly related to the types of backups taken and frequency of those backups. If a database is in simple recovery mode and full database backups are taken each night, your restore options are limited. Conversely, full recovery databases that have multiple filegroups and take a variety of different types of backups have a greater number of options that can be used to restore the database.

The following sections describe a number of restore scenarios to give you a taste of the types of restores you may encounter. The scenarios include some restores performed with T-SQL and others performed with SSMS.

Restoring to a Different Database

You can restore a database backup to a different database. The database you're restoring to can be on the same server or a different server, and the database can be restored to a different name, if needed. These types of restores are common in development environments where a production backup is recovered on a development server or multiple copies of the same development database are restored to different database names for use by different groups.

Listing 14.7 shows the T-SQL `RESTORE` command you can use to create a new database named `AdventureWorks2008_COPY` from the backup of the `AdventureWorks2008` database. Take note of the `MOVE` options that specify where the database files for the new

AdventureWorks2008_COPY database will exist. Each MOVE option must refer to the logical name for the file and include a physical file location that is a valid location on the server. In addition, the referenced file cannot be used by another database. The only exception is when you are restoring to the database that is using the files and the REPLACE option is used.

LISTING 14.7 Restore to a Different Database

```
RESTORE DATABASE [AdventureWorks2008_COPY]
FROM DISK = N'C:\mssql12008\backup\AdventureWorks2008.bak'
WITH FILE = 1,
MOVE N'AdventureWorks2008_Data' TO
N'C:\mssql12008\data\AdventureWorks2008_Copy.mdf',
MOVE N'AdventureWorks2008_Log' TO
N'C:\mssql12008\data\AdventureWorks2008_Copy_log.ldf',
NOUNLOAD, STATS = 10
```

TIP

A restore of a database backup taken from another server can cause problems after the restore completes. The problems are caused by broken relationships between the database users captured in the backup file and the associated logins on the server to which the backup is restored. The relationships are broken because each login receives a unique ID assigned to it when it is added. These unique IDs can and will be different across servers, even though the logins may have the same name. The unique ID from the login is stored with each database user in order to identify the login that the user is associated with. When the unique ID for the login is different or not found, you get spurious errors when trying to connect to the database with these users or when trying to administer these users in SSMS.

The `sp_change_users_login` system stored procedure is designed to correct these broken relationships. You can run this procedure with the "report" option in the database in question to help identify any problems (that is, `sp_change_users_login "report"`). The stored procedure also has options to fix the broken relationships. For example, `sp_change_users_login "autofix", "myuser"` fixes the relationship for the "myuser" database user. You should check SQL Server Books Online for further options and details on this stored procedure.

Another quick-and-dirty means for fixing orphaned database users is to delete the users from the database and then re-create them. Of course, the login must exist on the server, and all the permissions associated with the database user must be reestablished. Permissions can be overlooked or missed with this method, so it is safer to stick with the `sp_change_users_login` procedure.

Restoring a Snapshot

Database snapshots, which were introduced in SQL Server 2005, provide a fast method for capturing a transactionally consistent view of a database. The snapshot is created as another read-only database linked to the original database from which the snapshot was taken. As changes are made to the original database, the database engine uses a copy-on-write method to keep the snapshot consistent.

After a snapshot is taken, you can revert back to the snapshot at a later time and restore the original database to the state it was in when the snapshot was taken. You do not create the snapshot by backing up a database, but you can restore it using methods similar to restoring a backup. The following examples shows the syntax to revert a database back to a database snapshot:

```
RESTORE DATABASE { database_name | @database_name_var }
FROM DATABASE_SNAPSHOT database_snapshot_name
```

Database snapshots are available only with the Enterprise or Development Editions of SQL Server. They are discussed in more detail in Chapter 32, “Database Snapshots.”

Restoring a Transaction Log

Transaction log restores deserve special attention because of their dependency on other backup types. Typical transaction log restores occur after a full or differential database restore has occurred. After this base is established, the transaction log restores must be done in the same sequential order as the backups that were taken.

Fortunately, SSMS does a good job of presenting the available backups in the order in which they must be applied. You can do the entire restore sequence with SSMS, including a full restore followed by a restore of any other backups, including transaction log backups. To restore transaction log backups (independent of other backups), you can select the Transaction Log option. Figure 14.9 shows a sample screen for restoring transaction logs in the AdventureWorks2008 database.

The transaction logs shown in Figure 14.9 are listed in the order in which they were taken and the order in which they need to be applied. You can uncheck some of the available backups, but you are not allowed to select backups that are not in the correct sequence. In other words, you can uncheck backups from the bottom of the list, but if you uncheck backups toward the top of the list, all backups found below that item are unchecked as well.

It is important to remember that you can restore transaction log backups only to a database that is in the NORECOVERY or STANDBY state. Make sure that every restore prior to the last one uses one of these options. When you restore the last transaction log, you should use the RECOVERY option so that the database is available for use.

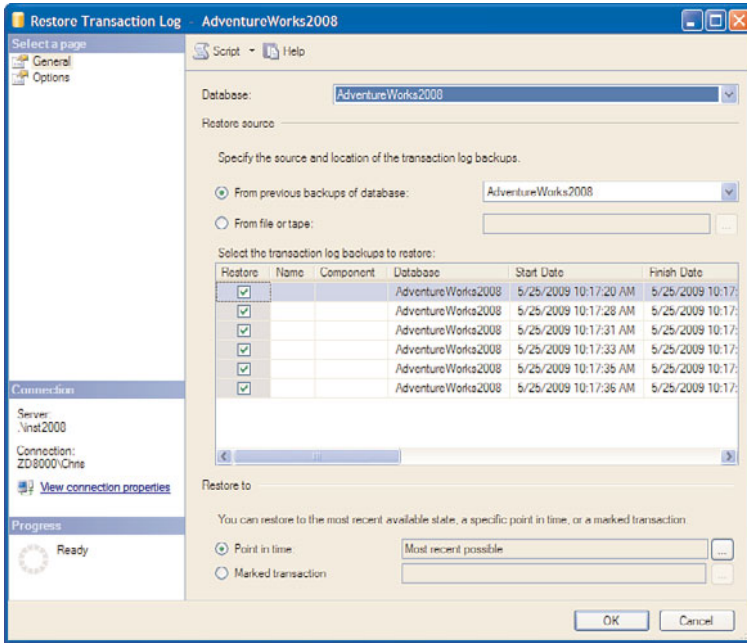

FIGURE 14.9 Transaction Log Restore.

Restoring to the Point of Failure

A disk failure on a drive that houses database files is a reality that some database administrators must deal with. This situation can give pause to the most seasoned administrators, but it is a situation that can be addressed with little or no data loss. Don't panic! You need to first identify the available backups.

NOTE

It is hoped the disk that experienced a failure is not the same disk that houses your backups. Database backups should always be stored on separate media. One of the best approaches is to write the backups to a drive that does not contain any other SQL Server files and write the contents of that drive to tape. This minimizes the possibility of losing one of those all-important backups.

The backup components that you need to restore to the point of failure include the following:

- ▶ A backup of the tail of the transaction log
- ▶ A full database backup or file/filegroup backup to establish a base

- The full sequence of transaction log backups created since the full database backup

The following sections describe the detailed steps for recovery that relate to these backup components.

NOTE

The restore steps outlined in the following sections do not address the recovery of the actual disk that failed. The recovery of hardware, such as a disk, is beyond the scope of this book, but it needs to be addressed to get your environment back to the state it was in prior to the failure.

Backing Up the Tail of the Transaction Log

The first thing you should do in the event of a damaged database is to back up the tail of the transaction log. The tail of the transaction log is found in the active SQL Server transaction log file(s). This tail is available only for databases that are in full or bulk-logged recovery mode. This tail contains transactions not backed up yet. The following example shows how to back up the tail of the log for the AdventureWorks2008 database using T-SQL:

```
BACKUP LOG [AdventureWorks2008]
TO DISK = N'C:\mssql12008\backup\log\AdventureWorks2008_Tail.trn'
WITH NO_TRUNCATE
```

NO_TRUNCATE prevents the transactions in the log from being removed and allows the transaction log to be backed up, even if the database is inaccessible. This type of backup is possible only if the transaction log file is accessible and was not on the disk that had the failure.

Recovering the Full Database Recovery

After you back up the tail of the transaction log, you are ready to perform a full database restore. This restore, which is based on a full database backup or a file/filegroup backup, overwrites the existing database. It is imperative that the full database restore be done with the NORECOVERY option so that the transaction log backups and tail of the log can be applied to the database as well. The following example restores a full backup of the AdventureWorks2008 database, using the T-SQL RESTORE command:

```
RESTORE DATABASE [AdventureWorks2008]
FROM DISK = N'C:\mssql12008\backup\AdventureWorks2008.bak'
WITH FILE = 1, NORECOVERY, NOUNLOAD, REPLACE, STATS = 10
```

Upon completion of this type of restore, the database appears in the SSMS Object Explorer with "(Restoring...)" appended to the end of the database name. The database is now ready for transaction log backups to be applied.

Restoring the Transaction Log Backup

The final step in recovery is to apply the transaction log backups. These backups include all the transaction log backups since the last full backup plus the tail of the log you backed up after the media failure. If differential backups were taken since the last full backup, you can apply the last differential backup and apply only those transaction log backups that have occurred since the last differential backup.

You can restore transaction log backups by using T-SQL or SSMS. To restore with SSMS, you can right-click the database in the restoring state and select the Transaction Log Restore option. The Restore Transaction Log screen lists the available transaction log backups, including the backup of the transaction log tail. You need to select all the transaction logs, including the tail. You should make sure to go to the Options tab and select the Recovery option so that your database is available after the restore completes.

Alternatively, you can use T-SQL to perform the transaction log backup restores. The following example shows a series of transaction log restores. The first two restores are done with the `NORECOVERY` option. The last command restores the tail of the log and uses the `RECOVERY` option to make the database available for use:

```
RESTORE LOG [AdventureWorks2008]
FROM DISK =
N'C:\mssql12008\backup\AdventureWorks2008_backup_200906180922.trn'
WITH FILE = 1, NORECOVERY, NOUNLOAD, STATS = 10
GO
RESTORE LOG [AdventureWorks2008]
FROM DISK =
N'C:\mssql12008\backup\AdventureWorks2008_backup_200906180923.trn'
WITH FILE = 1, NORECOVERY, NOUNLOAD, STATS = 10
GO
RESTORE LOG [AdventureWorks2008]
FROM DISK =
N'C:\mssql12008\backup\log\AdventureWorks2008_Tail.trn'
WITH FILE = 3, NOUNLOAD, STATS = 10
GO
```

When many transaction log backups are involved, using T-SQL to perform the restores can be challenging. The restores must occur in the proper order and refer to the proper location of the backup file(s). Restores done with SSMS are typically less prone to error.

Restoring to a Point in Time

Databases in the full or bulk-logged recovery models can be restored to a point in time. This type of restore is similar to the point-of-failure scenario covered previously, but it allows for a more precise restore operation. These restores allow the database to be recovered to a time prior to a particular event. Malicious attacks or erroneous updates are some examples of events that would justify a point-in-time restore.

NOTE

There are some limitations on point-in-time restores of databases set to the bulk-logged recovery model. Point-in-time restores are not possible on transaction log backups that contain bulk load operations. Point-in-time restores can occur using transaction log backups that occurred prior to the bulk load operation, as long as a bulk load did not occur during the time of these backups.

A point-in-time restore can be done using one of the following:

- ▶ A specific date/time within the transaction log backup
- ▶ A specific transaction name inserted in the log
- ▶ An LSN

Point-in-time restores can be done with T-SQL or SSMS. Figure 14.10 shows the General page that allows you to specify the Point in Time option. The default is to restore to the most recent time possible, but you can click on the ellipsis to display the Point in Time Restore dialog box, which is shown in the middle of Figure 14.10. You can select the date to restore to by using the date drop-down and enter the time to restore to as well.

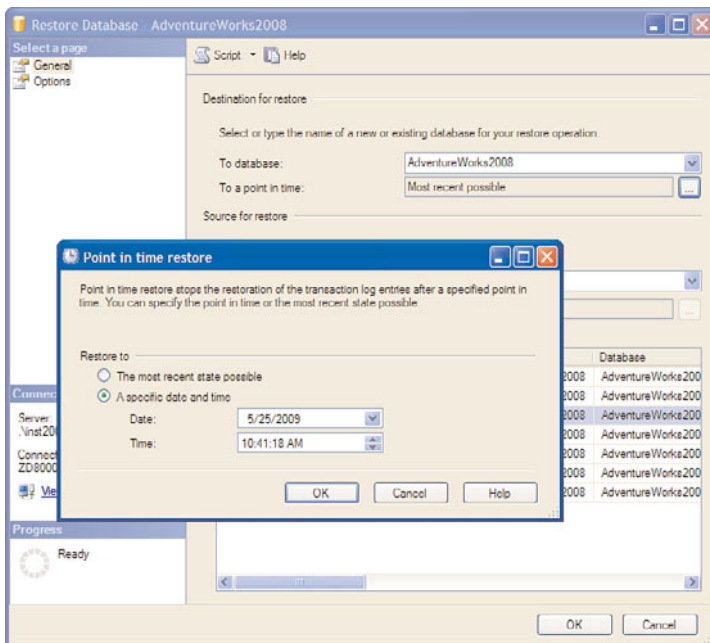

FIGURE 14.10 A point-in-time restore.

Online Restores

Online restores were new to SQL Server 2005 and continue to be supported in SQL Server 2008. They allow a filegroup, file, or specific page within a file to be restored while the rest of the database is online. The file or filegroup that is being restored to must be offline during the duration of the online restore.

TIP

You should take a full backup of a database immediately before taking a read-only file offline. This simplifies the online restore process and eliminates the need to apply a bunch of transaction log backups prior to the online restore. This applies only to databases in full or bulk-logged recovery.

The following example demonstrates how to take a read-only file offline:

```
ALTER DATABASE AdventureWorks2008
MODIFY FILE (NAME = 'AdventureWorks2008_ReadOnlyData', OFFLINE)
```

When the file is offline, you can perform a restore to that file without affecting the rest of the database. The following example shows an example of an online restore of a read-only file to the AdventureWorks2008 database:

```
RESTORE DATABASE [AdventureWorks2008]
FILE = N'AdventureWorks2008_ReadOnlyData'
FROM DISK = N'C:\mssql12008\backup\AdventureWorks2008_ReadOnlyData.bak'
WITH FILE = 1, NOUNLOAD, STATS = 10, RECOVERY
```

Restoring the System Databases

The SQL Server 2008 system databases that can be restored are the master, msdb, model, and distribution databases. Each of these databases performs an essential role in the operation of SQL Server. If these databases are damaged or lost, they can be restored from database backup files in a similar fashion to user databases.

The master database, which contains information about other databases and is required to start SQL Server, has some special restore considerations. It must be operational before restores of other system databases can be considered. When you are restoring the master database, there are two basic scenarios. The first scenario involves a restore of the master database when the master database currently used by SQL Server is operational. In the second scenario, the master database is unavailable, and SQL Server is unable to start.

The first master database restore scenario is less involved and typically less stressful than the second. In the first scenario, your SQL Server can be up and running until the time you want to do the restore. When you are ready to do the restore, the SQL Server instance must be running in single-user mode. The server can be started in single-user mode via a

command prompt window. You stop the currently running SQL Server service, open a command prompt window, navigate to the directory where the `sqlservr.exe` file exists (typically `C:\Program Files\Microsoft SQL Server\MSSQL.1\MSSQL\Binn\`), and run the following command:

```
sqlservr.exe -m
```

When this command is executed, the SQL Server instance is running in the command prompt window. This window must be kept open for the SQL Server instance to keep running. The service for SQL Server appears as stopped, but the database engine is truly running.

The `-m` parameter places the server in single-user mode and allows a single administrator connection to the server. You can use that one connection to connect to the server to use the Object Explorer, a database query window in SSMS, SQLCMD, or any other tool that allows you to establish a connection and run commands against the database server. If you use the SSMS Object Explorer connection, you can right-click on the `master` database and select the Restore option. You need to enter `master` for the database to restore and select the overwrite option. You can instead run a T-SQL `RESTORE` command to achieve the same result.

When the restore of the `master` database is complete, SQL Server is automatically shut down. If you performed the restore using Object Explorer, you can expect to get an error message at the end of the restore process because SQL Server was shut down. You can simply close the command prompt window you used earlier and establish a new connection to the database server. All the databases, logins, and so on that were present prior to the backup are reestablished.

In the second scenario, the `master` database is damaged or unavailable, and SQL Server cannot start. If SQL Server is unable to start, you must reestablish a base environment like that which existed when SQL Server was initially installed. Using the `REBUILDDATABASE` option in `setup.exe` is one way to re-create all the system databases and reestablish this base environment. The `REBUILDDATABASE` parameter is part of a SQL Server installation that is done from the command prompt. You need the installation media for the edition of SQL Server installed on the machine. After you insert the disk and when you have access to the installation files, you can use the following syntax to launch the Setup program from a command prompt window:

```
start /wait <CD or DVD Drive>\setup.exe /qn
INSTANCENAME=<InstanceName> REINSTALL=SQL_Engine
REBUILDDATABASE=1 SAPWD=<NewStrongPassword>
```

InstanceName should be set to `MSSQLSERVER` for a default instance of SQL Server or the name of the instance, if it is not the default. In addition, a new SA password needs to be supplied for the `SAPWD` parameter. The `/qn` parameter suppresses all the setup dialog boxes and error messages and causes the installation to run silently. If you want to receive more information during the installation, you can specify the `/qb` parameter.

NOTE

If you get a message about a missing Windows Installer, you can find that software on the SQL Server media in the `Redist` folder. You may also find that the `setup.exe` file is not found on the root of your installation media. If this is the case, you need to change the directory in the command prompt window to the location of the `setup.exe` file on the installation media prior to executing the command to launch the setup program. Finally, remember to reinstall any service packs or patches you may have installed. The execution of the command prompt setup reverts the server back to the original software release.

At the end of the installation, all the system database files are installed to their original locations. This includes the original `master.mdf`, `mastlog.ldf`, `msdbdata.mdf`, and `msdblog.ldf` files, as well as the related database files for the other system databases. Any of the user databases you may have added to the server are no longer known by the master database and in turn are not available in the Object Explorer or other database tools.

If you have a backup of the master database, you can restore it after the command prompt installation is complete. You follow the procedures outlined in the first scenario, earlier in this section, to restore the master database from a backup. At the completion of the restore, any user databases present at the time of the master database backup are now available. You can also run restores for other system databases at this time, including the msdb database, which contains all your scheduled jobs and history.

If you do not have a backup of the master database, this is not the end of the world. You still have the option of manually attaching your user databases or restoring them from backup files. Attaching the database is typically much faster than restores from backup files and is the preferred method. You must also reestablish logins, backup devices, server triggers, and any other server-level objects stored in the master database. Depending on your environment, this can be a lengthy operation, but you can easily avoid it by making those all-important system database backups.

Additional Backup Considerations

A sound backup plan goes beyond the commands and tools described thus far in this chapter. There are several other considerations, detailed in the following sections, that should be considered as well.

Frequency of Backups

How often you back up your databases depends on many factors, including the following:

- ▶ The size of your databases and your backup window (that is, the time allocated to complete the task of backing up the database)

- ▶ The frequency of changes to the data and method by which it is changed
- ▶ The acceptable amount of data loss in the event of a failure
- ▶ The acceptable recovery time in the event of a failure

First, you must establish what your backup window will be. Because SQL Server allows dynamic backups, users can still access the database during backups; however, this affects performance. This means you should still schedule backups for low-activity periods and have them complete in the shortest possible time.

After you establish your backup window, you can determine your backup method and schedule. For example, if it takes 4 hours for a full backup to complete, and the database is quiescent between midnight and 6:00 a.m., you have time to perform a full backup each night. On the other hand, if a full backup takes 10 hours, and you have a 2-hour window, you should consider monthly or weekly backups, perhaps in conjunction with filegroup, differential, and transaction log backups. In many decision-support databases populated with periodic data loads, it might suffice to back up once after each data load.

Backup frequency is also directly tied to acceptable data loss. In the event of catastrophic failure, such as a fire in the server room, you can recover data only up to the point of the last backup moved offsite. If it is acceptable to lose a day's worth of data entry, nightly backups might suffice. If your acceptable loss is an hour's worth of data, hourly transaction log backups would have to be added to the schedule.

Your backup frequency affects your recovery time. In some environments, a weekly full backup plus transaction log backups taken every 10 minutes provide an acceptable data loss factor. A failure a few days after backup would require a full database restore and the application of hundreds of transaction logs. Adding a daily differential backup in this case would vastly improve restore time. The full and differential backups would be restored, and then six logs would be applied for each hour between the differential backup and the time of failure.

Using a Standby Server

If the ability to quickly recover from failure is crucial to your operation, you might consider implementing a standby server. Implementing a standby server involves backing up the production server and then restoring it to the standby server, leaving it in recovery mode. As transaction logs are backed up on the production server, they are applied to the standby server. If a failure occurs on the production server, the standby server can be recovered and used in place of the production server. If the production server is still running, you should not forget to back up the current log with the `NO_TRUNCATE` option and restore it to the standby server as well before bringing it online.

NOTE

Another advantage of restoring backups to a standby server is that it immediately validates your backups so you can be assured of whether they are valid. There is nothing worse than finding out during a recovery process that one of the backup files is damaged or missing.

The `STANDBY =undo_file_name` option plays a key role in the application of transaction logs to the standby server. When the database and subsequent log backups are restored to the standby server with this option, the database is left in recovery mode but is available as a read-only database. Now that the standby database is available for queries, it can actually reduce load on the production database by acting as a decision support system (DSS). Database Consistency Checks (DBCC) can be run on it as well, further reducing the load on the production system.

For the database to be available for reads, the data must be in a consistent state. This means that all uncommitted transactions must be rolled back. This rollback is usually handled by the `RECOVERY` option during a restore. In the case of a standby server, this would cause a problem because you would intend to apply more logs, which could, in fact, commit those transactions. This situation is handled by the `undo_file_name` clause of the `STANDBY` option. The file specified here holds a copy of all uncommitted transactions rolled back to bring the standby server to a consistent, read-only state. If those transactions subsequently commit a log restore, this undo information can be used to complete the transaction.

The application of hundreds or thousands of transaction logs to the standby server can be challenging. Fortunately, SQL Server 2008 includes log shipping, which automates the transfer of logs to the standby server. Log shipping, which can be configured in SSMS, uses SQL Server Agent jobs on the primary server to back up the transaction log and copy it to a folder on the standby server. SQL Server Agent on the standby server then executes a load job to restore the log. Automating your standby server with log shipping reduces administration and helps to ensure that the standby database is up-to-date. For further details on log shipping, see Chapter 19, “Replication.” Log shipping isn’t a form of replication but is covered in Chapter 19 as an alternative to replication.

Snapshot Backups

Snapshot backups are developed in conjunction with independent hardware and software vendors. These backups are not related to SQL Server database snapshots and are not accessible from any of the SQL Server tools. They utilize backup and restore technology and can provide relatively fast backup and restore operations. Snapshot backups are typically utilized on very large databases that are unable to perform database backups and restores in a timely fashion using SQL Server’s conventional backup and restore resources.

Considerations for Very Large Databases

When it comes to backup and recovery, special consideration must be given to very large databases, which are known as VLDBs. A VLDB has the following special requirements:

- ▶ **Storage**—Size might dictate the use of tape backups over the network or a disk.
- ▶ **Time**—As your time to backup increases, the frequency of backups might have to be adjusted.
- ▶ **Method**—How you back up your database is affected by its size. Differential or file and filegroup backups might have to be implemented.

- ▶ **Recovery**—Partial database recovery, such as restoring a file or filegroup, might be required due to the prohibitive time required to restore the entire database.

When designing a VLDB, you must integrate your backup plan with storage, performance, and availability requirements. Larger databases take longer to back up because the backup sizes are larger, and restores on this type of database can take much longer to complete than with a smaller database.

Maintenance Plans

SQL Server includes maintenance plans that provide database maintenance tasks, including optimization, integrity checks, and backups. The backup options available in the maintenance plans are comprehensive and include the capability to regularly schedule full, differential, and transaction log backups. This type of automation is essential to ensure that your backups are taken with a reliable tool at regular intervals.

You can create maintenance plans from within SSMS. If you open the Management node in the Object Explorer, you see a node named Maintenance Plans. If you right-click this node, you can select New Maintenance Plan to create a plan from scratch, or you can select Maintenance Plan Wizard to have a wizard guide you through the creation of a new maintenance plan. The following options that relate to backups are available as part of a maintenance plan:

- ▶ Back Up Database (Full)
- ▶ Back Up Database (Differential)
- ▶ Back Up Database (Transaction Log)

Using these tasks in a maintenance plan is a great start to a solid backup and recovery plan. Refer to Chapter 33, “Database Maintenance,” for further details about creating a maintenance plan.

Summary

Having a database environment without a solid backup and recovery plan is like owning a home without an insurance policy to protect it. If you develop a plan to minimize the possibility of losing a database, you have essentially bought an insurance policy for your data. In the event of a problem, you can call on the backups that you have invested in and recover the loss with a minimal amount of cost.

Chapter 15, “Database Mail,” explores a comprehensive mail feature offered with SQL Server 2008. Database Mail allows you to send email notifications from SQL Server. These notifications can be tied to scheduled jobs and alerts within SQL Server, including jobs that can execute those all-important database backups.

CHAPTER 15

Database Mail

Database Mail is SQL Server 2008's emailing component, built as the replacement for SQL Mail. Although SQL Mail can still be enabled in SQL Server 2008 (for backward compatibility, although it is deprecated), it's a simple task to convert all your existing SQL Mail code and SQL Agent Mail notifications to Database Mail. And you'll surely want to.

What's New in Database Mail

Database Mail is an enterprise-class implementation designed with all the features you'd expect from this next-generation database server, most of which are not available in SQL Mail. These features include support for multiple email profiles and accounts, asynchronous (queued) message delivery via a dedicated process in conjunction with Service Broker, cluster-awareness, 64-bit compatibility, greater security options (such as governing of mail attachment size and prohibition of file extensions), and simplified mail auditing. Database Mail also utilizes the industry-standard Simple Mail Transfer Protocol (SMTP), signaling the end of reliance on Extended Messaging Application Programming Interface (Extended MAPI).

Database Mail has more capabilities and is more scalable and reliable than SQL Mail, especially when stressed with the heavier usage scenarios common today. And, thankfully, it's a good deal easier to successfully configure than its predecessor.

IN THIS CHAPTER

- ▶ What's New in Database Mail
- ▶ Setting Up Database Mail
- ▶ Sending and Receiving with Database Mail
- ▶ Using SQL Server Agent Mail
- ▶ Related Views and Procedures

Setting Up Database Mail

Unlike with SQL Mail, setting up profiles and accounts for use with Database Mail is easy to accomplish, thanks mainly to the Database Mail Configuration Wizard, found in the SQL Server Management Studio (SSMS) Object Browser. You can use this wizard both to set up and manage Database Mail. Before using it, you need to switch on the Database Mail feature, which is off by default, in keeping with Microsoft's secure-by-default approach. Follow these steps to do so.

Configure the Database Mail XPs configuration option by running the following T-SQL code in a new query window (while logged in as sysadmin, of course):

```
use Master
GO
sp_configure 'show advanced options', 1;
GO
RECONFIGURE;
GO
sp_configure 'Database Mail XPs', 1;
GO
RECONFIGURE
GO
Configuration option 'show advanced options' changed from 0 to 1. Run the
RECONFIGURE statement to install.
Configuration option 'Database Mail XPs' changed from 0 to 1. Run the
RECONFIGURE statement to install.
```

If you ever want to disable Database Mail, you can run this:

```
sp_configure 'Database Mail XPs', 0;
```

This statement prevents Database Mail from starting in response to a call to `sysmail_start_sp` (discussed later in this chapter). If Database Mail is running when you make this call, it sends unsent queued mail until the mail sending process (`DatabaseMail.exe`) has been idle for the duration of the `DatabaseMailExeMinimumLifeTime` configuration setting (discussed later in this chapter); then it stops.

You also need to enable Service Broker in `msdb` (if not done already) because Database Mail relies on it as part of its implementation. To do this, you stop the SQL Server Agent service and then execute the following script:

```
USE master
GO
ALTER DATABASE msdb SET ENABLE_BROKER
```

You can check the status of Service Broker on msdb by using the following code:

```
Use Master
GO
SELECT is_broker_enabled
FROM sys.databases
WHERE name = 'msdb'
GO
is_broker_enabled
-----
1
(1 row(s) affected)
```

To receive message send requests from outside the SQL Server instance, you need to create an endpoint (preferably a certificate-secured one) associated with Service Broker. To accomplish this, refer to the “Service Broker Routing and Security” section in Chapter 49, “SQL Server Service Broker” (on the CD), or consult the “Create Endpoint” topic in Books Online.

To complete this configuration, you need to return to SSMS and establish a connection to the same SQL Server instance for which you just enabled Database Mail. You connect the Object Browser to that instance and expand the Management folder to reveal the Database Mail node. Then you right-click the Database Mail node and select the Configure Database Mail menu option to launch the Database Mail Configuration Wizard.

Creating Mail Profiles and Accounts

After you pass the Database Mail Configuration Wizard’s welcome screen, you are presented with the opportunity to set up Database Mail (“for the first time”). You can achieve this by creating the required profiles, profile security settings, SMTP accounts, and system-wide mail settings. You should leave the first radio button (Set Up Database Mail by Performing the Following Tasks) selected and then click Next.

NOTE

In Database Mail, you use mail profiles. A *mail profile* is simply a securable container for a group of SMTP accounts that is used when sending mail. In contrast to SQL Mail, with Database Mail, you can set up multiple profiles containing multiple accounts, allowing for finer-grained administrative control. You can create one profile for administrators and another for regular users, for example, or create distinct profiles dedicated to various software applications.

Note also that to use Database Mail, you no longer need to run the SQL Server or SQL Server Agent Windows services under user accounts (rather than using the default, LocalSystem), nor do you need to install Microsoft Outlook (or any other Extended MAPI client) on the machine hosting SQL Server 2008.

In the New Database Mail Account screen that appears (see Figure 15.1), you name (using a valid `sysname`) and describe your first profile in the provided text boxes, and then you

click Add to add your first SMTP account. This process is much like the process of setting up the SMTP (or sending) portion of your email accounts with your regular email client software. To create the SMTP account, you specify a name, an optional description, a user display name, an email address, an optional reply address, a server name, a port, and an authentication mode, which is used to authenticate to the specified SMTP server (as required by your SMTP provider). For many non-Windows SMTP providers, anonymous (no authentication) or basic (simple user name/password) authentication is usually required. If your provider requires Windows Authentication, the credentials under which the SQL Server Windows service runs are supplied to the SMTP server at runtime.

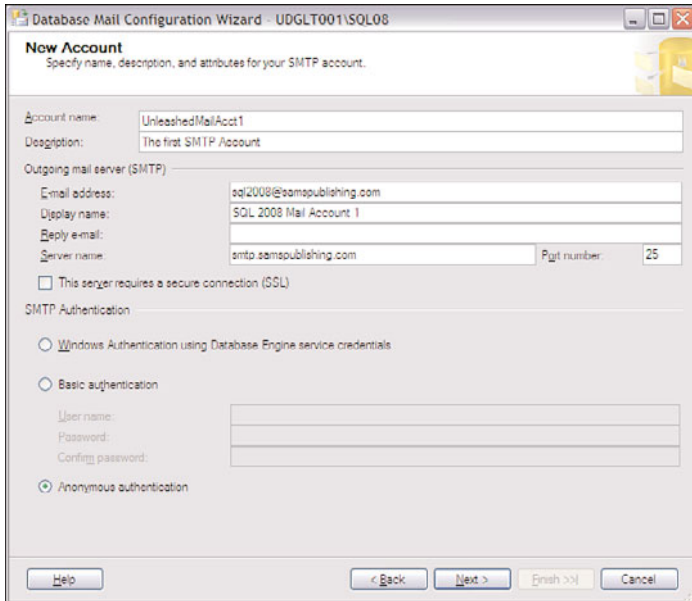

FIGURE 15.1 Using the Database Mail Configuration Wizard to set up SMTP accounts.

Instead of using the wizard, you can add a new profile via T-SQL. For example, the following three examples introduce the Database Mail stored procedures `sysmail_add_profile_sp`, `sysmail_add_account_sp`, and `sysmail_add_profileaccount_sp`.

The first script creates the new profile:

```
EXEC msdb.dbo.sysmail_add_profile_sp
    @profile_name = 'Default SQL 2008 Profile',
    @description = 'Used for general-purpose emailing.'
```

The second script creates the new SMTP account:

```
EXEC msdb.dbo.sysmail_add_account_sp
    @account_name = 'UnleashedMailAcct1',
```

```
@description = 'The first SMTP Account.',  
@email_address = 'sql2008@sampublishing.com',  
@display_name = 'SQL 2008 Mail Account 1',  
@mailserver_name = 'smtp.sampublishing.com' ;
```

The third script associates this new account with the new profile:

```
EXEC msdb.dbo.sysmail_add_profileaccount_sp  
@profile_name = 'Default SQL 2008 Profile',  
@account_name = 'UnleashedMailAcct1',  
@sequence_number = 1;
```

The great thing you'll find when adding SMTP accounts is that Database Mail allows you to provide more than one SMTP account for the same profile. You can order the SMTP accounts by priority (using the Move Up/Move Down buttons) so that if a mail send via the top-level (or first) account fails, the second account will be used to retry sending, and so on. This is called *SMTP failover priority*, and there are two mail settings that control how it works. These settings, found on the Configure System Parameters screen of the wizard, are `AccountRetryAttempts` and `AccountRetryDelay`. `AccountRetryAttempts` specifies how many mail send retries Database Mail will make before failing over to the SMTP account of next-highest priority. `AccountRetryDelay` specifies (in seconds) how long to wait between mail send retries. These features represent a big improvement in reliability over SQL Mail, which had no such retry capabilities.

After adding the new account to the profile, click Next to set up the profile security settings on the Manage Profile Security screen. Database Mail profiles have two levels of security (with two corresponding tabs on the wizard screen):

- ▶ **Public**—The profile can be used by all `msdb` users.
- ▶ **Private**—The profile can be used only by specific users or members of a specific role. (Note that to send mail, users must have `DatabaseMailUserRole` membership in `msdb`. Use `sp_addrolemember` to accomplish this.) Specify these users on the Private Profiles tab of the Manage Profile Security screen.

In this case, check the check box under the Public column of the data grid on the Public tab; then click the word No under the Default Profile column. A drop-down list appears, allowing you to make the profile the default (by changing the selection to Yes). The default profile on the server is used when you invoke `sp_send_dbmail` (the successor to `xp_sendmail`) without specifying any profile name for the `@profile_name` parameter. It's a good idea to have a default profile set up for general mailing purposes, especially when testing.

To set profile security using T-SQL, run the following call to the stored procedure `sysmail_add_principalprofile_sp`:

```
exec msdb.dbo.sysmail_add_principalprofile_sp  
@profile_name = 'Default SQL 2008 Profile',  
@principal_name = 'public',  
@is_default = 1 ;
```

A third way to configure all the previously mentioned mail objects (in the form of a T-SQL script) is to use an SMSS Database Mail query template. To do this, you open the Template Explorer via the View menu (or by pressing Ctrl+Alt+T), and then you expand to the Database Mail folder and double-click Simple Mail Database Configuration. Then you connect to your SQL Server instance and, from the Query menu, select the Specify Values for Template Parameters option (or press Ctrl+Shift+M) to fill in the desired parameter values, which correspond to the parameters of the stored procedures mentioned previously.

Using T-SQL to Update and Delete Mail Objects

To delete or update profiles, accounts, profile-account associations, and profile security settings (note: do so in reverse order), you use the stored procedures shown in Table 15.1.

TABLE 15.1 T-SQL Stored Procedures

Stored Procedure Name	Purpose
<code>sysmail_delete_profile_sp</code>	Delete a profile
<code>sysmail_delete_account_sp</code>	Delete an account
<code>sysmail_delete_principalprofile_sp</code>	Delete the association between a profile and a user or role (revokes permission for the principal on use of the profile)
<code>sysmail_delete_profileaccount_sp</code>	Delete the association between a profile and an account
<code>sysmail_update_profile_sp</code>	Update a profile
<code>sysmail_update_account_sp</code>	Update an account
<code>sysmail_update_principalprofile_sp</code>	Update the association between a profile and a user or role
<code>sysmail_update_profileaccount_sp</code>	Update the association between a profile and an account

For example, to delete a profile, you execute this:

```
exec msdb.dbo.sysmail_delete_profile_sp @profile_name='Undesireable Profile Name'
```

To update a profile's security, changing it from the default to the nondefault profile, you execute the following:

```
exec msdb.dbo.sysmail_update_principalprofile_sp
    @profile_name = 'Default SQL 2008 Profile',
```

```
@principal_name = 'public',  
@is_default = 0;
```

Alternatively, you can simply return to the wizard and select one of the Manage options to alter or drop any of the settings or objects. (Of course, under the covers, the wizard probably uses all these stored procedures.)

Setting System-wide Mail Settings

You use the Configure System Parameters screen in the Database Mail Configuration Wizard to configure the system-wide Database Mail settings. (Click Next on the Select Configuration Task screen to reach this screen, if you haven't already.) You've seen the first two settings that appear in the grid (AccountRetryAttempts and AccountRetryDelay) in an earlier section ("Creating Mail Profiles and Accounts") as they relate to SMTP failover priority. These are the other four:

- ▶ **Maximum File Size (Bytes)**—This setting specifies the maximum size of any one email attachment.
- ▶ **Prohibited Attachment File Extensions**—This setting specifies which potentially dangerous or undesirable attachment types to ban from exchanged emails.
- ▶ **Database Mail Executable Minimum Lifetime (seconds)**—This setting specifies how long (minimally) the database mail process (that is, DatabaseMail.exe, which is activated by Service Broker) should run idly before closing after it finishes emptying the mail send queue.
- ▶ **Logging Level**—This setting specifies the quality of email auditing to use, and it can be set to Normal (errors only), Extended (errors, warnings, and informational messages; this is the default), or Verbose (the same as Extended, plus success messages and other messages that are useful when you debug problems with DatabaseMail.exe). To view Database Mail's primary log, right-click the Database Mail folder in the Object Browser and then click the View Database Mail Log menu option. Examine and maintain the log by using the Log File Viewer that is launched. You can also use the built-in stored procedure `sysmail_delete_log_sp` to clear the log, or query the `msdb.sysmail_event_log` view to see its contents in tabular format.

To change any of these configuration settings via T-SQL script, use the `sysmail_configure_sp` stored procedure. `sysmail_configure_sp` takes two parameters: the name of the setting (minus any spaces) and its new value. The following example uses the `sysmail_configure_sp` procedure to change `AccountRetryDelay` to two minutes:

```
exec msdb.dbo.sysmail_configure_sp 'AccountRetryDelay', 1200
```

Testing Your Setup

The final step in setting up Database Mail is to ask SQL Server to send a test email. To do this, right-click the Database Mail folder in the Object Browser and then click the Send Test E-mail menu option.

If the test fails, click Troubleshoot, and SMSS opens the “Troubleshooting Database Mail” Books Online topic, which provides a solid set of troubleshooting steps to get you started.

If the mail is sent by SQL Server and successfully received in your client software’s inbox, you can proceed to the next section to learn how to use the `sp_send_dbmail` stored procedure to send email from T-SQL. Otherwise, look for more troubleshooting help in the “Related Views and Procedures” section of this chapter.

Sending and Receiving with Database Mail

If you’re building client applications that rely heavily on Database Mail, it’s crucial to gain an in-depth understanding of its underlying architecture. The following sections provide detailed information on its inner workings.

The Service Broker Architecture

As noted earlier, SQL Server relies on Service Broker (SSB) to activate the Database Mail process (`DatabaseMail.exe`) used to send mail. `DatabaseMail.exe` uses ADO.NET to connect to SQL Server and to read from and write to SSB queues (found in `msdb`) that hold send requests and send statuses in the form of typed SSB messages. You can view these queues (`InternalMailQueue` and `ExternalMailQueue`) in the Object Browser by selecting Service Broker and then the Queues folder. If you look a bit further in the Object Browser, you see how the mail transmission architecture is implemented (in part) as an SSB application, as you find the corresponding internal and external Database Mail SSB services (`InternalMailService` and `ExternalMailService`), SSB message types (`SendMail` and `SendMailStatus`), and a single SSB contract (`SendMail/v1.0`).

SSB’s involvement with Database Mail works like this:

1. `sp_send_dbmail` (as the SSB *initiator*) is invoked and returns immediately. Under the covers, this adds an SSB message of type `SendMail` to the SSB mail queue, activating the undocumented internal stored procedure `sp_ExternalMailQueueListener`. Note that the mail message itself is saved to one or more of the `msdb` tables (such as `sysmail_unsentitems` and `sysmail_attachments`) if there are any attachments.
2. SSB launches `DatabaseMail.exe` (running under the credentials of the SQL Server service), which, in turn, connects back to SQL Server, using Windows Authentication.
3. `DatabaseMail.exe` reads the queued SSB send message, retrieves the mail message data, sends the email, and, finally (acting as the SSB *target*), places a message of type `SendMailStatus` in the mail status queue, reporting on the mail sending success or failure.
4. When there’s nothing left to be sent in the outbound queue, and the maximum process idle time has been reached, `DatabaseMail.exe` exits.

By using SSB, Database Mail inherits the reliability of the SSB message transmission architecture. If you want to learn more about Service Broker and how its constructs work, consult Chapter 49 (on the CD) for full details.

Sending Email

The SSB queues that Database Mail uses must first be enabled before you can send mail from a session. You do this by executing the `msdb` stored procedure `sysmail_start_sp`. This procedure is similar to its predecessor, `xp_startmail` (as it must be called before sending), except that it has no parameters and, of course, has nothing to do with MAPI. It returns `0` or `1`, indicating success or failure. If you don't call this procedure, you receive this error message:

```
Mail not queued. Database Mail is stopped. Use sysmail_start_sp to
start Database Mail.
```

To temporarily disable SSB's activation of the mail process, you execute `sysmail_stop_sp` (also with no parameters), which returns `0` or `1`. If you send mail from code after this disabling this process, these messages will be queued. The external process is not started until `sysmail_start_sp` is called again. To check on the status of Database Mail, you can execute `sysmail_help_status_sp` (with no parameters). To check on the status of the queues, you execute `sysmail_help_queues_sp`.

After you execute `sysmail_start_sp`, you're ready to begin sending mail using the `sp_send_dbmail` stored procedure. It has 21 parameters, most of which are optional. As the query engine will tell you if you try to execute it with no or too few parameters, at least one of the following parameters must be specified: `@body`, `@query`, `@file_attachments`, or `@subject`. You also must specify one of the following: `@recipients`, `@copy_recipients`, or `@blind_copy_recipients`.

NOTE

For the following T-SQL examples to work, you must first configure a default profile using either the Database Mail Configuration Wizard or Database Mail stored procedures, as detailed earlier.

A minimally parameterized test call might look like the following:

```
exec msdb.dbo.sp_send_dbmail @body='Testing...', @subject='A Test',
@recipients='test@samspublishing.com'
go
Mail Queued.
```

Table 15.2 describes the parameters, their types, and the `xp_sendmail` parameters to which they may correspond, to help you along in converting your existing T-SQL code.

TABLE 15.2 Parameters for Database Mail Stored Procedure `sp_send_dbmail`

Parameter	Description	xp_sendmail Parameter to Which It Corresponds
<code>@profile_name</code>	The sysname of the profile whose SMTP accounts will be used to send.	Not available in <code>xp_sendmail</code> .
<code>@recipients</code>	A <code>varchar(max)</code> semicolon-delimited list of the recipients' email addresses.	Same as <code>xp_sendmail</code> .
<code>@copy_recipients</code>	A <code>varchar(max)</code> semicolon-delimited list of the carbon copy recipients' email addresses.	Same as <code>xp_sendmail</code> .
<code>@blind_copy_recipients</code>	A <code>varchar(max)</code> semicolon-delimited list of the blind carbon copy recipients' email addresses.	Same as <code>xp_sendmail</code> .
<code>@subject</code>	The <code>nvarchar(255)</code> email subject.	Same as <code>xp_sendmail</code> .
<code>@body</code>	The <code>nvarchar(max)</code> email body.	Was <code>@message</code> in <code>xp_sendmail</code> .
<code>@body_format</code>	One of the two <code>varchar(20)</code> email format type strings, either 'HTML' or 'TEXT' (the default).	Not available in <code>xp_sendmail</code> .
<code>@importance</code>	One of the three <code>varchar(6)</code> email importance strings, either 'Low', 'Normal' (the default), or 'High'.	Not available in <code>xp_sendmail</code> .
<code>@sensitivity</code>	One of the four <code>varchar(12)</code> email sensitivity strings, either 'Normal' (the default), 'Personal', 'Private', or 'Confidential'.	Not available in <code>xp_sendmail</code> .
<code>@file_attachments</code>	An <code>nvarchar(max)</code> semicolon-delimited list of absolute paths to files to attach.	Was <code>@attachments</code> in <code>xp_sendmail</code> .

TABLE 15.2 Parameters for Database Mail Stored Procedure `sp_send_dbmail`

Parameter	Description	xp_sendmail Parameter to Which It Corresponds
@query	An <code>nvarchar(max)</code> T-SQL code string to be executed when the message is sent. The code is executed in a different session than the calling session, so variable scope is a consideration.	Same as <code>xp_sendmail</code> .
@execute_query_database	The sysname of the database in which the T-SQL in query is to be executed.	Was <code>@dbuse</code> in <code>xp_sendmail</code> .
@attach_query_result_as_file	A bit value indicating whether the results of the T-SQL in query should be an attachment (1) or appended to the body (0; the default).	Was <code>@attach_results</code> in <code>xp_sendmail</code> .
@query_attachment_filename	The <code>nvarchar(255)</code> filename for the attached query results (as per <code>@query</code> and <code>@attach_query_result_as_file</code>). If not specified, the generated filename is arbitrary (usually <code>QueryResults [some number].txt</code>)	In <code>xp_sendmail</code> , the first filename in <code>@attachments</code> was used.
@query_result_header	A bit value indicating whether the query result (1; the default) should include the column headers.	Was <code>@no_header</code> in <code>xp_sendmail</code> .
@query_result_width	An <code>int</code> value (defaulting to 256; you specify a number between 10 and 32767) indicating how wide a line in the query results should be before line wrapping occurs.	Was <code>@width</code> in <code>xp_sendmail</code> .
@query_result_separator	A <code>char(1)</code> value (defaulting to a space) that indicates the query results column separator.	Was <code>@separator</code> in <code>xp_sendmail</code> .

TABLE 15.2 Parameters for Database Mail Stored Procedure `sp_send_dbmail`

Parameter	Description	xp_sendmail Parameter to Which It Corresponds
@exclude_query_output	A bit value that indicates whether to suppress the query output (such as rowcounts, print statements, and so forth) from being printed on the query console. 0 (do not suppress) is the default.	Was @no_output in xp_sendmail.
@append_query_error	A bit value that indicates whether to send the email if the query to be executed raises an error. If set to 1, the error message is appended to the query output, and the query window for the session also displays the error ("A severe error occurred on the current command. The results, if any, should be discarded."). If set to 0 (the default), the message is not sent, and sp_send_dbmail returns 1.	Not available in xp_sendmail, but similar to @echo_error.
@query_no_truncate	A bit value that indicates whether to truncate query results having long values (such as varchar(max), text, xml, and so on) greater than 256. It defaults to 0 (off). Microsoft warns that using this can slow things down, but it is the only way to properly send these types.	Not available in xp_sendmail.
@mailitem_id	An output parameter, an int value indicating the unique mailitem_id of the message. You see this as a column in the views discussed in the section "Related Views and Procedures," later in this chapter.	Not available in xp_sendmail.

Note that the @type and @set_user parameters for xp_sendmail are not available. @type, of course, is obsolete because it is MAPI specific. @set_user is also obsolete because the content of the T-SQL to be executed may contain an EXECUTE AS statement.

Now that you're familiar with the flurry of mail sending options, let's look at a few examples and then examine how to track your sent messages by using the system views. Both of the following examples rely on sending via the default profile of the current user context. If the user has a default private profile assigned, it is used. If not, the default public profile is used (as in these examples). If there is no default public profile, an error is raised.

The example shown in Listing 15.1 sends an email containing an xml result to a recipient as an attached Extensible Application Markup Language (XAML) document, retrieved from the `AdventureWorks2008.Production.Illustration` column.

LISTING 15.1 Sending XML as an Attachment with Database Mail

```
USE AdventureWorks2008
GO
DECLARE
    @subject nvarchar(255),
    @body varchar(max),
    @query nvarchar(max),
    @IllustrationId int,
    @query_attachment_filename nvarchar(255),
    @mailitem_id int

SELECT
    @IllustrationId = pi.IllustrationId,
    @subject = 'XAML for "' + pm.Name + '" attached. '
FROM Production.Illustration pi
JOIN Production.ProductModelIllustration pmi
ON pmi.IllustrationId = pi.IllustrationId
JOIN Production.ProductModel pm
ON pm.ProductModelID = pmi.ProductModelID

SELECT
    @body =
        N'Attached, please find the XAML diagram for illustration #' +
        CAST(@IllustrationId as nvarchar(10)) +
        '. A XAML browser plug-in is required to view this file.'

SELECT @query =
    N'SELECT Diagram FROM Production.Illustration
    WHERE IllustrationId = ' + CAST(@IllustrationId as nvarchar(10))

SELECT @query_attachment_filename = N'PM_' +
    CAST(@IllustrationId as nvarchar(10)) + '.xml'
```

```

exec msdb.dbo.sp_send_dbmail
    @subject=@subject,
    @body=@body,
    @recipients='test@sampublishing.com',
    @query=@query,
    @execute_query_database='AdventureWorks2008',
    @attach_query_result_as_file=1,
    @query_attachment_filename=@query_attachment_filename,
    @query_no_truncate=1,
    @exclude_query_output=1,
    @query_result_width=32767,
    @mailitem_id=@mailitem_id OUTPUT

```

```

SELECT sent_status, sent_date
FROM msdb.dbo.sysmail_allitems
WHERE mailitem_id = @mailitem_id
GO
sent_status sent_date
-----
unsent      NULL
(1 row(s) affected)

```

Note that you must set `@query_no_truncate` to 1 and `@query_result_width` to the maximum (to be safe) value for the attached query results to contain consistently well-formed XML. In addition, you should not include any carriage returns or line feeds in the body of the message, or the SMTP servers may not be able to send it.

The example in Listing 15.2 sends some query results as a comma-separated value (CSV) file that can be imported into programs such as Microsoft Excel. (You need to use the Get External Data command to accomplish this with Excel 9.)

LISTING 15.2 Sending CSV Data as an Attachment with Database Mail

```

USE AdventureWorks2008
GO
DECLARE @mailitem_id int, @tab char(1)
SET @tab = char(13)

exec msdb.dbo.sp_send_dbmail
    @subject='D. Margheim, Contact Info',
    @body='Attached is Diane Margheim's contact info, in CSV format.',
    @recipients='test@sampublishing.com',
    @query=N'SELECT BusinessEntityID, Title, FirstName, MiddleName, LastName
    FROM Person.Person
    WHERE BusinessEntityId = 8',
    @execute_query_database='AdventureWorks2008',

```

```
@attach_query_result_as_file=1,
@query_attachment_filename='DMargheim.csv',
@exclude_query_output=1,
@query_result_separator=',',
@mailitem_id=@mailitem_id OUTPUT

SELECT sent_status, sent_date
FROM msdb.dbo.sysmail_allitems
WHERE mailitem_id = @mailitem_id
GO
sent_status sent_date
-----
unsent      NULL
(1 row(s) affected)
```

Notice that in both of these code listings, the values selected from the `sent_status` and `sent_date` columns of `sysmail_allitems` indicate that the mail has not yet been sent. The reason is that mail sending (like all other SSB messaging) is asynchronous: The message is immediately queued, and the Mail process later picks it up and sends it. To find out more about system views such as `sysmail_allitems`, see the section “Related Views and Procedures,” later in this chapter.

Receiving Email

The only way for SQL Server 2008 to receive email is by using the legacy stored procedures, such as `sp_processmail`, with SQL Mail. Database Mail does not support receiving incoming messages because there is no IMAP or POP3 support. This may have something to do with the fact that receiving email can represent a major security risk. Imagine what a denial-of-service attack on a database cluster could do to an organization. Or consider the danger of an incoming email request resulting in the execution of a query such as `DROP DATABASE X`. Most SQL Server data is too precious to jeopardize in this manner. Microsoft has also made it clear that SQL Mail will be phased out in the next release of SQL Server. Plus, there are many better alternatives to using this methodology, such as using native Web services (as discussed in Chapter 48, “SQL Server Web Services”), using .NET CLR-integrated assembly code (as discussed in Chapter 45, “SQL Server and the .NET Framework”), or building a dedicated Service Broker application (as discussed in Chapter 49).

Using SQL Server Agent Mail

As with SQL Server 2000, SQL Server 2008’s Agent has the capability to send email notifications. They may be triggered by alerts or scheduled task completions, such as jobs. SQL Server 2008 provides the option of using either SQL Mail or Database Mail to do the sending, but SQL Mail will soon be phased out, and Database Mail is by far the more robust choice. As with Database Mail, SQL Server Agent Mail is turned off by default, and you must configure it via SMSS or T-SQL, as described in the following sections.

Job Mail Notifications

The following sections show an example in which you create a SQL Server Agent Mail operator that SQL Server Agent will notify when a job completes.

Creating an Operator

First, you need to create an operator. To do so, using the Object Browser, you expand the SQL Server Agent node and then right-click the Operators folder and select New Operator. Then you should name this new operator Test Database Mail Operator and provide an email address for testing purposes in the Email Name text box. You can use any valid email address you can access with your email client software. You click OK to save the new operator.

Enabling SQL Agent Mail

Next, you need to enable SQL Server Agent to use Database Mail. You right-click the SQL Server Agent node and then select Properties. On the left side of the Properties dialog that appears (see Figure 15.2), you click the Alert System link. Under the Mail Session group, you check the Enable Mail Profile check box. In the Mail System drop-down list, you select Database Mail (this is also the place where you can choose SQL Mail, if you desire). In the Mail Profile drop-down list, you select the default SQL 2008 profile you created earlier and then click OK. By doing this, you are telling SQL Server Agent to use the SMTP servers in your default profile to send email. You need to restart SQL Server Agent by using the right-click menu.

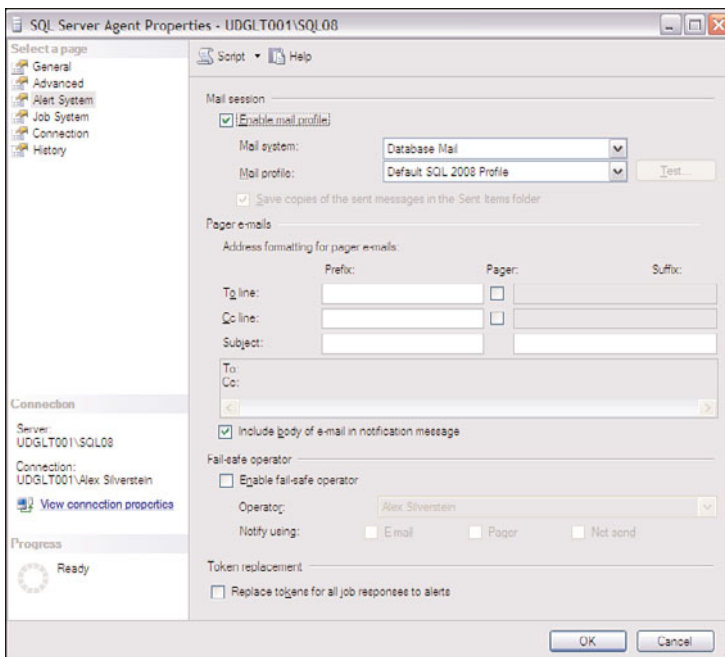

FIGURE 15.2 Using the SQL Server Agent Properties dialog to configure Database Mail.

Creating the Job

Next, you need to create the job. You begin by right-clicking the Jobs folder and then selecting New Job. You should name the job Database Mail Test Job and select an owner. Then you should check the Enabled check box near the bottom of the dialog and click the Steps link on the left side of the dialog. Next, you click the New button and add a step named Test Mail Step 1. You should leave the type as Transact-SQL and then change the database selection to AdventureWorks2008. In the Command text box, you enter the following code:

```
RAISERROR('This is simply a test job.', 10, 1)
```

Next, you click the Advanced link on the left side of the dialog, and in the On Success Action drop-down list, you select Quit the Job Reporting Success. Then you click the Notifications link on the left side of the dialog. Next, under Actions to Perform When the Job Completes, you check the Email check box and select the operator you just created. From the drop-down to the right, you select When the Job Completes and then click OK to save the job.

Testing the Job-Completion Notification

To test the email configuration and notification you just set up, you right-click the job name under the Jobs folder and then select Start Job. If everything is set up properly, an email message appears in your inbox, indicating the job's successful completion. Its body text might look something like this:

```
JOB RUN:      'Database Mail Test Job' was run on 5/7/2009 at 8:37:22 PM
DURATION:     0 hours, 0 minutes, 0 seconds
STATUS:       Succeeded
MESSAGES:     The job succeeded. The Job was invoked by User [TestUser].
               The last step to run was step 1 (Test Mail Step 1).
```

Alert Mail Notifications

As another example, in the following sections, you'll create a simple user-defined alert that you can trigger directly from T-SQL script.

Creating an Alert

You start by creating an alert. To do this, you use the Object Browser to expand the SQL Server Agent node; then you right-click the Alerts node and select New Alert. In the Alert Properties dialog that appears (see Figure 15.3), you name the new alert Database Mail Test Alert and make sure the Enabled check box is checked. For the Event type, you leave the selection on SQL Server Event Alert. Under Event Alert Definition, select AdventureWorks2008 from the Database Name drop-down list, and then click the Severity option button and choose 010 - Information. Next, check the Raise Alert When Message Contains check box and type the phrase This is a Test in the Message Text text box.

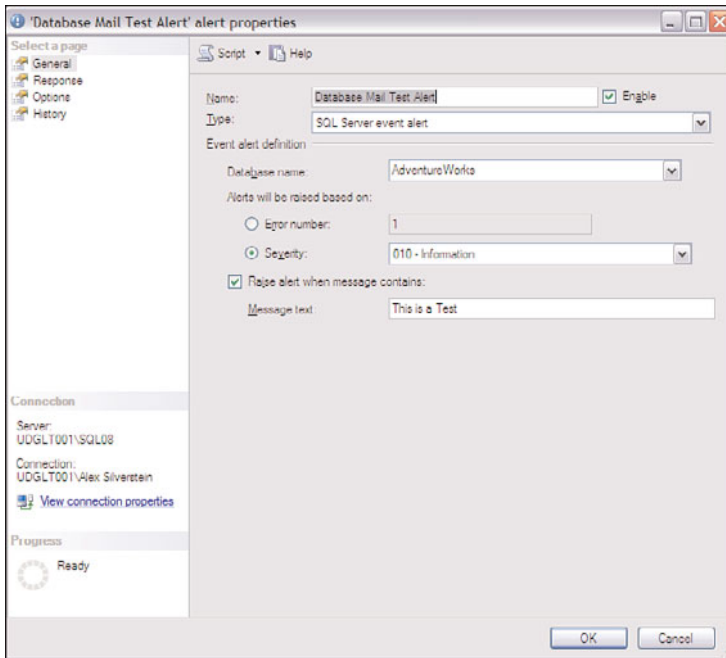

FIGURE 15.3 Creating a SQL Server event alert with a Database Mail notification.

On the left side of the alert properties dialog, you click the Response link. Then you check the Notify Operators check box and, in the Operator list, check the Email check box to the right of the Test Database Mail Operator grid row. Finally, you click OK to close and save the new custom alert.

Testing the Alert Notification

To test your new alert notification, you open a new query window in SMSS and enter the following code:

```
USE AdventureWorks2008
go
RAISERROR('This is an alert mail test', 10, 1) WITH LOG
go
'This is an alert mail test'
```

Because you specified `WITH LOG`, this simple statement writes an event to the Windows Event log, which in turn triggers the alert because the database context, message text, and severity all match the conditions of the alert. An email message should have appeared in your inbox, indicating the alert's successful triggering. This message should contain body text such as this:

```
DATE/TIME:      5/7/2009 9:00:45 PM
DESCRIPTION:    Error: 50000 Severity: 10 State: 1 This is an alert
```

```
mail test
COMMENT:      (None)
JOB RUN:      (None)
```

Related Views and Procedures

To report on the status of all your Database Mail objects without relying on wizards and properties pages, you need some tabular views and stored procedures. `msdb` contains many system tables, views, and corresponding stored procedures that make this task easy. The following section lists the tables (or views) and their columns, noting the stored procedure (if any) that you can use to read from them.

Viewing the Mail Configuration Objects

The first set of `msdb` objects we'll review are those related to system objects such as profiles, profile security, and accounts:

- ▶ **sysmail_profile**—Contains basic profile data, including the unique `profile_id`, name, description, `last_mod_datetime`, and `last_mod_user` name. You execute `sysmail_help_profile_sp` to retrieve this data by `@profile_name` or `@profile_id`.
- ▶ **sysmail_principalprofile**—Contains profile security settings, including the `profile_id`, associated principal (or user) (`principal_SID`), profile default status (`is_default`: 1 for yes or 0 for no), `last_mod_datetime`, and `last_mod_user` name. You execute `sysmail_help_principalprofile_sp` to retrieve this data by `@profile_name`, `@profile_id`, `@principal_name`, or `@principal_id` (not principal SID). Here's an example:

```
exec msdb.dbo.sysmail_help_principalprofile_sp
    @profile_name='Default SQL 2008 Profile'
```

- ▶ **sysmail_account**—Contains basic account data, including the unique `account_id`, name, description, `email_address`, `display_name`, `replyto_address`, `last_mod_datetime`, and `last_mod_user` name. You execute `sysmail_help_account_sp` to retrieve this data by `@account_id` or `@account_name`.
- ▶ **sysmail_server**—Contains account SMTP server data, including the unique related `account_id` and `servertype`, `servername`, `port`, server username, server authentication data (`credential_id`), SSL status (`enable_ssl`), `last_mod_datetime`, and `last_mod_user` name. (`sysmail_help_account_sp` returns data from this table as well.)
- ▶ **sysmail_servertype**—Contains `servertype` data for accounts' servers. (SMTP is the only currently supported type, although it seems this system was built for extensibility, as the columns `is_incoming` and `is_outgoing` may leave the door open for adding POP or IMAP servers sometime in the future.) Also includes `last_mod_datetime` and `last_mod_user` name. (`sysmail_help_account_sp` returns data from this table as well.)

To join `sysmail_account`, `sysmail_server`, and `sysmail_servertime` (as `sysmail_help_account_sp` seems to do), you can try a query such as the following:

```
SELECT *
FROM msdb.dbo.sysmail_account a
JOIN msdb.dbo.sysmail_server s
ON a.account_id = s.account_id
JOIN msdb.dbo.sysmail_servertime st
ON st.servertime = s.servertime
```

- ▶ **sysmail_profileaccount**—Maintains the profile-account relationship, including the `profile_id`, `account_id`, account priority `sequence_number`, `last_mod_datetime`, and `last_mod_user name`. You execute `sysmail_help_profileaccount_sp` to retrieve this data by `@account_id`, `@account_name`, `@profile_id`, or `@profile_name`.
- ▶ **sysmail_configuration**—Contains the system-wide mail configuration settings (`paramname`, `paramvalue`, `description`), and when and by whom each was last modified (`last_mod_datetime` and `last_mod_user name`). You execute `sysmail_help_configure_sp` to query this data by `@parameter_name`. Here's an example:

```
exec msdb.dbo.sysmail_help_configure_sp
    @parameter_name='accountretrydelay'
```

Viewing Mail Message Data

The second set of `msdb` objects (and perhaps the more important ones) we'll review are those used to discover the status of mail messages.

The first thing you need to do is to check on the status of the mail messages you've attempted to send, without relying on inboxes to tell you if they've been received. Several views in `msdb` enable this, most of which may be filtered by mail account, sending user, send date, status, and more. To begin this process, you query the view `sysmail_allitems`, which contains all the data about your messages (subjects, recipients, importance, and so on) as well as `send_request_date`, `sent_date`, and `sent_status`. Here's an example:

```
SELECT mailitem_id, subject, sent_status
FROM msdb.dbo.sysmail_allitems
go
mailitem_id    subject                                                    sent_status
-----
1              Database Mail Test                                         sent
2              C. Adams, Contact Info                                     sent
3              XAML for HL Touring Seat/Saddle attached.                 sent
4              SQL Server Job System: 'Database Mail Test Job'           sent
```

(4 row(s) affected)

Because all these messages have a `sent_status` of `sent`, the contents of this recordset are analogous to what you'd find if you queried the view `sysmail_sentitems`. But suppose your `sent_status` column read failed. In that case, you'd start by querying the `sysmail_faileditems` view (a subset of `sysmail_allmailitems`) in conjunction with `sysmail_event_log` (which contains the detailed textual reasons why failures have occurred). Here's an example:

```
SELECT f.subject, f.mailitem_id, l.description
FROM msdb.dbo.sysmail_event_log l
JOIN msdb.dbo.sysmail_faileditems f
ON f.mailitem_id = l.mailitem_id
WHERE event_type = 'error'
ORDER BY log_date
go
subject                mailitem_id    description
-----
Database Mail Test      3              The mail could not be sent because[...]the
string is not in the form required for an e-mail address
```

(1 row(s) affected)

Note that the quality of the contents of `sysmail_event_log` depends on the `Log Level` system-wide mail configuration setting (discussed earlier in the section “Setting System-wide Mail Settings”). The `Log File Viewer` also uses this table's contents. To permanently delete its contents, you use the stored procedure `sysmail_delete_log_sp`.

To query how many messages are queued (waiting to be sent) and for how long, you use the `sysmail_unsentitems` view. Here's an example:

```
SELECT
    mailitem_id,
    subject,
    DATEDIFF(hh, send_request_date, GETDATE()) HoursSinceSendRequest
FROM msdb.dbo.sysmail_unsentitems
```

If you're unsure why messages aren't being sent, you can try the following:

- ▶ Execute `sysmail_help_queue_sp`, whose resulting `state` column tells the state of the mail transmission queues: `INACTIVE` (off) or `RECEIVES_OCCURRING` (on). To see the status for only the `mail` (outbound) or `status` (send status) queues, you use the `@queue_type` parameter.
- ▶ Execute `sysmail_help_status_sp`, whose resulting `Status` column tells you the state of Database Mail itself: `STOPPED` or `STARTED`.

Summary

This chapter showed how Database Mail has elevated the status of emailing with SQL Server from somewhat difficult to use to enterprise class. Microsoft has achieved this goal by relying on cross-platform industry standards, by making configuration easy, by providing a comprehensive set of system objects for storage and tracking, by adding failover capability, and by utilizing the Service Broker infrastructure.

Chapter 16, “SQL Server Scheduling and Notification,” digs much deeper into configuring SQL Server Agent jobs and alerts, as well as using Database Mail for job and alert notifications.

CHAPTER 16

SQL Server Scheduling and Notification

Automation is the key to efficiency, and the SQL Server Agent is your automation tool in SQL Server 2008. This chapter delves into the administrative capabilities of the SQL Server Agent and its capability to schedule server activity and respond to server events.

The SQL Server Agent, which runs as a Windows service, is responsible for running scheduled tasks, notifying operators of events, and responding with predefined actions to errors and performance conditions. The SQL Server Agent can perform these actions without user intervention, utilizing the following:

- ▶ **Alerts**—*Alerts* respond to SQL Server or user-defined errors, and they can also respond to performance conditions. An alert can be configured to run a job as well as notify an operator.
- ▶ **Jobs**—A *job* is a predefined operation or set of operations, such as transferring data or backing up a transaction log. A job can be scheduled to run on a regular basis or called to run when an alert is fired.
- ▶ **Operators**—An *operator* is a user who should be notified when an alert fires or a job requests notification. The operator can be notified by email, by pager, or via the `NET SEND` command.

IN THIS CHAPTER

- ▶ What's New in Scheduling and Notification
- ▶ Configuring the SQL Server Agent
- ▶ Viewing the SQL Server Agent Error Log
- ▶ SQL Server Agent Security
- ▶ Managing Operators
- ▶ Managing Jobs
- ▶ Managing Alerts
- ▶ Scripting Jobs and Alerts
- ▶ Multiserver Job Management
- ▶ Event Forwarding

NOTE

The SQL Server Agent is not supported with the SQL Server Express Edition or SQL Server Express Advanced Edition. It is supported in all the other editions of SQL Server 2008, however. You can use the Windows Task Scheduler as an alternative for scheduling when using the SQL Server Express Editions. The Task Scheduler has basic scheduling capabilities but does not compare to the robust features found in the SQL Server Agent.

What's New in Scheduling and Notification

A new feature added to SQL Server 2008 Scheduling and Notification is the capability to execute PowerShell scripts. PowerShell is a command-line scripting language that allows administrators to achieve greater control and productivity. SQL Server 2008 comes with several PowerShell snap-ins that give you access to a variety of SQL Server objects. Scripts that are written to access these objects can be run from SQL Server jobs using the new PowerShell job type. You can find a more detailed discussion of PowerShell's capabilities in the next chapter, "Administering SQL Server 2008 with PowerShell."

Policy-Based Management is another new feature in SQL Server 2008. This feature does not fall directly under Scheduling and Notification, but it provides related management features. For example, some of the multiserver concepts discussed later in this chapter can be replaced or augmented through the use of Policy-Based Management. This feature is covered in Chapter 22, "Administering Policy Based Management."

Configuring the SQL Server Agent

The primary configuration settings for the SQL Server Agent are located within the Object Explorer and SQL Server Configuration Manager. Most of the settings that define how the SQL Server Agent will execute are defined via the SQL Server Agent Properties accessible from the Object Explorer. The SQL Server Configuration Manager contains settings related to the SQL Server Agent's service. The service settings are limited but contain important properties such as the Startup Account for the SQL Server Agent.

Configuring SQL Server Agent Properties

Figure 16.1 shows the SQL Server Agent Properties dialog that appears when you right-click and select Properties on the SQL Server Agent node located on the root of the Object Explorer tree.

You can set several different types of properties in the SQL Server Agent Properties dialog. The General options are displayed by default, and they include the capability to set the

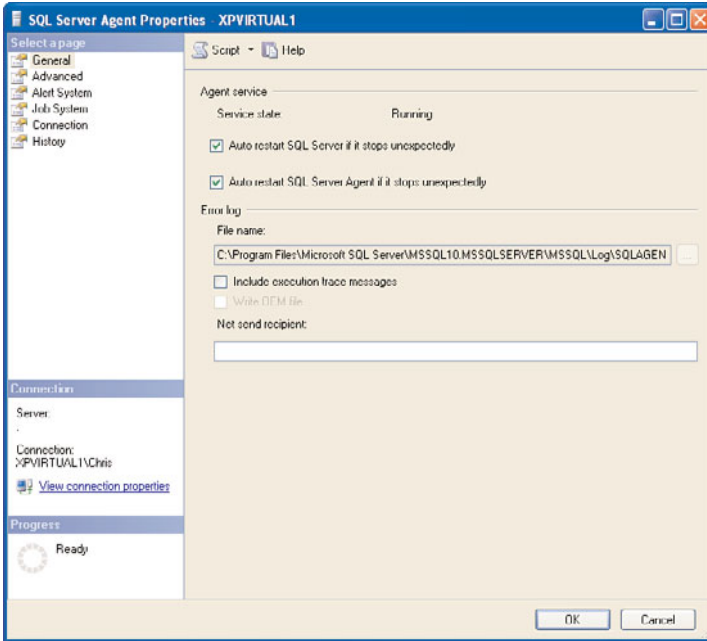

FIGURE 16.1 SQL Server Agent properties.

auto restart options and define an error log for the SQL Server Agent. Selecting the option Auto Restart SQL Server Agent If It Stops Unexpectedly is best for most installations. There is usually a heavy dependency on the Agent performing its actions, and you probably want the service to be restarted if it has been inadvertently stopped.

The Advanced page contains options for event forwarding and idle CPU conditions. The event forwarding options are discussed in detail in the section “Event Forwarding,” later in this chapter. The idle CPU options define conditions related to the execution of jobs that have been set up to run when the CPU is idle. You can define idle CPU conditions such as the average CPU percentage that the CPU must be below to be considered idle.

The Alert System page is related to configuring email notification and is discussed in the “Configuring Email Notification” section, later in this chapter.

The Job System page has an option to set the shutdown time-out interval. This option determines the amount of time the SQL Server Agent waits for jobs to complete before finalizing the shutdown process. There is also an option related to proxy accounts discussed in the “SQL Server Agent Proxy Account” section, later in this chapter.

The Connection page includes an option to set an alias for the local host server. This option is useful if you cannot use the default connection properties for the local host and need to define an alias instead.

The History page options are related to the amount of job history that will be retained. You have the option to limit the size of the job history log and/or remove job history that is older than a set period of time.

TIP

Careful attention should be given to the amount of history that is retained. Every time a job is run, the history of that execution and the related detail is saved. The need for careful monitoring is particularly true when dealing with SQL Server instances that have a large number of databases. The msdb database contains the job history records and can become sizable over time if the history is not removed. For example, we have seen environments where close to 700 databases were installed on one SQL Server instance. The company was performing SQL Server log backups every 15 minutes on each of these databases and full backups each night. When you do the math (4 log backups/hour * 700 databases = 2800 backups/hour), you can see that the amount of history written to the msdb database can be significant.

Configuring the SQL Server Agent Startup Account

The startup account defines the Microsoft Windows account the SQL Server Agent service uses. The selection of this account is critical in defining the level of security that the SQL Server Agent will have. Access to resources on the server on which SQL Server is running and access to network resources are determined by the startup account. This selection is particularly important in cases in which the SQL Server Agent needs to access resources on other machines. Examples of network access that the SQL Server Agent might need include jobs that write backups to a drive on another machine and jobs that look for files found on other servers on the network.

The startup account for the SQL Server Agent is set initially during the installation of SQL Server, but you can change it by using several different tools such as the Windows Service Control Manager and SQL Server Configuration Manager. The Windows Service Control Manager is a good tool for viewing all the services on your server, but changes to the SQL Server services are better made through the SQL Server Configuration Manager. The Configuration Manager is more comprehensive and makes additional configuration settings, such as Registry permissions, that ensure proper operation.

The SQL Server Configuration Manager is a consolidated tool that allows you to manage network options and services related to SQL Server. To launch this tool, you select Start, Microsoft SQL Server 2008, Configuration Tools. Figure 16.2 shows an example of the Configuration Manager with the SQL Server 2008 services selected for viewing. To change the startup account for the SQL Server Agent, you can right-click on its service and select Properties.

The startup account used by the SQL Server Agent is initially determined during the installation of SQL Server. You have the option of choosing one of several built-in accounts, or you can select a domain account. The built-in accounts are available by default and do not

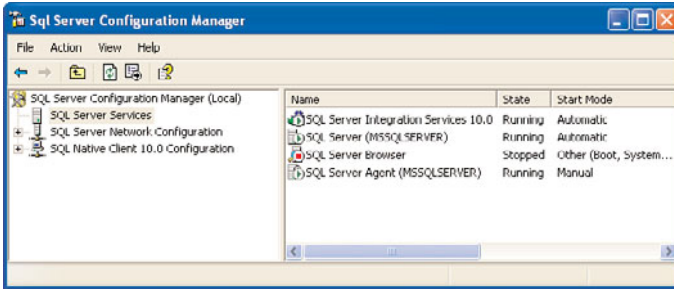

FIGURE 16.2 SQL Server Agent service properties.

require any network administration to use them. These accounts, however, should be used with caution because they can provide network access to the SQL Server Agent that may not be desired. Generally, you want to provide the minimum amount of security necessary for the SQL Server Agent to perform its tasks.

The recommended startup account for the SQL Server Agent is a Windows account. You specify a Windows startup account for SQL Server Agent by using the This Account option on the Service Properties window. The Windows account can be a local user account or domain user account. It must be a member of the SQL Server sysadmin fixed server role on the local SQL Server instance. The use of this type of startup account provides the most flexibility and allows you to tailor the network and local resources that the SQL Server Agent has permission to access.

The Windows account does not have to be a member of the Windows administrators group. In fact, exclusion from the administrators group is recommended in most cases. This approach adheres to the principle of least privileges, which says that you should limit the amount of security provided to only that which is needed. In many cases, inclusion in the administrators group is not needed and only increases exposure to security threats.

The Windows account you choose with the This Account option must have certain security rights to be able to function as the startup account for SQL Server. The account must have permission to log on as a service. You can set this permission and others by using the Local Security Policy application, which can be found under Administrative Tools. You can select the Local Policies node and then select User Rights Assignment to display a list of all the security settings, including Log On as a Service Policy. You should make sure the account you chose or the group that it is in is included in this policy.

TIP

The Local Security Policy editor can be hard to find. In most operating systems, you can click Start Run then enter **secpol.msc** to launch the Local Security Policy editor.

Configuring Email Notification

The SQL Server Agent can send email notifications; it can send email via SQL Mail or Database Mail. SQL Mail was retained for backward compatibility. It utilizes an Extended Messaging Application Programming Interface (Extended MAPI) interface to send email and requires that you install an email application (such as Outlook) that supports Extended MAPI communication on the computer that is running SQL Server.

Database Mail, which is now the recommended mail solution for the SQL Server Agent, is the focus of this section. It was added in SQL Server 2005, and it utilizes Simple Mail Transfer Protocol (SMTP) instead of Extended MAPI to send mail. This simplifies email setup and has many benefits over SQL Mail, including the following:

- ▶ There is no requirement that an email client be installed on the SQL Server machine.
- ▶ Email is queued for later delivery if the mail server stops or fails.
- ▶ Multiple SMTP servers can be specified so that mail continues to be delivered in the event that one of the SMTP servers stops.
- ▶ Database Mail is cluster aware.

Database Mail is disabled by default in SQL Server 2008 but can be enabled using the Database Mail Configuration Wizard. This wizard provides a comprehensive means for configuring Database Mail. The Database Mail Configuration Wizard is not launched from the SQL Server Agent node. Instead, you can launch it by expanding the Management node, right-clicking Database Mail, and selecting Configure Database Mail. This wizard guides you through the configuration of mail profiles, SMTP accounts, and other options relevant to Database Mail. The Configuration Wizard and many other details related to Database Mail are discussed in detail in Chapter 15, “Database Mail.”

After you set up Database Mail and confirm that it is working properly, you can select it as your mail system for the SQL Server Agent to send mail. You do this by right-clicking the SQL Server Agent node in the Object Explorer and selecting Properties. Then you select the Alert System page in the SQL Server Agent Properties dialog, and the screen shown in Figure 16.3 appears. In this figure, Database Mail is selected as the mail system, along with a mail profile for Database Mail created with the Database Mail Configuration Wizard. The mail profile you select can have multiple SMTP accounts assigned to it. This allows for redundancy in the event that the mail cannot be sent to one of the SMTP accounts.

To ensure proper functioning of the alert system, you should restart the SQL Server Agent service after the alert system has been configured. If you experience problems sending notifications via the SQL Server Agent, you should check the service account that SQL Server is running under. If the SQL Server Agent is running with the local system account, resources outside the SQL Server machine will be unavailable; this includes mail servers that are on other machines. You should change the service account for the SQL Server Agent to a domain account to resolve this issue. Chapter 15 provides more information on using Database Mail in SQL Server 2008.

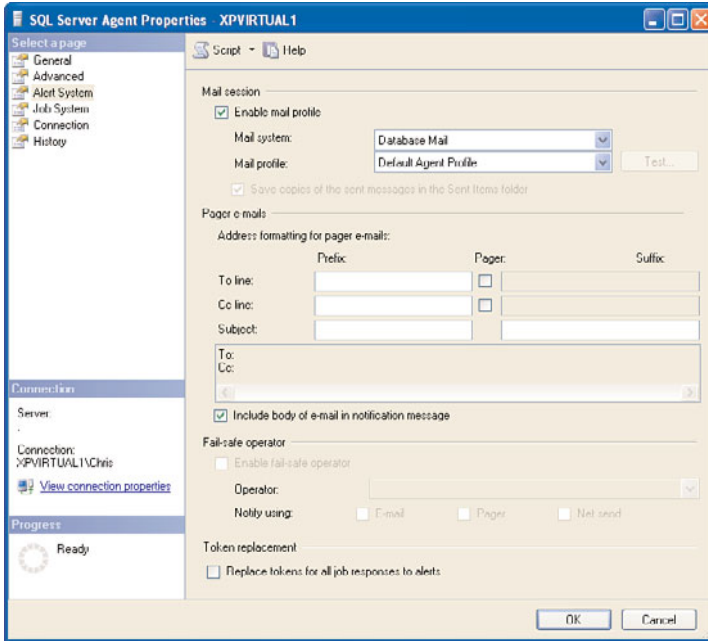

FIGURE 16.3 The Alert System page of the SQL Server Agent Properties dialog.

SQL Server Agent Proxy Account

Proxy accounts allow non-Transact-SQL (non-T-SQL) job steps to execute under a specific security context. By default, only users in the sysadmin role can execute these job steps. Non-sysadmin users can be assigned to a proxy account to allow them to run the special job steps. In SQL Server 2000, a single proxy account was provided for this function. With SQL Server 2008, multiple proxy accounts can be established, each of which can be assigned to a different SQL Server Agent subsystem.

To establish a proxy account for the SQL Server Agent, you must first create a credential. A *credential* contains the authentication information necessary to connect to a resource outside SQL Server. The credential is typically linked to a Windows account that has the appropriate rights on the server. To create a credential, you open the Security node in the Object Explorer, right-click the Credentials node, and select New Credential. You give the credential a name, enter an identity value that corresponds to a valid Windows account, and provide a password for the account.

After creating a credential, you can create a new proxy account and link it to the credential. To create a new proxy account, you expand the SQL Server Agent node in the Object Explorer tree, right-click Proxies, and select New Proxy Account. Figure 16.4 shows an example of the New Proxy Account dialog. In this example, the proxy name and credential name are the same, but they do not need to be. The only subsystem selected for the

sample proxy account in Figure 16.4 is the operating system, but a proxy account can be linked to multiple subsystems.

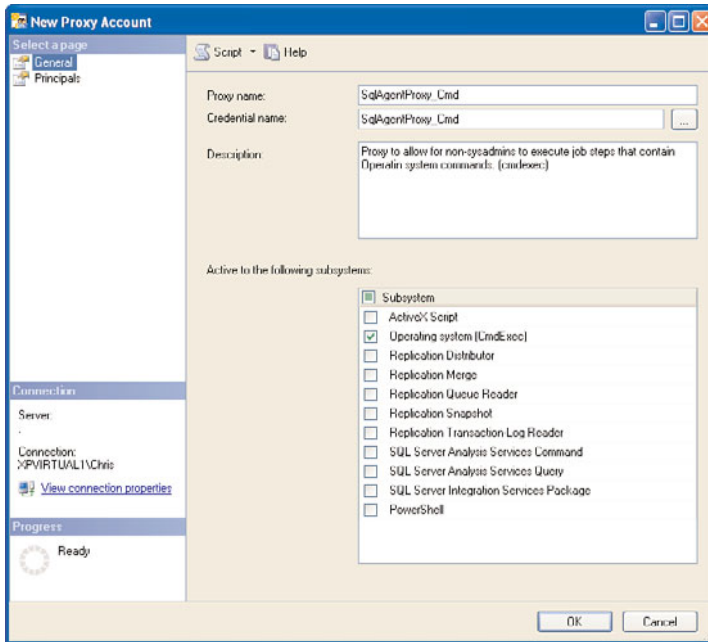

FIGURE 16.4 Creating a new proxy account.

After a proxy account is created, a sysadmin can assign one or more SQL logins, msdb roles, or server roles to the proxy. You do this by using the Principals page of the New Proxy Account dialog. A proxy account can have zero or many principals assigned to it. Conversely, a principal can be assigned to many different proxies. Linking non-admin principals to the proxy allows the principal to create job steps for subsystems that have been assigned to the proxy.

Proxy accounts are referenced within a SQL Server Agent job step. The General page of the Job Step Properties dialog contains a Run As drop-down that lists valid accounts or proxies that can be used to run the particular job step. After you add a proxy account, you see it in this drop-down list. Keep in mind that the account is not visible for a T-SQL job step that does not utilize a proxy account. Steps that utilize the T-SQL subsystem execute under the job owner's context and they do not utilize a proxy account.

Viewing the SQL Server Agent Error Log

The SQL Server Agent maintains an error log that records information, warnings, and error messages concerning its operation. A node named Error Logs is located in the SQL Server Agent tree in the Object Explorer. The Error Logs node contains multiple versions of the

SQL Server Agent error log. By default, a maximum of 10 versions of the error log are displayed under the Error Logs node. The versions displayed include the current error log and the last 9 versions. Each time the SQL Server Agent is restarted, a new error log is generated, with a name that includes a time stamp. The first part of the current version's name is Current. Names of older logs start with Archive #, followed by a number; the newer logs have lower numbers. The SQL Server error log works in much the same way as the SQL Server Agent's error log.

TIP

You can cycle the error log at any time without stopping and starting the SQL Server Agent. To do so, you right-click the Error Logs node in the Object Explorer and select Recycle; a new error log is then generated. You can also use the `msdb.dbo.sp_cycle_agent_errorlog` stored procedure to cycle the error log. You need to remember to also select the Refresh option to show the latest available error logs.

To view the contents of any of the logs, you need to double-click the particular log. Double-clicking a particular log file launches the Log File Viewer. The Log File Viewer contains the SQL Server Agent error logs in addition to logs that are associated with other SQL Server components, including Database Mail, SQL Server, and Windows NT. Figure 16.5 shows a sample Log File Viewer screen with the current SQL Server Agent error log selected for display. The Log File Viewer provides filtering capabilities that allow you to focus on a particular type of error message, along with other viewing capabilities that are common to all the logs available for viewing.

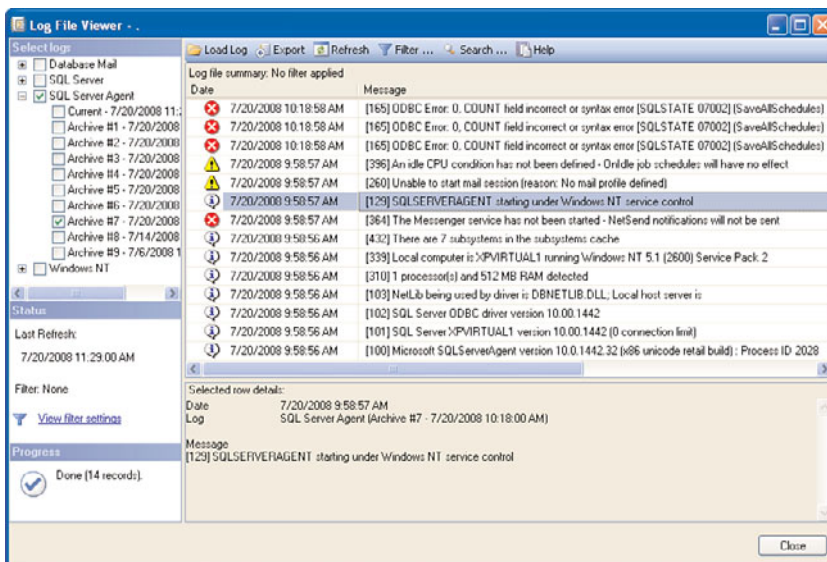

FIGURE 16.5 The SQL Server Agent error log.

SQL Server Agent Security

Many changes were made to the security model related to the SQL Server Agent in SQL Server 2005. In the past, everyone could view the SQL Server Agent. Starting in SQL Server 2005, logins must be a part of the `sysadmin` server role or assigned to one of three `msdb` database roles to be able to view and modify the SQL Server Agent. The SQL Server Agent node does not appear in the Object Explorer tree if the login does not have the appropriate permissions. Following are the `msdb` database roles and their basic permissions:

- ▶ **SQLAgentUserRole**—Users with this permission can create and manage local jobs and job schedules that they own. They cannot create multiserver jobs or manage jobs that they do not own.
- ▶ **SQLAgentReaderRole**—Users with this permission can view jobs that belong to other users in addition to all the permissions associated with `SQLAgentUserRole`.
- ▶ **SQLAgentOperatorRole**—Users with this permission can view operators and alerts and control jobs owned by other users. The job control on jobs owned by other users is limited to stopping or starting and enabling or disabling those jobs. `SQLAgentOperatorRole` also has all the permissions available to `SQLAgentUserRole` and `SQLAgentReaderRole`.

`SQLAgentUserRole` has the fewest privileges, and each subsequent role has increasing levels of security. In addition, each subsequent role inherits the permissions of the roles with fewer permissions. For example, `SQLAgentReaderRole` can do everything that `SQLAgentUserRole` can do and more. Refer to the topic “Implementing SQL Server Agent Security” in SQL Server Books Online for a detailed list of all the permissions related to the new database roles.

Managing Operators

Operators are accounts that can receive notification when an event occurs. These accounts are not linked directly to the user and login accounts that are defined on the server. They are basically aliases for people who need to receive notification based on job execution or alerts. Each operator can define one or more electronic means for notification, including email, pager, and the `NET SEND` command.

To add a new operator, you expand the SQL Server Agent node in the Object Explorer and right-click the Operators node. Then you select New Operator from the right-click menu. Figure 16.6 shows the New Operator screen, with many of the fields populated for the creation of a new operator named LauraG.

The General page of the New Operator screen allows you to enter the name of the operator, the notification options, and the “on duty” scheduled for the operator. The operator name can be any name, but it must be unique within the SQL Server instance and must be no more than 128 characters. The operator name can be the same as another login or user on the server, but this is not required.

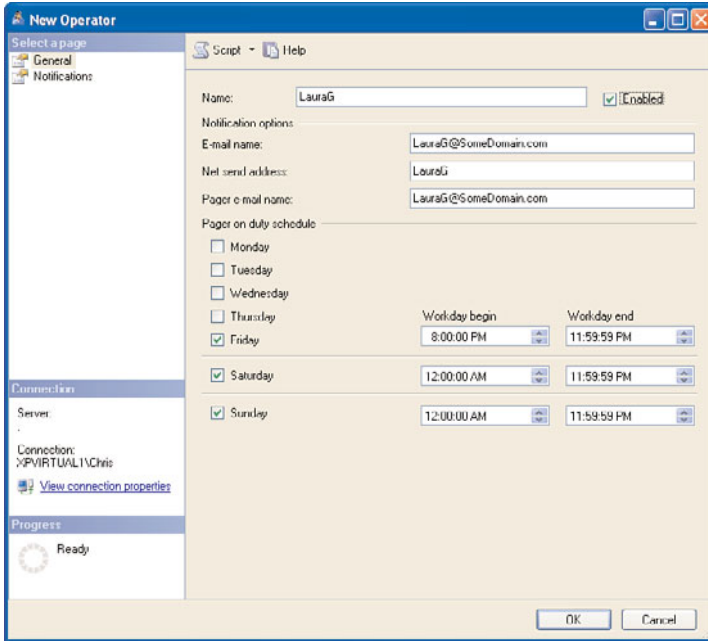

FIGURE 16.6 Creating a new operator.

The notifications options are the key to operators. You create operators so that you can then define notification options and have messages sent from SQL Server.

If you use the email notification option, the email address you specify must be a valid address that can be reached via Database Mail or SQL Mail. One of the two mail options must be configured before the email functionality will work. If Database Mail is configured, the email is sent via an SMTP server. To send email with SQL Mail, SQL Server must be able to access a Microsoft Exchange server, and you must have the Extended MAPI client installed on the SQL Server machine.

The NET SEND notification option causes a pop-up window to appear on the recipient's computer; this window contains the notification text. In the Net Send Address text box, you specify the name of the computer or user that is visible on the network to the SQL Server machine. For NET SEND to work, the Messenger service on SQL Server must be started. This Messenger service must also be started on the machine that is receiving the NET SEND message. You can test the basic NET SEND capabilities by executing NET SEND at the command prompt. The basic syntax for NET SEND follows:

```
NET SEND {name | * | /domain[:name] | /users} message
```

The following example uses the NET SEND command to send the message "Test net send message" to the operator LauraG:

```
NET SEND LauraG "Test net send message"
```

The final notification option is through a pager email address. Pager email requires that third-party software be installed on the mail server to process inbound email and convert it to a pager message. The methods for implementing pager email and the available software are dependent on the pager provider. You should contact your pager vendor for implementation details.

If you implement pager notification, you can also define the pager schedule for the operator. The Pager on Duty Schedule section of the New Operator dialog allows you to define the days and times when the operator will be available to receive a page. The General page includes a check box for each day the operator can receive a page. It also includes the Workday Begin and Workday End settings, which you can use to define the valid time periods to receive a page.

The other page available when defining a new operator is the Notifications page, which displays the alerts and jobs for which the operator will receive notifications. For a new operator, the Alert List or Job List is empty, as shown in Figure 16.7.

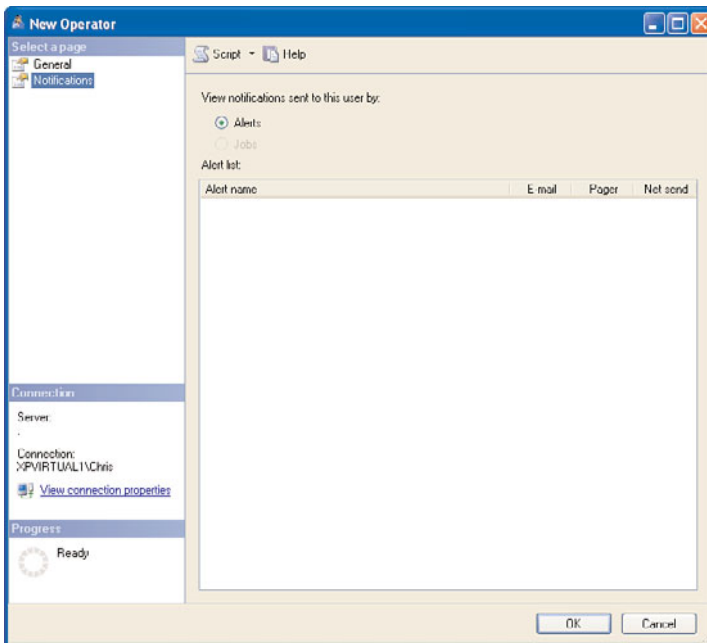

FIGURE 16.7 The Notifications page of the New Operator dialog.

You'll have a better understanding of the usefulness of operators after you read the following discussions of jobs and alerts. Jobs and alerts can have operators linked to them for notification purposes.

Managing Jobs

A *job* is a container for operations that can be executed by the SQL Server Agent. Jobs can be run once or scheduled to run on a regular basis. Jobs provide the basis for SQL Server automation and allow for the execution of many different types of operations, including T-SQL, SQL Server Integration Services (SSIS) packages, and operating system commands.

Defining Job Properties

The Jobs node is located under SQL Server Agent in the Object Explorer. You right-click the Jobs node and select New Job to create a new SQL Server Agent job. A New Job dialog like the one shown in Figure 16.8 appears.

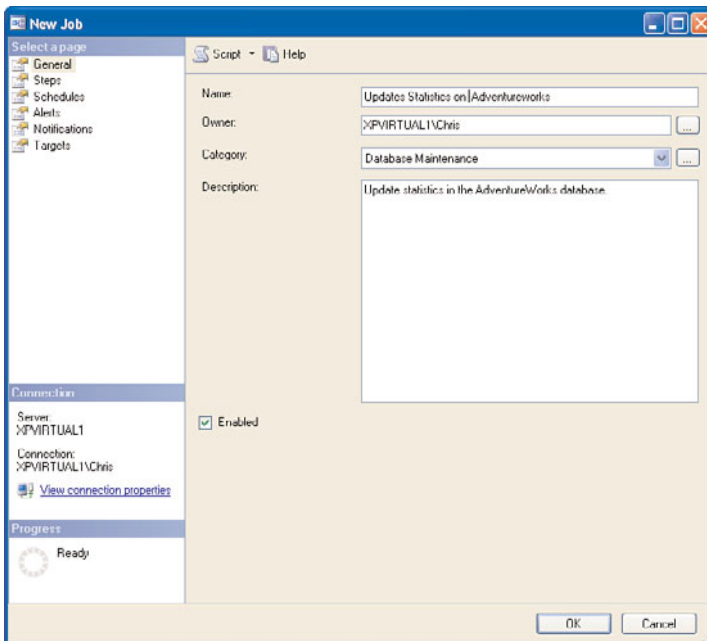

FIGURE 16.8 The New Job dialog.

NOTE

Only logins that are part of one of the msdb fixed database roles or are members of the sysadmin fixed server role are able to create or modify jobs.

The General properties page shown in Figure 16.8 contains the basic information about the job, including the name and description. The owner of the job defaults to the login

for the person creating the job; however, if the login of the person creating the job is part of the `sysadmin` fixed server role, the default can be changed. You use the Category selection to group or organize jobs. There are several predefined categories for selection, including Database Maintenance and Log Shipping. The default category is set to `[Uncategorized(local)]`.

Defining Job Steps

After you add the general information for a new job, you are ready to add the job steps that actually perform the work. To do this, you select the Steps page on the left side of the New Job dialog, and the job steps for this job are listed. To create a new job step, you click the New button, and a New Job Step dialog like the one shown in Figure 16.9 appears.

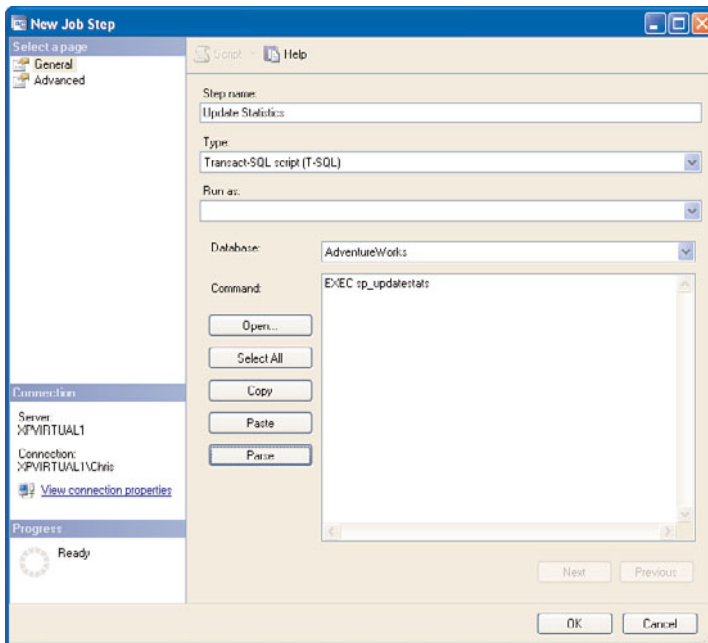

FIGURE 16.9 The New Job Step dialog.

A step name is the first piece of information you need to provide for the job step. It can be up to 128 characters long and must be unique within the job. Then you need to select a job step type. The SQL Server Agent can run a variety of types of job steps, including the following:

- ▶ ActiveX script (Visual Basic, Java, Perl script)
- ▶ Operating System (CmdExec)
- ▶ PowerShell

- ▶ Replication Distributor
- ▶ Replication Merge
- ▶ Replication Queue Reader
- ▶ Replication Snapshot
- ▶ Replication Transaction Log Reader
- ▶ SQL Server Analysis Services Command
- ▶ SQL Server Analysis Services Query
- ▶ SQL Server Integration Services Package
- ▶ Transact-SQL script (T-SQL)

SQL Server Analysis Services Command, Server Analysis Services Query, and SQL Server Integration Services Package are types that were added in SQL Server 2005. They provide integration with SQL Server Analysis Services (SSAS) and SSIS. Chapters 45, “SQL Server and the .NET Framework,” and 46, “SQLCLR: Developing SQL Server Objects in .NET,” provide detailed discussions of these technologies. The PowerShell job type was added in SQL Server 2008; further information on PowerShell is provided in Chapter 17, “Administering SQL Server 2008 with PowerShell.”

The Step properties page displays different information, depending on the type of step selected. When the Transact-SQL script (T-SQL) type is selected, you see a window similar to the one shown in Figure 16.9. If you choose the SQL Server Integration Services Package type, the Step properties page changes to allow you to enter all the relevant information needed to execute an SSIS package.

In many cases (including T-SQL), a command window is available to input the step commands. With a T-SQL command, you can enter the same type of commands you would enter in a query window. You click the Parse button to validate the SQL and ensure proper syntax. The Operating system (CmdExec) type allows you to enter the same types of commands that you can enter in a command prompt window. Each step type has its own command syntax that you can test in the native environment to ensure proper operation.

You can select the Advanced page to configure job flow information and other information related to the job step. On Success Action allows you to specify the action to perform when the current job step completes. Actions include the execution of the next job step (if one exists) and the ability to set job status based on the step completion. The same selection options also exist for On Failure Action.

The Retry options define the options that relate to retrying the job step in the event that the job step fails. Retry Attempts defines the number of times the job step will be re-executed if it fails. Retry Intervals (Minutes) defines the amount of time (in minutes) between retry attempts.

TIP

The Retry options are useful for polling scenarios. For example, you might have a job step that tests for the existence of a file during a given period of the day. The job can be scheduled to start at a time of day when the file is expected. If the file is not there and the step fails, Retry Attempts can be set to poll again for the file. Retry Interval determines how often it retries, and the combination of Retry Attempts and Retry Interval determines the total polling window. For example, if you want to check for the file for 2 hours, you can set Retry Attempts to 24 with a Retry Interval of 5 minutes. If the job step fails more than the number of retries, the step completes in failure.

The last set of options on the Advanced page relate to the output from the job step. Job step output can be saved to an output file that can be overwritten each time the job step is run, or the output can be appended each time. The Log to Table option writes the job step output to the `sysjobstepslogs` table in the `msdb` database. The table contains one row for each job step with the Log to Table option enabled. If Append Output to Existing Entry in Table is enabled, the `sysjobstepslogs` data row for the step can contain output for more than one execution. If this option is not selected, the table contains only execution history for the last execution of the step.

CAUTION

If you choose the Append Output to Existing Entry in Table option, the size of the `sysjobstepslogs` table will grow over time. You should consider using the `sp_delete_jobsteplog` stored procedure to remove data from the `sysjobstepslogs` table. This stored procedure has several different parameters that allow you to filter the data that will be removed. You can use these parameters to remove log data by job, job step, date, or size of the log for the job step.

Defining Multiple Jobs Steps

You can define multiple jobs steps in a single job. This allows you to execute multiple dependent job actions. The job steps run one at a time (serially), and you can specify the order of the job steps. The job order and the related dependencies are called *control of flow*.

Figure 16.10 shows an example of a job that has multiple dependent job steps. Take note of the On Success and On Failure columns, which define the control of flow. For example, if step 1 succeeds, the next step occurs. If step 1 fails, no further steps are executed, and the job quits, reporting a job failure. The control of flow is slightly different for the second step, whereby the control of flow passes to the next step on success but flows to the fourth step if a failure occurs.

The control of flow is defined on each job step. As discussed earlier in this chapter, the Advanced tab of the New Job Step dialog provides drop-down lists that allow you to specify the actions to take on success and on failure. In addition, the Steps page that lists all of a job's steps allows you to specify the start step for the job. The drop-down box at

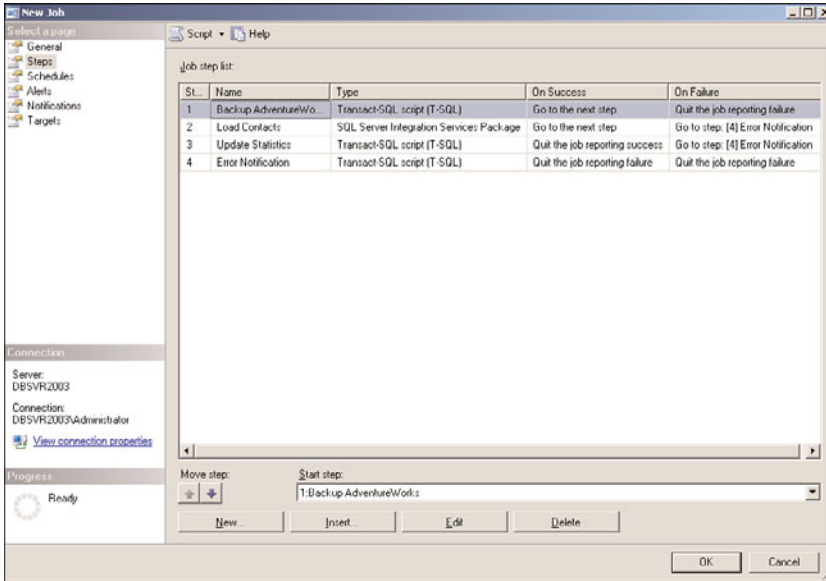

FIGURE 16.10 Multiple job steps.

the bottom of the Steps page provides this function. You can also use the Move Step arrows to change the start step. Manipulating the start step is useful when you're restarting a job manually, as in the case of a job failure; in this situation, you might want to set the job to start on a step other than the first step.

NOTE

SSIS provides the same type of flow control capabilities as the SQL Server Agent. In fact, maintenance plans that contain multiple related actions (such as optimization, backup, and reporting) utilize SSIS packages. A scheduled job starts an SSIS package, which executes the package in a single step, but the actual maintenance steps are defined within the package. The SSIS Designer utilizes a graphical tool that depicts the flow of control and allows you to modify the individual steps.

Defining Job Schedules

The SQL Server Agent contains a comprehensive scheduling mechanism you can use to automate the execution of your jobs. A job can have zero, one, or more schedules assigned to it. You can view the schedules associated with a job by selecting the Schedules page of the Job Properties screen. To create a new schedule for a job, you can click the New button

at the bottom of the Schedules page. Figure 16.11 shows the New Job Schedule Properties page, with a sample schedule and options defined. The options on this screen vary, depending on the frequency of the job schedule. For example, if the frequency of the schedule shown in Figure 16.11 were changed from daily to weekly, the screen would change to allow for the selection of specific days during the week to run the job.

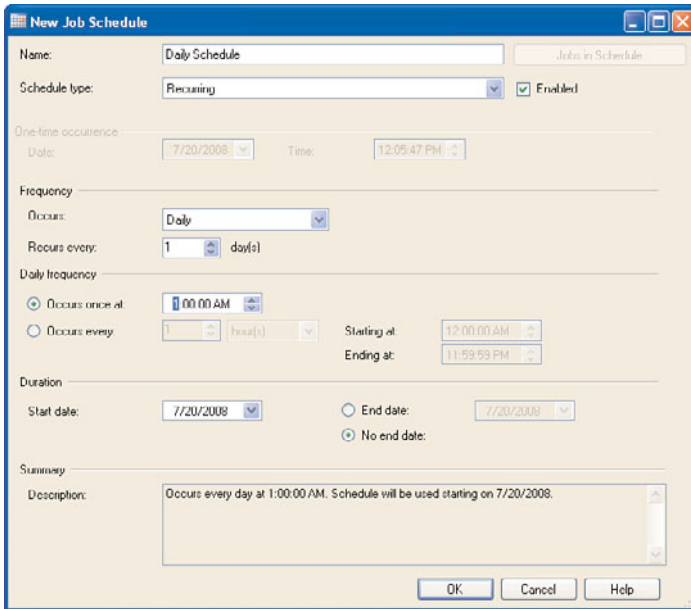

FIGURE 16.11 The New Job Schedule Properties page.

You have the ability to share job schedules so that one job schedule can be utilized by more than one job. When you select the Schedule page, a Pick button is available at the bottom of the page. If you click the Pick button, a screen appears showing all the defined schedules. If you highlight one of the schedules in the list and click OK, the schedule is linked to the related job. You can also view all the jobs associated with a particular schedule by editing the schedule and clicking the Jobs in Schedule button in the top-right portion of the Job Schedule Properties screen.

Tracking multiple job schedules and schedule execution can be challenging in an environment that has many jobs and schedules. The `sp_help_jobs_in_schedule`, and `sp_help_jobactivity` stored procedures are helpful system stored procedures that are found in the msdb database. The `sp_help_jobs_in_schedule` stored procedure provides information about the relationship between jobs and schedules. The `sp_help_jobactivity` stored procedure provides point-in-time information about the runtime state of SQL

Server jobs. This stored procedure returns a lot of information, including recent job executions, the status of those executions, and the next scheduled run date.

Defining Job Notifications

The Notifications page of the Job Properties dialog, as shown in Figure 16.12, allows you to define the notification actions to perform when a job completes.

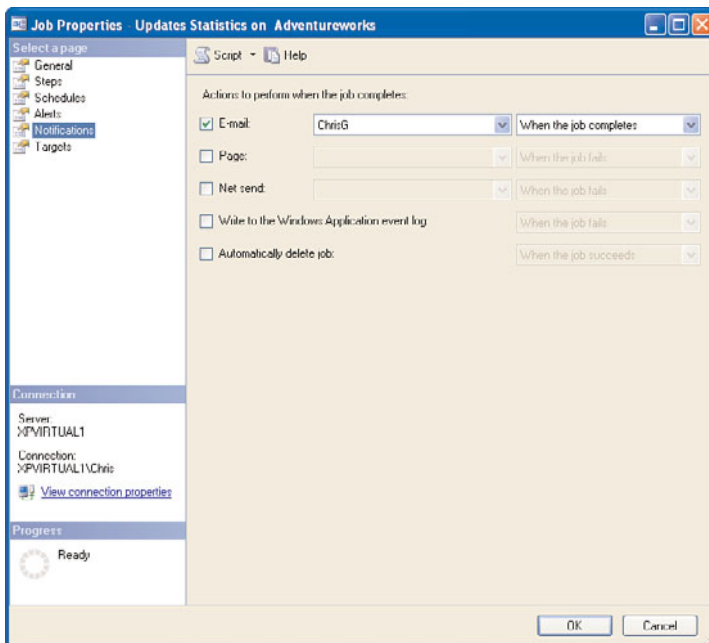

FIGURE 16.12 The Notifications page of the Job Properties dialog.

As discussed earlier in this chapter, notifications can be sent via email, pager, or NET SEND command. The notifications for a Schedule Job can be sent based on the following events:

- ▶ When the job succeeds
- ▶ When the job fails
- ▶ When the job completes

Each of these events can have a different notification action defined for it. For example, a notification might send an email if the job succeeds but page someone if it fails.

You also have the option of writing notification information into the Windows Application event log or automatically deleting the job when it completes. These two

options are also available on the Notifications page. Writing events to the Application log is a useful tracking mechanism. Monitoring software is often triggered by events in the application log. The automatic job deletion options are useful for jobs that will be run only once. As with the other notification options, you can set up the delete job action such that it is deleted only when a specific job event occurs. For example, you might want to delete the job only if the job succeeds.

Viewing Job History

You view job history via the Log File Viewer, which is a comprehensive application that allows for many different types of logs to be viewed. You right-click a job in the SQL Server Agent and select History to display the Log File Viewer. Figure 16.13 shows the Log File Viewer with several examples of job history selected for viewing.

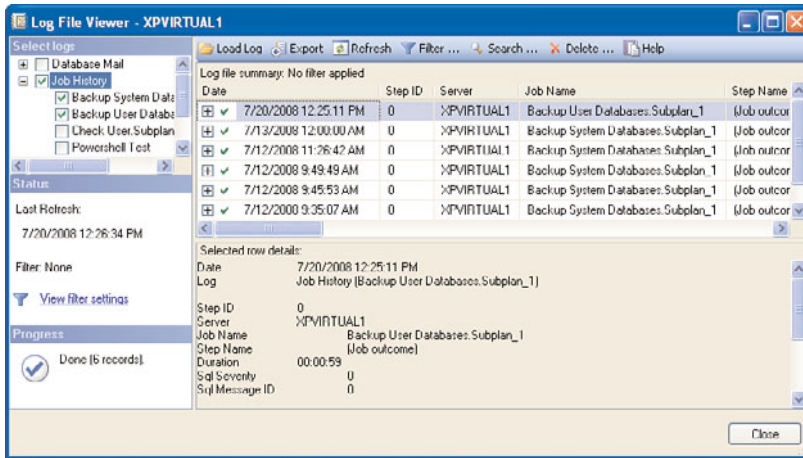

FIGURE 16.13 Job history shown in the Log File Viewer.

Compared to viewing job history in SQL Server versions prior to SQL Server 2005, the current form of the Log File Viewer has some distinct advantages for viewing job history. In the Log File Viewer, you can expand multiple jobs for viewing at one time. To view job step details, you expand the job entries and select a job step. You can use the row details shown below the log file summary to troubleshoot job errors and isolate problems. The Log File Viewer also has filtering capabilities that allow you to isolate the jobs to view. Click on the Filter button and the Filter Settings dialog appears. You can filter jobs by using a number of different settings, including User, Start Date, and Message Text. You must click the Apply Filter button for the selected filtering option to take effect.

The amount of history that is kept is based on the history settings defined for the SQL Server Agent. You access the history settings by right-clicking the SQL Server Agent node, selecting Properties, and then selecting the History page on the left part of the screen. The settings available on the History page are shown in Figure 16.14. By default, the job

history log is limited to 1,000 rows, with a maximum of 100 rows per job. You can also select the Automatically Remove Agent History option and select a period of time to retain history. This setting causes the SQL Server Agent to periodically remove job history from the log. This is a good approach for keeping the size of the log manageable.

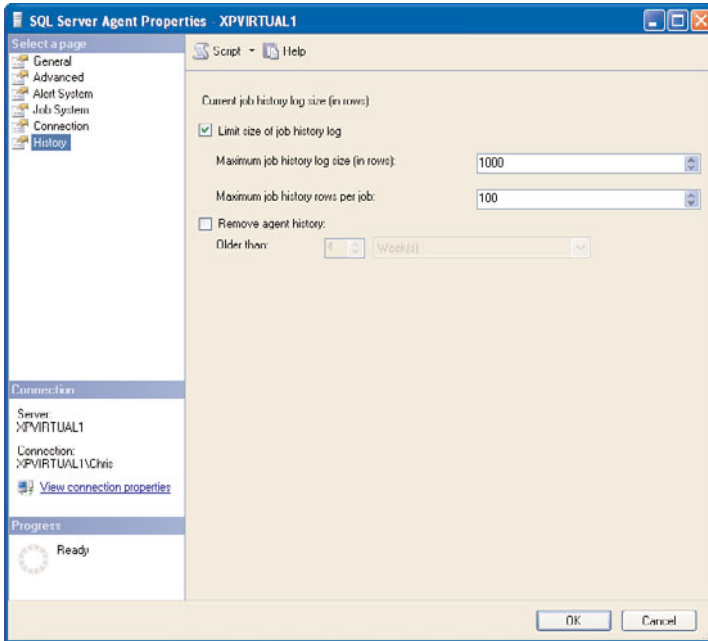

FIGURE 16.14 Job history settings.

Managing Alerts

The SQL Server Agent can monitor events that occur on the database server and automatically respond to these events with alerts. Alerts can be fired based on SQL Server events, performance conditions, and Windows Management Instrumentation (WMI) events. After an alert is fired, the SQL Server Agent can respond by notifying an operator or executing a job. This provides a proactive means for identifying and reacting to critical conditions on a database server.

Defining Alert Properties

To define alerts, you select the SQL Server Agent node in the Object Explorer tree and then right-click on the Alerts node and select New Alert. Figure 16.15 shows an example of the New Alert dialog that appears.

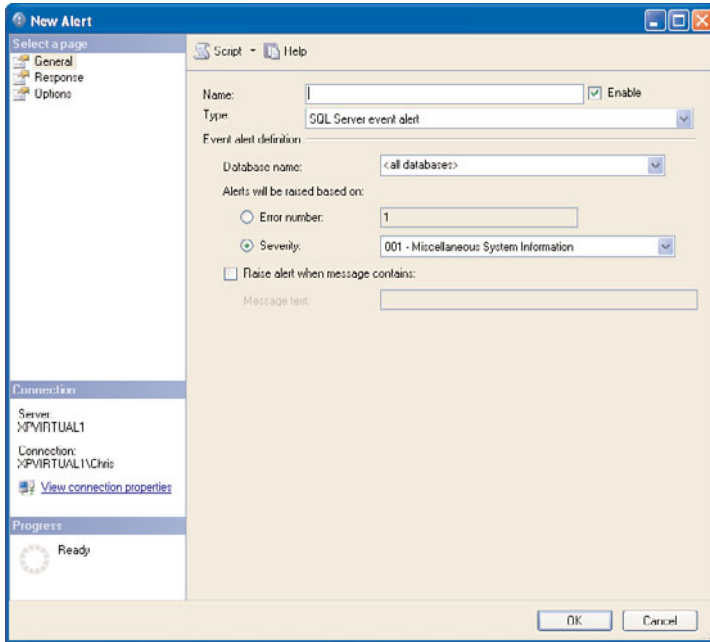

FIGURE 16.15 The General page of the New Alert dialog.

The General page selected in Figure 16.15 allows you to define the basic alert properties, including the name of the alert and type of event you want the alert to respond to. The default type of alert, the SQL Server event alert, is triggered by SQL Server events that write to the Windows Application event log. SQL Server writes to the Application event log when the following events occur:

- ▶ When sysmessages errors with a severity of 19 or higher are generated. You can use the `sys.sysmessages` catalog view to view all the sysmessages that are stored in the server. You can create new user-defined messages by using the `sp_addmessage` stored procedure; they must have a `msg_id` (or error number) that is greater than 50,000. The error message must be created before you can reference the error number in an alert.
- ▶ When sysmessages errors are generated by the database engine. These messages have error numbers lower than 50,000 and are installed by default.
- ▶ When any `RAISERROR` statement is invoked with the `WITH LOG` option. The `WITH LOG` statement forces the event to be written to the Application event log. Messages generated with `RAISERROR` that have a severity level greater than 18 are required to write to the Application event log.

- ▶ When `sysmessages` have been altered with the `sp_altermessage` statement to write to the application log. The `sp_altermessage` command has a `write_to_log` parameter that you can use to modify error numbers found in `sys.messages`. When the `write_to_log` parameter is set to `WITH_LOG`, these message automatically write to the Application event log, regardless of whether the `WITH_LOG` option is used when the error is raised.
- ▶ When application calls are made to `xp_logevent` to log an event to the application log.

The bottom portion of the General page of the New Alert dialog allows you to define which events in the Application event log the alert should respond to. You can have the event respond to a specific error number, the error severity level, or specific text that is contained in the error message. The `sys.sysmessages` catalog view contains a complete list of all the error message details for all the supported languages. You can use the following `SELECT` statement to list the error messages for the English language:

```
SELECT * FROM SYS.SYSMESSAGES
where msglangid = 1033
order by msglangid, error
```

You can define an alert for hundreds of messages. For example, you can define an alert that responds to changes to database options. You do this by selecting error number 5084, which is triggered whenever a change is made to the database options. You can also narrow the scope of the alert to look at a specific database by using the Database Name drop-down. This limits the alert to errors that occur in the specific database you choose. The default option is to look at all databases.

The two other types of alerts you can define are SQL Server performance condition alerts and WMI event alerts. A SQL Server performance condition alert reacts to performance conditions on the server. Figure 16.16 shows an example of this type of alert.

When you select a SQL Server performance condition alert, you need to select the performance object and counter for that object to monitor. The SQL Server performance objects and counters available on the General page of the New Alert dialog are a subset of those available in the Windows Performance Monitor application. These performance metrics encompass key indicators, such as memory, CPU, and disk space.

After selecting the object and counter, you need to define the performance threshold for the alert at the bottom of the General page, below the Alert if Counter label. In the example shown in Figure 16.16, the alert is monitoring the transaction log file for the AdventureWorks database. The threshold has been set such that the alert will fire if the transaction log for this database rises above 2KB.

The WMI event alerts use WMI to monitor events in an instance of SQL Server. The SQL Server Agent can access SQL Server events by using the WMI provider for server events by issuing WMI Query Language (WQL) statements. WQL is a scaled-down version of SQL that contains some WMI-specific extensions. When a WMI query is run, it essentially creates an event notification in the target database so that a related event will fire. The

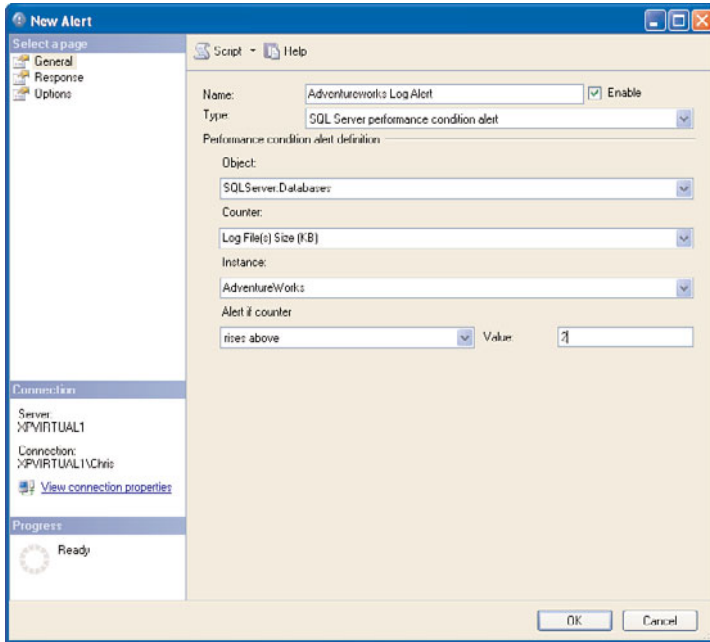

FIGURE 16.16 A SQL Server performance condition alert on the General page.

number of WMI events is extensive. Refer to the “WMI Provider for Server Events Classes and Properties” topic in SQL Server Books Online for a complete list.

Figure 16.17 shows an example of a WMI event alert. This example uses a WQL query that detects any Data Definition Language (DDL) changes to any of the databases on the server. After the alert is created, you can test it by running a DDL statement against the database (for example, `alter table Person.address add newcol int null`).

Defining Alert Responses

The definition of an alert has two primary components. As discussed earlier in this chapter, the first component involves the identification of the event or performance condition that will trigger the alert. The second part of an alert definition involves the desired response when the alert condition is met. You can define an alert response by using the Response page on the alert’s Properties screen. Figure 16.18 shows a sample response that has been configured to use `NET SEND` on a message to the operator named `ChrisG`.

Operator notification and job execution are the two responses to an alert. Operator notification allows for one or more operators to be notified via email, pager, or the `NET SEND` command. Job execution allows for the execution of a job that has been defined in the SQL Server Agent. For example, you could execute a job that does a database backup for an alert that is triggered based on database size. You can define both job execution and operator notification in a single alert; they are not mutually exclusive.

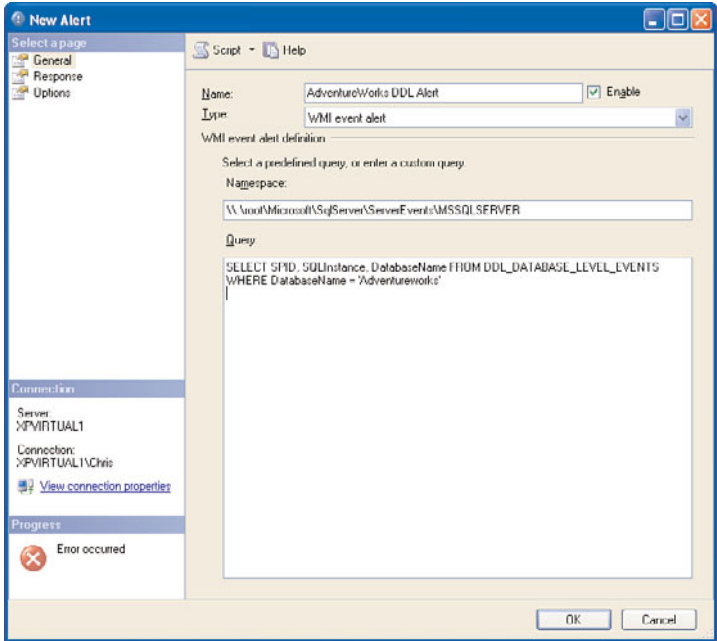

FIGURE 16.17 The General page showing a WMI event alert.

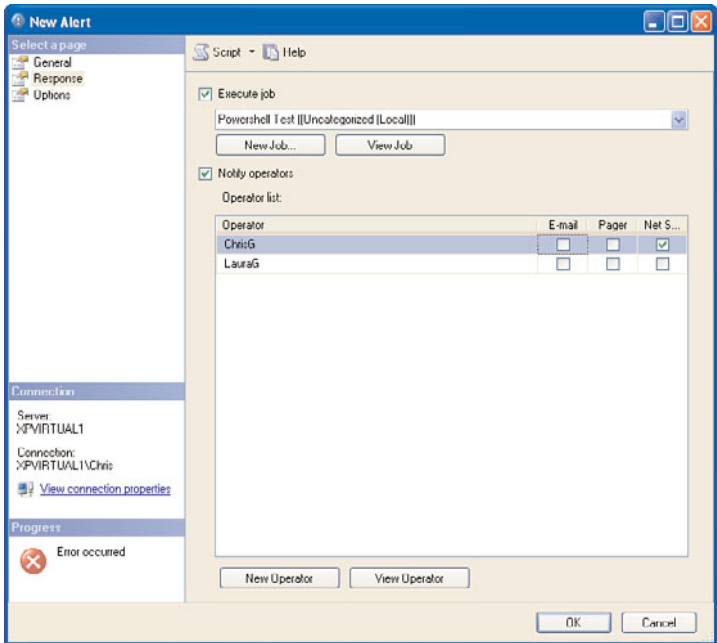

FIGURE 16.18 Configuring an alert response.

You can further define an alert response by using the Options page of an alert's Properties window (see Figure 16.19).

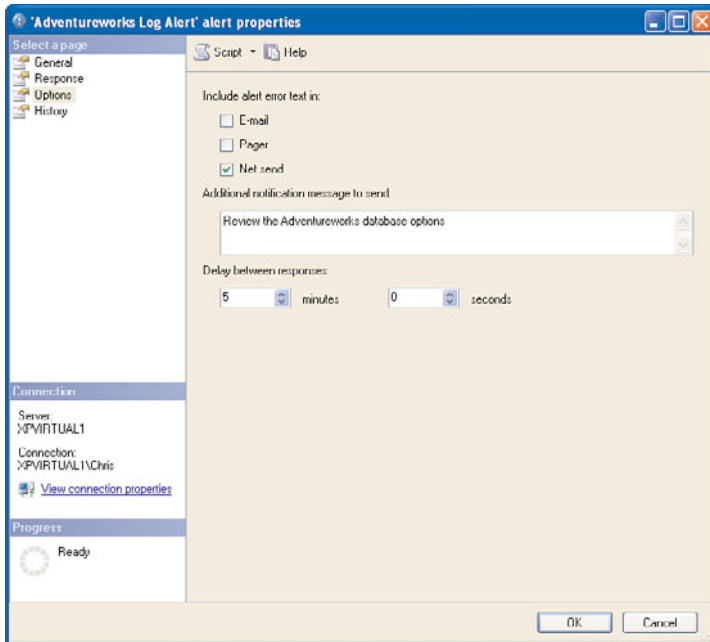

FIGURE 16.19 Alert options.

You can include an alert's error text in the operator notification message on this page. This alert error text provides further details about why the alert was fired. For example, if you have an alert that is triggered by changes to database options, the alert error text would include the actual option that was changed. You can also define additional notification text that is included when the message is sent. This message could include directives for the operators or additional instructions. Finally, you can define the amount of time that the alert will wait before responding to the alert condition again. You do this by using the Delay Between Responses drop-downs (Minutes and Seconds) to set the wait time. This capability is useful in situations in which an alert condition can happen repeatedly within a short period of time. You can define a response delay to prevent an unnecessary large number of alert notifications from being sent.

Scripting Jobs and Alerts

SQL Server has options that allow for the scripting of jobs and alerts. As with many of the other objects in SQL Server, you might find that it is easier and more predictable to generate a script that contains the jobs and alerts on the server. You can use these scripts to

reinstall the jobs and alerts or deploy them to another server. You can right-click the job or alert you want to script and choose a scripting option to generate the T-SQL for the individual object. You can also select the Job or Alerts node to view the Object Explorer Details that lists all the objects. You can also display the Object Explorer Details through the View menu or by selecting it as the active tab. When Object Explorer Details is selected, you have the option of selecting one or more jobs to script. You can select multiple jobs by holding down the Ctrl key and clicking the jobs you want to script.

Figure 16.20 shows a sample Object Explorer Details for jobs, with several of the jobs selected for scripting. To generate the script, you simply right-click one of the selected jobs and select the Script Job As menu option to generate the desired type of script.

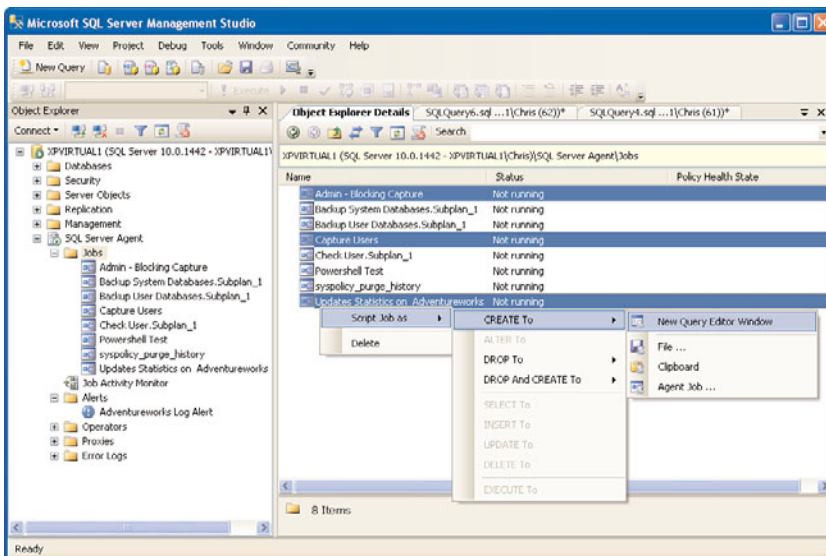

FIGURE 16.20 Script generation for jobs.

NOTE

With SQL Server 2008, you can also filter the jobs you want to script by using the filtering capabilities that are available on the Object Explorer Details. For example, you can filter on jobs whose names contain specific text. After you filter the jobs, you can script the jobs that are displayed. The filtering options and the capability to selectively script jobs are particularly useful in environments in which many jobs and alerts exist.

Multiserver Job Management

Multiserver job management allows you to centralize the administration of multiple *target* servers on a single *master* server. The master server is a SQL Server instance that contains the job definitions and status information for all the enlisted target servers. The target servers are SQL Server instances that obtain job information from the master server and continually update the master server with job statistics.

Multiserver job management is beneficial in SQL Server environments in which there are many instances to manage. You can establish jobs, operators, and execution schedules one time on the master server and then deploy them to all the target servers. This promotes consistency across the enterprise and can ease the overall administrative burden. Without multiserver job management, administrative jobs must be established and maintained on each server.

Creating a Master Server

The first step in creating a multiserver environment involves the creation of a master server. SQL Server 2008 provides the Master Server Wizard, which simplifies this task. You launch the Master Server Wizard by right-clicking the SQL Server Agent node in the Object Explorer and selecting Multi Server Administration and Make This a Master. The Master Server Wizard then guides you through the creation of an operator to receive multiserver job notifications and allows you to specify the target servers for SQL Server Agent jobs.

Figure 16.21 shows the Master Server Wizard screen that allows you to add information related to the master server's operator. The operator created on the master server, named MSXOperator, is the only one that can receive notifications for multiserver jobs.

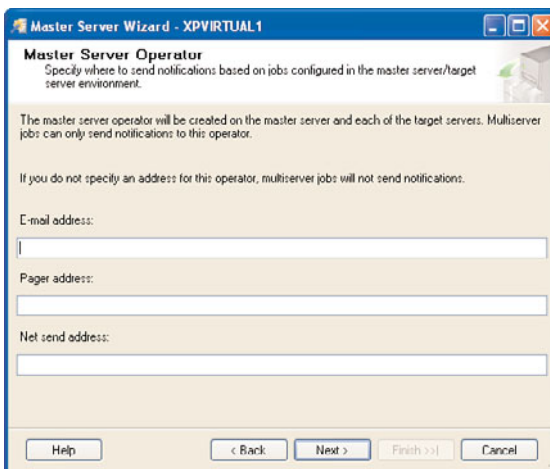

FIGURE 16.21 The Master Server Wizard.

The Master Server Wizard also validates the service accounts that the SQL Server Agent uses on the target servers. These accounts are typically Windows domain accounts that are in the same domain as the master server. The service accounts are important because the target servers utilize Windows security to connect to the master server and download jobs for the SQL Server Agent. The validation process and security considerations are simplified if the master server and target servers are run with the same domain account.

Enlisting Target Servers

The Master Server Wizard allows you to enlist one or more target servers. Enlisting a target server identifies it to the master server and allows the master server to manage the administration of its jobs. You can also enlist additional target servers after the wizard completes. You do this by right-clicking the SQL Server Agent node of the target server and then selecting Multi Server Administration and then Make This a Target. Doing so launches the Target Server Wizard, which guides you through the addition of another target server. The Target Server Wizard performs some of the same actions as the Master Server Wizard, including the following:

- ▶ It ensures that the SQL Server versions on the two servers are compatible.
- ▶ It ensures that the SQL Server Agent on the master server is running.
- ▶ It ensures that the Agent Startup account has rights to log in as a target server.
- ▶ It enlists the target server.

Creating Multiserver Jobs

After setting up the master and target servers, you can create jobs on the master server and specify which target servers they should run on. Periodically, the target servers poll the master server. If any jobs defined for them have been scheduled to run since the last polling interval, the target server downloads the jobs and runs them. When a job completes, the target server uploads the job outcome status to the master server.

Event Forwarding

Event forwarding is another multiserver feature that allows a single SQL Server instance to process events for other servers in your SQL Server environment. This involves the designation of an alerts management server to which other servers can forward their events. You enable the alerts management server by right-clicking the SQL Server Agent node and selecting Properties. When the Properties page appears, you click the Advanced page (see Figure 16.22).

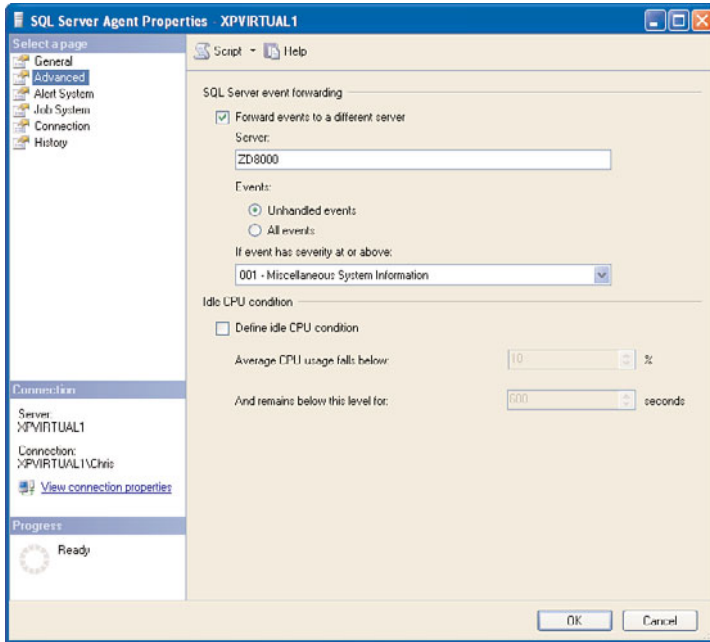

FIGURE 16.22 Configuring event forwarding.

To configure event forwarding, you select the Forward Events to a Different Server option on the Advanced page. You can then select the SQL Server instance you want as the alerts management server by using the Server drop-down. The servers shown in the drop-down are those that have been registered in SSMS. If the server you want does not appear in the drop-down, you need to choose Registered Servers from the View menu and ensure that the server is registered.

You can choose to forward unhandled events, all events, or only a subset of the events. The default is to send all unhandled events, but you can customize this for your needs. You can further limit the messages that are forwarded by specifying the severity level that the message must have in order to be forwarded. For example, you can configure the servers to forward only fatal error messages that have a severity greater than or equal to Level 19. In this scenario, you could define alerts on the alerts management server that respond to these fatal errors and notify operators that specialize in their resolution.

You need to consider a number of trade-offs when using event forwarding. You need to weigh the benefits of central administration and a lack of redundancy against the disadvantages of having a single point of failure and increased network traffic. The available network bandwidth, number of servers involved in event forwarding, and stability of the alerts management server are some of the key factors you need to think about in making your decision.

Summary

The SQL Server Agent in SQL Server 2008 delivers a powerful set of tools to make your administrative life easier. It provides automation in the form of jobs, operators, and alerts that help you deliver a consistent and healthy database environment. After you have set up the appropriate automation with the SQL Server Agent, you can rest assured that you have been proactive in managing your database environment.

PowerShell is another tool to help with your automation needs. This new tool, that was integrated into SQL Server 2008, provides a powerful command-line facility you can use to access SQL Server objects. This tool is discussed in Chapter 17.

This page intentionally left blank

CHAPTER 17

Administering SQL Server 2008 with PowerShell

- ▶ Overview of PowerShell
- ▶ PowerShell Scripting Basics
- ▶ PowerShell in SQL Server 2008
- ▶ Step-By-Step Examples

Windows PowerShell is Microsoft's next-generation scripting language. More and more server-based products are being released with various levels of support for this scripting language.

This chapter provides an overview of what Windows PowerShell is and describes some of the basic features of Windows PowerShell that SQL Server 2008 users should find useful. It also presents examples that demonstrate the use of these features with SQL Server 2008.

SQL Server 2008 includes additional features to support PowerShell. The chapter also presents step-by-step examples showing how to use Windows PowerShell for various OS and database tasks.

What's New with PowerShell

The integration of Windows PowerShell into the SQL Server environment is new to SQL Server 2008. The PowerShell scripting language has been around for some time, but it was not installed with prior versions of SQL Server or integrated into the SQL Server environment. With SQL Server 2008, it is installed, and there are now means for easily accessing SQL Server objects via this powerful scripting shell.

The SQLPS utility is at the crux of the new PowerShell integration in SQL Server 2008. SQLPS is a command-line shell that loads and registers SQL Server snap-ins that provide access to SQL Server via PowerShell. There is no need to manually reference or load the SQL Server libraries, which is

necessary if you launch the PowerShell environment independently using the native PowerShell (`powershell.exe`) utility.

In SQL Server 2008, the new SQLPS utility has also been integrated into the SQL Server Management Studio (SSMS) environment. You can launch a SQLPS session by right-clicking on an object in the Object Explorer tree and selecting Start PowerShell. A SQLPS command window is launched with the path for that object already referenced. You can now work with the properties of that object in a command-line environment that provides options that go beyond the traditional GUI environment.

The integration of SQLPS is also visible in the SQL Server Agent. You can now add PowerShell job steps to SQL Server jobs. The PowerShell commands that you can enter for the job step are the same as you would enter interactively in a PowerShell session. This new kind of job step allows you to schedule PowerShell commands and integrate PowerShell actions with other SQL Server Agent job steps.

Overview of PowerShell

Windows PowerShell is Microsoft's next-generation automation and scripting language. It is built on the Microsoft .NET 2.0 Framework.

Windows PowerShell was first released to the public in November 2006 as version 1.0. It was released as a separate install for Windows XP and Windows 2003, and shortly after, an install for Windows Vista was made available. Since its release, Windows PowerShell has been downloaded over two million times.

NOTE

From this point on, we refer to Windows PowerShell simply as *PowerShell*.

When Windows Server 2008 was released, PowerShell was provided with the operating system. To have access to PowerShell, you simply had to add the Windows PowerShell feature through the new Server Manager.

NOTE

Currently, PowerShell is not available on Windows Server 2008 Core because of the .NET Framework requirement. Server 2008 Core officially doesn't support the .NET Framework.

In 2008, Microsoft announced that PowerShell is now part of its Common Engineering Criteria for 2009 and beyond. This announcement basically means that all of Microsoft's server products should have some level of PowerShell support. Microsoft Exchange 2007 was the earliest server-class product to come out with full PowerShell support. In fact, all of Exchange's administrative tasks are based on PowerShell. The PowerShell functionality in Exchange is actually named Exchange Management Shell.

NOTE

PowerShell 1.0 is installed by default when SQL Server 2008 client software or Database Services are installed. Keep in mind that PowerShell 1.0 is not the latest version available. The next version, PowerShell version 2, is available for download and is installed by default with newer operating systems such as Windows Server 2008 R2. V2 introduces a number of new features that are not covered in this chapter.

NOTE

The intent of this chapter is to introduce the basic concepts and functionality of PowerShell and how it integrates with SQL Server 2008. Use of more advanced features is beyond the scope of what can be covered in a single chapter.

For more information on PowerShell, be sure to check out the main PowerShell address at <http://www.microsoft.com/powershell> and also the PowerShell team blog at <http://blogs.msdn.com/powershell>.

A number of script examples and resources are also available in the Microsoft Technet PowerShell Script Center: <http://technet.microsoft.com/en-us/scriptcenter/powershell.aspx>

If you want to get into some of the more advanced features and capabilities of PowerShell, you may also want to check out a PowerShell-specific book such as *Windows PowerShell Unleashed* from Sams Publishing.

Start Using PowerShell Now

PowerShell supports all the regular DOS commands and can run scripts written in any other language (the script engine specific to that scripting language still needs to be used). If any kind of scripting is currently being done, there is no reason why users can't start using PowerShell now, even if they are not using its vast functionality.

Common Terminology

Here are some of the common terms used when working with PowerShell:

- ▶ **Cmdlet**—This is the name given to the built-in commands in PowerShell. Cmdlets are the most basic component within PowerShell and are used when doing anything in PowerShell. They are always of the form “verb-noun.” Cmdlets also have arguments called *parameters*, and values can be passed to these parameters.
- ▶ **Script**—With automation comes the requirement for scripts. Using scripts is as simple as putting a single cmdlet in a file and then executing the file. In PowerShell, scripts have the extension `.ps1` and can be executed or invoked by simply calling it as `./my_script.ps1`.
- ▶ **Pipeline**—This PowerShell functionality allows a series of cmdlets to be combined together using the pipe character (`|`). The output from one cmdlet is then piped to the following cmdlet for further processing.

- ▶ **Provider**—Using this PowerShell functionality, a data store is presented to the user in a format similar to a file system. Some of the “core” cmdlets are typically used to do various tasks such as creating items like files and/or folders.
- ▶ **Snap-in**—PowerShell functionality can be extended with the use of snap-ins. They are basically DLL files written in a .NET programming language such as C# or VB.NET. DBAs can load these snap-ins in their PowerShell session to add additional functionality such as additional cmdlets and/or providers.
- ▶ **Tab completion**—This PowerShell functionality allows the user to press the Tab key to autocomplete supported commands and parameters.
- ▶ **Aliases**—These are shorter names that can be used for cmdlets. For example, some typical UNIX and DOS commands have had aliases for them created in PowerShell. These aliases map to the actual PowerShell cmdlet.

Object-Based Functionality

As mentioned earlier, PowerShell is built on the .NET Framework. This implies that everything within PowerShell is object based. This is a familiar concept for anyone who is already familiar with the .NET Framework or .NET programming languages such as C# or VB.NET.

This object-based functionality is an important concept to remember if you want to dive deeper into PowerShell. PowerShell provides many features, and it can also use additional features provided by other .NET assemblies.

SQL Server Management Objects

SQL Server Management Objects (SMO) are a very useful tool to advanced users and developers when dealing with the automation of SQL Server 2005 and 2008. A lot of the features within SQL Server (core engine, agent, mail, and so on) are packaged into easy-to-access .NET libraries that can be accessed from PowerShell.

Most of the functionality provided by the new PowerShell support in SQL 2008 is based on SMO.

As for SQL Server 2005, PowerShell can still be used to administer this version via SMO. The only difference is that the relevant assemblies must be loaded manually.

WMI

Windows Management Instrumentation (WMI) is a Windows service that provides remote control and management. PowerShell provides some built-in support for retrieving information via WMI.

Although the main goal of WMI may be to provide remote access, it can also be used locally and can provide a wealth of information about a system. For example, WMI can be

used to easily query disk space and installed patches. Examples of using WMI are shown later in this chapter.

Installing PowerShell

As of Windows Server 2008, adding the PowerShell feature is easy using the new Server Manager application. With previous versions of Windows, PowerShell was a separate install, which required downloading and installing an external package.

To install PowerShell on Server 2008, start Server Manager, go to the Features node, then click Add Features, and simply check the box for Windows PowerShell, as shown in Figure 17.1.

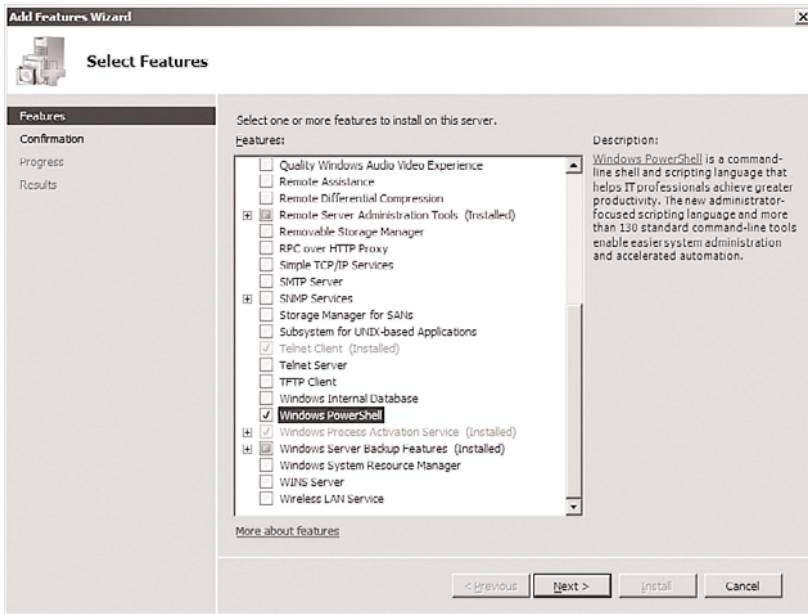

FIGURE 17.1 Selecting the Windows PowerShell feature.

PowerShell Console

You can access PowerShell directly from the Start menu, by opening All Programs, and choosing Windows PowerShell 1.0, then finally Windows PowerShell (alternatively, on some systems, such as Windows 7, you can find the Windows PowerShell folder under the Accessories folder in the Start menu). The Windows PowerShell console opens, as shown in Figure 17.2.

FIGURE 17.2 Opening the PowerShell console.

NOTE

The prompt displayed in examples of the PowerShell console in this chapter has been changed from the default.

Scriptable and Interactive

PowerShell can be used as a scripting language, by creating reusable scripts that can automate various tasks, and it can also be used interactively, by opening up a console window and entering commands line by line.

In interactive mode, PowerShell is intelligent enough to know when a command is not complete and actually displays `>>` on a new line when it believes a complete command has not been entered.

Default Security

After PowerShell has been installed, it is very secure out of the box. Here are two of the default security features:

- ▶ PowerShell cannot run any scripts. If you attempt to double-click on any `.ps1` script, it simply opens the contents in Notepad.
- ▶ PowerShell cannot be accessed remotely.

Execution Policy

By default, PowerShell can only be used interactively from the console. This is part of the default security. To be able to actually run scripts, you must set the execution policy. The easiest way to set this policy is to use the `Set-ExecutionPolicy` cmdlet, as follows:

```
PS>Set-ExecutionPolicy RemoteSigned
```

Basically, when you use the value `RemoteSigned`, PowerShell is set to be able to run scripts that have been created locally, but if a script is downloaded from the Internet, for example, it must be signed.

NOTE

The details of the different execution policy settings available or the advantages and disadvantages of different possibilities are not covered in this chapter. Using `RemoteSigned` is one of the better trade-offs between functionality and security for most users.

Profiles

As users become more and more familiar with PowerShell, they typically develop customizations that they may want to save for the next time PowerShell is opened. PowerShell has several profiles that can be used to configure user and system-wide settings. The system-wide profile is easy to access using the following:

```
PS>notepad $profile
```

NOTE

On a new install, this file typically doesn't exist, so don't be surprised if a window pops up asking you to create the file. Adding commands to the profile is usually as easy as adding the exact same commands that you would execute in the shell directly into the profile.

Built-in Help Features

As mentioned earlier, cmdlets are the most basic component of PowerShell. Three of these cmdlets are essential in attempting to learn PowerShell. Even advanced users may still use these cmdlets on a daily basis:

- ▶ **Get-Command**—This cmdlet is essential in discovering what commands can be used and what might be available on the system to help with a certain task.
- ▶ **Get-Help**—When you are looking for additional details, specifically on other cmdlets, this is the main cmdlet to use.

- **Get-Member**—Absolute beginners don't typically start using this cmdlet when first initiated into PowerShell, but for advanced users, and easier discovery, this cmdlet is very useful.

Let's look at each of these cmdlets in more detail.

Get-Command

The `Get-Command` cmdlet can be used to get a listing of an entire list of cmdlets on the system, but it can also be used to get cmdlets that can be used for a specific task or purpose. For example, `Get-Command` alone in the console prints the entire list of available cmdlets available in the current console:

```
PS>Get-Command
```

If this is the first time you have ever opened a PowerShell console, how do you write to the console? How about displaying something as simple as "Welcome to SQL 2008"? You can pass something basic to `Get-Command`, such as the string `"*write*"`:

```
PS>Get-Command *write*
```

What results is a listing of all the cmdlets that have the string `"write"` in any part of their name.

In addition, the preceding command also displays any applications and aliases (aliases are discussed later in this chapter) found in the current user's path.

PowerShell can be pretty smart. The preceding sample is actually a shortcut for something longer like this:

```
PS>Get-Command -Name *write*
```

Based on how the cmdlet is programmed, cmdlets can automatically assign a particular value to a parameter even when the parameter isn't explicitly typed out.

Originally, we were looking for a cmdlet to display something on the console and found the cmdlet `Write-Host`. Let's try it:

```
PS>Write-Host "Welcome to SQL 2008"
```

Get-Help

The learning curve with PowerShell can be relatively steep. Sometimes you can find a particular command for a particular task, such as the `Write-Host` cmdlet in the preceding section, but you might not always be sure how to actually use it. `Write-Host` is simple, but what if `Write-Host` had other useful features, or help was required for some other cmdlet?

`Get-Help` is a very useful cmdlet. Just using `Get-Help` alone provides some default help information:

```
PS>Get-Help
```

To get help on a particular cmdlet, you can use `Get-Help` and pass the other cmdlet as an argument:

```
PS>Get-Help Write-Host
```

That approach might not provide a lot of useful information; perhaps the `-Full` and `-Examples` parameters are more useful:

```
PS>Get-Help Write-Host -Full
```

Passing the `-Full` parameter gives a detailed description of the cmdlet and all its parameters (including what types of values they accept). If you are a more experienced user, the `-Examples` parameter is very useful, because it just gives some examples of using the cmdlet, which is an easy way to remember the syntax of a particular command:

```
PS>Get-Help Write-Host -Examples
```

NOTE

`Get-Help` works on other cmdlets, but it can also be used when you are looking for additional details on other concepts in PowerShell. To get a listing of the built-in help for various concepts in PowerShell, you can run the command `Get-Help about_*`.

Get-Member

Because everything in PowerShell is object based, some of the features that can be accessed are always visible. To find out more about a particular object, you can use the `Get-Member` cmdlet to look at all its members (the more interesting members of a .NET object are usually its properties and methods).

Using something simple like `"AdventureWorks2008R2"`, you can easily look at PowerShell's members (possibly without having to consult any .NET developer-focused documentation). `"AdventureWorks2008R2"` is a string—in other words, a combination of alphanumeric characters (that can include spaces). The following example is another way to display a string in the PowerShell console:

```
PS>"AdventureWorks2008R2"
```

PowerShell automatically recognizes this is a simple string and displays it.

A string can be easily displayed to the console, but what else can you do with a string object? In the .NET Framework, a string is really a `System.String` object. The .NET Framework provides a lot of functionality that can be used to deal with strings. Now let's consider another example:

```
PS>" AdventureWorks2008R2"|Get-Member
```

From the preceding command, more information is displayed now, including `TypeName: System.String`, which confirms that this is a `System.String` object. One particular feature that `Get-Member` indicates is that there is a `ToLower` method supported by this particular object:

```
PS> "AdventureWorks2008R2".ToLower()
```

In this example, the `ToLower` method of the `System.String` object is used to change the string into all lowercase letters.

PowerShell Scripting Basics

The following sections cover some of the basics of scripting with PowerShell. We hope this information will help you understand how you can use PowerShell in various situations to automate various tasks.

A Few Basic Cmdlets

Following is a list of a few basic cmdlets and how they can be used, with a brief example:

- ▶ **Get-ChildItem** (aka `dir`, `gci`)—Cmdlet used to list child items in a provider. Mostly used to list things such as files and directories in a file system. Example: `Get-ChildItem *.ps1`
- ▶ **Select-Object**—Cmdlet used to retrieve only specific properties. See `Get-Help Select-Object -Examples` for examples.
- ▶ **Group-Object**—Cmdlet used to group objects based on their properties. See `Get-Help Group-Object -Examples` for examples.
- ▶ **Sort-Object**—Cmdlet used to sort objects based on their properties. See `Get-Help Sort-Object -Examples` for examples.
- ▶ **Read-Host**—Cmdlet used to read input from the screen, usually from a user, before continuing. Example: `Read-Host "Enter a database name".`
- ▶ **Measure-Command**—Cmdlet used to measure how much time a particular scriptblock took to run. Example: `Measure-Command {Get-Command}`.
- ▶ **Write-Host**—Cmdlet used to basically display output to the console. This cmdlet was covered earlier.
- ▶ **New-Object**—Cmdlet used to create an instance of a .NET (or COM) object. Examples are provided later.
- ▶ **Get-Alias**—Cmdlet used to get a listing of the aliases on the system. `Get-Alias`, with no arguments, lists all the aliases configured on the local system.
- ▶ **Get-Content**—Cmdlet used to read the contents of a file. Typically, only text-based files are supported. Example: `Get-Content my_script.ps1`.

- ▶ **Add-Content**—Cmdlet used to add or append content to a file. Example: `Add-Content my_file.txt "testing"`.
- ▶ **Set-Content**—Cmdlet used to set the contents of a file (it overwrites any existing content). Example: `Set-Content my_file.txt "testing 123"`.
- ▶ **Start-Transcript**—Cmdlet used also with `Stop-Transcript` to record everything in the console to a specific text file. Example: `Start-Transcript`.

Creating a PowerShell Script

Creating a PowerShell script is as simple as placing a few commands into a `.ps1` script and then invoking that script. Here's a simple example of putting the `Write-Host` cmdlet into a script and then running it.

```
PS> add-content c:\temp\test.ps1 "Write-Host `testing`"
PS>c:\temp\test.ps1
testing
PS>
```

In the preceding example, a `Write-Host` cmdlet was placed in a file named `test.ps1`, and then the file was invoked. The output resulted in the string "testing" being output to the script. Notepad or any other simple text editor could also be used to create more complicated scripts.

Sample PowerShell scripts that directly apply to SQL Server administration are provided later in this chapter. Refer to the "The Step-By-Step Examples" section.

Adding Comments

Adding comments to a PowerShell script is as simple as adding the `#` character at the beginning of the line. To comment out entire blocks of code, you must use a `#` on each line.

NOTE

Another way to comment out blocks of code is to use something called a *here string*. This technique is not covered in this book.

Variables

Strings and objects were discussed earlier in this chapter. A very useful feature of PowerShell, and thus of SQL-PowerShell, is the ability to place objects into a variable. This allows you to run any kind of command and place any objects produced into a variable for later use.

Examples of using variables are presented later in this chapter. For now, a string can be easily saved as a variable:

```
PS>$var="AdventureWorks2008R2"
```

```
PS>$var
AdventureWorks2008R2
```

In the preceding example, the string is saved as the variable `$var` and then output to the script when the variable is simply invoked:

```
PS>$database=read-host "Enter a database name"
Enter a database name:AdventureWorks2008R2
PS>$database
AdventureWorks2008R2
```

The `Read-Host` cmdlet was introduced briefly already. In this example, the `Read-Host` cmdlet is used to read input from the console, and the information input is passed to the `$database` variable.

NOTE

When you perform certain actions in a script, a function, and even from the command line, the scope assigned to the variable or function determines how this variable will be seen by other scripts, functions, and so on. The details of scoping are not discussed any further, but it is still an important concept to remember as you use PowerShell more and more.

NOTE

You can issue the `Get-Help about_shell_variable` and `Get-Help about_scope` commands in Powershell for more information and examples about shell variables.

An example provided later in this chapter demonstrates that objects much more complicated than simple strings can be saved to a variable for later use.

Escaping Characters

Often a special character may be used—for example, in DOS commands—but PowerShell tries to interpret it differently. Let's consider the dollar sign character (`$`). PowerShell normally tries to interpret it as a variable:

```
PS C:\> $var="$5 discount"
PS C:\> $var
discount
PS C:\> $var="$`5 discount"
PS C:\> $var
$5 discount
PS C:\>
```

The preceding example shows how the escape character, which is the backtick (```), is used to escape the dollar sign, so that PowerShell doesn't try to interpret the character literally as the beginning of a variable.

NOTE

You can execute the `Get-Help about_escape_character` command in PowerShell for more information and examples.

Special Variable `$_`

In PowerShell, `$_` is a special variable that represents the current object in the pipeline. When several cmdlets are piped together, this special variable may be used often. Several examples of using this special variable are shown later in this chapter.

NOTE

A special variable named `$input` also represents objects passed along the pipeline, but we do not look at this variable in any further detail in this chapter.

NOTE

See `Get-Help about_automatic_variables` for more information and examples.

Joining Variables and Strings

The concept of objects was already introduced briefly. When you are dealing with simple strings, you can easily concatenate them together using the plus (+) sign to create a new string:

```
PS>$last_name="Doe"  
PS>$first_name="John"  
PS>$full_name=$last_name+", "+$first_name  
PS>$full_name  
Doe, John  
PS>
```

In this example, two variables containing simple strings are defined, and they are simply concatenated together to create a third variable, which is then displayed to the console.

NOTE

This kind of concatenation works when both variables are strings. An error may be returned if the variable is of another data type.

An example is provided later with the `AdventureWorks2008R2` database where string variables from two different columns in the same table will be joined together using this feature.

Passing Arguments

PowerShell has a special reserved variable named `$args`. It can be used with scripts and functions, and represents any arguments passed to the script or function when it is invoked, as shown here:

```
PS>add-content c:\temp\parameter.ps1 "`$args.count"
PS>add-content c:\temp\parameter.ps1 "`$args[0]"
PS>c:\temp\parameter.ps1 1 2 3
3
1
PS>
```

In the preceding example, a two-line script is created, and then it is invoked while passing some arguments to it. `$args.count` displays the number of arguments passed to the script, whereas `$args[0]` displays the value of the first argument only.

Later, an example of a PowerShell script that can do a database backup is provided. The example is extended to show how a script could be used to accept an argument that would be the name of the database the script will back up.

Using Param

A special construct, `param`, can be used to force the way arguments are passed to a script or function:

```
PS>function test_param {
>> param([string]$arg1)
>> write-host "Argument 1 is $arg1"
>> }
>>PS>test_param "testing"
Argument 1 is testing
PS>test_param -arg1 "testing"
Argument 1 is testing
PS>
```

In this example, `param` is used to specify that a parameter passed to this script will be a string object and will be contained in the variable `$arg1` for later use in the script.

NOTE

The biggest difference between using `param` or `$args` with arguments occurs when the number of arguments is known versus unknown. The `param` keyword should not be used when the number of arguments passed is not known.

NOTE

[string] is a shortcut in PowerShell where you specify that the argument, as in the preceding example, will be a string, and not something else such as a number or integer. A dozen or so of these shortcuts are available in PowerShell, and they are typically known as *type accelerators*.

Arrays

To PowerShell, *arrays* are simply a listing of data. They can be used for various tasks and can be created easily, as you can see here:

```
PS>$var="foo", "bar"  
PS>$var  
foo  
bar  
PS>
```

In this example, an array is created with two values, and then it is simply invoked, which simply results in outputting each element of the array, one per line. When an array is created, a reference can be made to a particular element of the array using a special “[]” syntax, like this:

```
PS>$var[0]  
foo  
PS>
```

NOTE

The first element of an array is the element zero; therefore, the first record in an array is retrieved by referencing the element id [0].

The count property is also useful as a property of array objects (remember that everything in PowerShell is a .NET object):

```
PS>$var.count  
2  
PS>
```

The count property is used to iterate through each element of an array.

NOTE

Arrays can also be defined in at least two other ways: with a type accelerator ([array]\$var is an example) or using a notation like this:

```
$var=@("foo", "bar").
```

Several other type accelerators are used in PowerShell, but they are not described in this chapter.

NOTE

You can execute the `Get-Help about_array` command for more information and examples on using arrays in PowerShell.

In a later example, this feature of retrieving a particular element of an array is used with the AdventureWorks2008R2 database.

Operators

A task commonly performed both from the console and also in scripts is to compare two strings against each other. The most common operators are as follows:

- ▶ **Arithmetic**—When comparing numbers or integers, for example:

```
5 -gt 4
```

- ▶ **Comparison**—When comparing strings, for example:

```
"user" -eq "user"
```

In both of these cases, a Boolean value is returned (True or False).

NOTE

Execute the `Get-Help about_operator` command for more information and examples.

Conditional Statements

Often in scripting, some kind of decision must be made by comparing values before a script or set of commands continues.

Operators can provide a simple example of how conditional statements work, as shown here:

```
PS>if("userA" -eq "userA")
>> {
>> Write-Host "Equal"
```

```
>> }
>> else
>> {
>>   Write-Host "Not equal"
>> }
>>Equal
PS>$user="userB"
PS>if("userA" -eq "$user")
>> {
>>   Write-Host "Equal"
>> }
>> else
>> {
>>   Write-Host "Not equal"
>> }
>>Not equal
PS>
```

The preceding code provides a simple example and shows how interactive the PowerShell console can be. The >> character is simply PowerShell informing the user that the commands entered are basically not complete, and more input is required.

A later example using the AdventureWorks2008R2 database uses a conditional statement to make a particular decision based on the results from evaluating a particular expression.

Functions

Quite often, as the usage of SQL-PowerShell increases, some efficiencies are gained by using functions. Functions are especially useful when you are creating things that are done on a regular basis either directly in the console or in a script.

For example, a long script may have been developed that contains several checks for the existence of a file, such as a long database filename, as in the following:

```
PS>Function test {
>> param($user1,$user2)
>> if("$user1" -eq "$user2")
>> {
>>   Write-Host "Equals"
>> }
>> else
>> {
>>   Write-Host "Not equal"
>> }
>> }
>>PS>test "userA" "userB"
Not equal
PS>test "userA" "userA"
```

Equals

PS>

Using the earlier example of comparing two strings, this example writes a function named `test`, so if future comparisons are required, the typing requirements will be greatly reduced.

NOTE

Execute the `Get-Help about_function` command in PowerShell for more information and examples.

In a later example, a function is used to create a quick reference for sending out an email via PowerShell.

Looping Statements

Often a script needs to loop through items and act on each. PowerShell supports several looping constructs. Examples of the `for` and `foreach` constructs are demonstrated here. Others, such as `while`, also exist but are not covered in this chapter.

```
PS>for($i=0;$i -lt 5;$i+=2){
>> $i
>> }
>>0
2
4
PS>
```

The preceding example shows a `for` loop. The method to jump or way to use a step is shown. A jump or step is indicated by the last part of the preceding `for` loop, where `$i+=2` is used. If this example had used `$i++` instead, the output would be each number from 0 to 5.

Here's an example of using `foreach`:

```
PS C:\book>dir
    Directory: Microsoft.PowerShell.Core\FileSystem::C:\book
Mode                LastWriteTime         Length Name
----                -
d----             8/4/2008  11:29 PM             directory
-a---             8/5/2008  12:01 AM              53 database.csv
-a---             8/4/2008  11:27 PM              0 file.ps1
-a---             8/4/2008  11:27 PM              0 file.txt
-a---             8/4/2008  11:47 PM             1813 list.csv
PS C:\book>$contents=dir
PS C:\book>$contents
```

```

Directory: Microsoft.PowerShell.Core\FileSystem::C:\book
Mode                LastWriteTime         Length Name
----                -
d----            8/4/2008  11:29 PM             directory
-a---            8/5/2008  12:01 AM             53 database.csv
-a---            8/4/2008  11:27 PM              0 file.ps1
-a---            8/4/2008  11:27 PM              0 file.txt
-a---            8/4/2008  11:47 PM            1813 list.csv
PS C:\book>foreach($each in $contents){
>> $each.name
>> }
>>directory
database.csv
file.ps1
file.txt
list.csv
PS C:\book>

```

In this example, within the `foreach` scriptblock, any number of commands could have been added, and they would have acted on each object.

NOTE

Use the `Get-Help about_for`, `Get-Help about_foreach`, and `Get-Help about_while` commands for more information and examples.

NOTE

Another feature that can also be useful in scripting is keywords, such as `break`, `continue`, and `return`. They can be used in various circumstances to basically end the execution of conditional statements and also looping statements. See `Get-Help about_break` and `Get-Help about_continue` for more information and examples.

Filtering Cmdlets

PowerShell also has a few useful filtering cmdlets:

- ▶ **Where-Object** (alias `where` and `?`)—Participates in a pipeline by helping to narrow down the objects passed along the pipeline based on some specific criteria.
- ▶ **ForEach-Object** (alias `foreach` and `%`)—Participates in a pipeline by applying a scriptblock to every object passed along the pipeline.

By looking at a few files and a directory contained within a test directly, we can easily demonstrate the use of both cmdlets:

```
PS C:\book> dir
```

```
Directory: Microsoft.PowerShell.Core\FileSystem::C:\book
```

Mode	LastWriteTime	Length	Name
d----	8/4/2008 11:29 PM		directory
-a---	8/4/2008 11:27 PM	0	file.ps1
-a---	8/4/2008 11:27 PM	0	file.txt

```
PS C:\book> dir|ForEach-Object{$_Name.ToUpper() }
```

```
DIRECTORY
```

```
FILE.PS1
```

```
FILE.TXT
```

```
PS C:\book> dir|Where-Object{$_PsIsContainer}
```

```
Directory: Microsoft.PowerShell.Core\FileSystem::C:\book
```

Mode	LastWriteTime	Length	Name
d----	8/4/2008 11:29 PM		directory

```
PS C:\book>
```

In this example, first the `ForEach-Object` cmdlet is demonstrated, where each object passed along from the `dir` command is acted on, and the name of the object (filename or directory name) is changed to uppercase.

Next, the `Where-Object` cmdlet is demonstrated, where each object passed along is evaluated this time to determine whether it is a file or directory. If it is a directory (the script-block `{$_PsIsContainer}` returns as `True`), the object continues along the pipeline, but in this case, the pipeline has ended.

NOTE

There is a `ForEach-Object` cmdlet and a `foreach` keyword, and they are not the same. Something useful to remember is that `ForEach-Object` would be used as part of a pipeline.

Formatting Cmdlets

Several formatting cmdlets are very useful:

- ▶ **Format-Table** (alias `ft`)—Cmdlet that prints out properties in a table-based format.
- ▶ **Format-List** (alias `fl`)—Cmdlet that prints out properties in a list-style format.

Some simple examples of `Format-Table` can be easily demonstrated, as you can see here:

```
PS C:\book\test> Get-Process powershell
Handles NPM(K) PM(K) WS(K) VM(M) CPU(s)
```

```

Id ProcessName
-----
2600 powershell

```

```

PS C:\book\test> Get-Process powershell | `
>> Format-Table -autosize handles,id
>>
Handles    Id
-----
561 2600

```

```
PS C:\book\test>
```

In this example, you use the `Get-Process` cmdlet to list the properties of the `powershell.exe` process. By default, the PowerShell formatting subsystem determines what properties to display. Using `Format-Table`, you modify the properties displayed. The `-autosize` parameter is used to shorten and align all the columns neatly.

NOTE

There are also `Format-Custom` and `Format-Wide` cmdlets. See the built-in help for each cmdlet for more information and examples.

Dealing with CSV Files

PowerShell provides two cmdlets that help greatly when you are dealing with files in the comma-separated value (CSV) format:

- ▶ **Import-Csv**—This cmdlet reads in a CSV file and creates objects from its contents.
- ▶ **Export-Csv**—This cmdlet takes an object (or objects) as input and create sa CSV file, as shown here:

```
PS>dir | Export-Csv c:\temp\file.csv
```

This simple example shows how to output the contents of the current directory to a CSV-formatted file. Looking at the contents of this file displays information about the objects, though, instead of just plain strings such as filenames.

The following example creates a simple CSV-formatted file and then is read in using the `Import-Csv` cmdlet. The `Select-Object` cmdlet is used to display only the database column:

```

PS C:\> cd c:\temp
PS C:\temp> Add-Content database.csv "server,database"
PS C:\temp> Add-Content database.csv "server1,database1"
PS C:\temp> Add-Content database.csv "server2,database2"
PS C:\temp> Get-Content database.csv

```

```

server,database
server1,database1
server2,database2
PS C:\temp> Import-Csv database.csv|Format-Table -AutoSize
server database
-----
server1 database1
server2 database2

PS C:\temp> Import-Csv database.csv|Select-Object database
database
-----
database1
database2

PS C:\temp>

```

NOTE

The `Format-Table` cmdlet is used in the preceding example simply to format the data in a more appropriate format for this book.

Dealing with Dates and Times

Being able to do date/time calculations is very useful. Fortunately PowerShell provides all kinds of quick date/time calculations. Some of the more common tricks are shown in the following example:

```

PS>[DateTime]::Now
Tuesday, August 05, 2008 2:01:22 PM

PS>([DateTime]::Now).AddDays(-1)
Monday, August 04, 2008 2:01:44 PM

PS>

```

Here, a .NET method is used to get a new value from the original object. This is done in a “single step,” in contrast to saving the object to a variable and then using the method on the variable. The use of a minus sign indicates that a value is being requested from the past.

Other common date/time methods include

- ▶ **AddHours**—Add/subtract based on a number of hours.
- ▶ **AddMilliseconds**—Add/subtract based on a number of milliseconds.
- ▶ **AddMinutes**—Add/subtract based on a number of minutes.

- ▶ **AddMonths**—Add/subtract based on a number of months.
- ▶ **AddSeconds**—Add/subtract based on a number of seconds.
- ▶ **AddYears**—Add/subtract based on a number of years.

-WhatIf / -Confirm Parameters

Several of the core PowerShell cmdlets support `-whatif` and/or `-confirm` parameters. The cmdlets that support these parameters could actually make system changes that cannot be reserved, such as deleting a file.

Consider the following example using these parameters:

```
PS>New-Item -Type File -Path file.tmp
```

```
Directory: Microsoft.PowerShell.Core\FileSystem::C:\book
```

Mode	LastWriteTime	Length	Name
-a---	8/4/2008 10:33 PM	0	file.tmp

```
PS>Remove-Item -Path file.tmp -WhatIf
```

```
What if: Performing operation "Remove File" on Target  
"C:\book\file.tmp".
```

```
PS>
```

Two new cmdlets are demonstrated in the preceding example: `New-Item`, used to create things such as files, and `Remove-Item`, used to delete or remove things such as files.

PowerShell in SQL Server 2008

This section covers what has been specifically added to SQL Server 2008 to provide support for PowerShell.

Adding PowerShell Support

NOTE

This discussion is based on SQL Server 2008 Enterprise Edition. SQL Server 2008 Express doesn't provide all the same features. For example, the Express version doesn't provide the SQL Server Agent functionality briefly discussed later.

Either during the initial installation of SQL 2008 or afterward while changing the installed features, you are able to add the SQL Server–specific PowerShell features by using the setup utility. The Management Tools-Basic feature must be added, as shown in Figure 17.3.

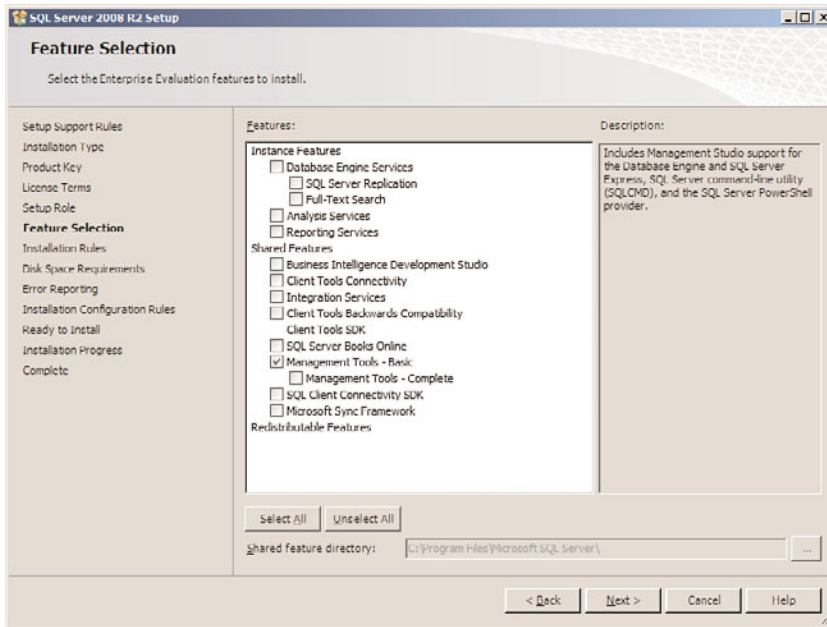

FIGURE 17.3 Installing the PowerShell features.

The Management Studio add-on is also required to get the PowerShell-specific features installed. This specific feature adds the following:

- ▶ **Management Studio**—The graphical user interface for managing SQL Server 2008
- ▶ **SQLCMD**—The utility that SQL scripters should already be familiar with
- ▶ **SQL Server PowerShell provider**—The PowerShell-specific extra functionality

NOTE

An added bonus is that you can install Management Studio by itself on either the server or another remote system, and be able to administer your SQL Server database remotely. Consideration should be given to whether the SQL Server is set up for remote connections, and the appropriate firewall changes have been made to the network and on the database server, if applicable.

Accessing PowerShell

Now that you have added the SQL Server–specific PowerShell features, you can access a SQL Server PowerShell session.

NOTE

From this point on, we make the distinction between PowerShell and SQL Server PowerShell. The details are discussed shortly, but for now *PowerShell* is the basic or default PowerShell console, and *SQL Server PowerShell* is a more restricted version of PowerShell that has all the SQL Server–specific PowerShell features packaged within it.

SQL Server PowerShell can be accessed in either of two ways:

- ▶ You can open SQL Server PowerShell via the SQL Server Management Studio by right-clicking on a particular object in the Object Explorer and selecting Start PowerShell, as shown in Figure 17.4. This way is handy because it provides a prompt in the SQL provider (which is discussed shortly) in the location of the object that was right-clicked.

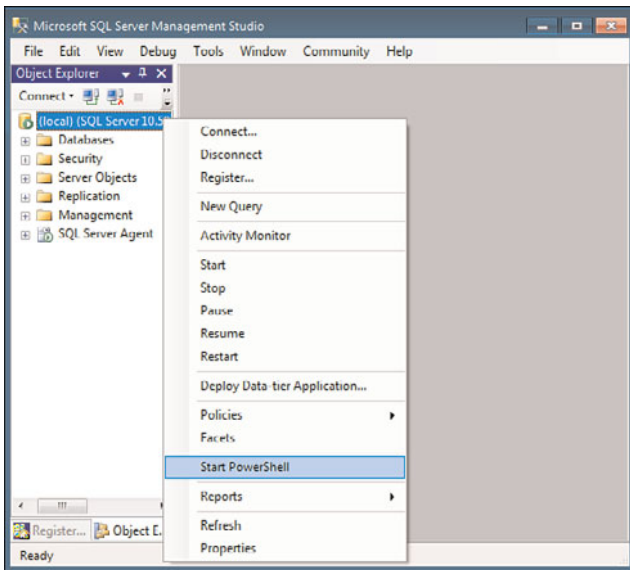

FIGURE 17.4 Accessing PowerShell via SSMS.

- ▶ You also can open SQL Server PowerShell directly from regular DOS or a regular PowerShell console by simply navigating to the appropriate location, as shown in Figure 17.5.

FIGURE 17.5 Accessing PowerShell using `sqlps.exe`.

NOTE

When you first open the shell, some errors may appear on the screen, which simply indicates that PowerShell execution policy should be set. This topic was covered near the beginning of the chapter. The execution policy for SQL Server PowerShell should also be `RemoteSigned`, at least.

SQL Server PowerShell

When you first get into SQL Server PowerShell, you might notice that this is a restricted version of the default PowerShell console. In other words, several of the core cmdlets are not available in SQL Server PowerShell, and others might not work exactly the same way. For example, invoking the `Get-Command` cmdlet alone with no other arguments does not list all the available commands.

NOTE

Running `Get-Command` in SQL Server PowerShell without any parameters might generate the following message:

```
Get-Command : Object reference not set to an instance of an object.
```

However, other invocations of this command work fine (such as the other examples of `Get-Command` in this section). Microsoft has identified this issue but as of this writing has not released a fix for it. Because the error occurs only within the SQL provider, the current workaround is to switch from the SQL Server provider to a different drive (such as `C:\`) before running `Get-Command`:

```
PS SQLSERVER:\> cd c:\
PS C:\> Get-Command
<output deleted>
PS C:\> cd SQLSERVER:
PS SQLSERVER:\>
```

NOTE

Profiles were discussed earlier in this chapter. The SQL Server PowerShell minishell also has its own profile, and you can manage it by simply typing `notepad $profile` in SQL Server PowerShell. A prompt may come up that the file cannot be found and asking whether it should be created.

SQL Provider

Earlier in this chapter, the term *provider* was briefly introduced. The SQL team decided to implement a SQL Server provider. What this provides is a layout of the SQL object structure, which resembles that of a regular file system.

You use the SQL provider when accessing SQL Server PowerShell via SQL Server Management Studio: depending on what object you right-click to access SQL Server PowerShell, a prompt opens in the context of that particular object. Basically, the way certain commands work is also affected by the current location within the SQL Server provider. Here are two different examples of being placed in different locations within the SQL Server provider. In the first example, the `AdventureWorks2008R2` database was right-clicked within SSMS, as shown in Figure 17.6. In the second example, a specific table (`Person.Address`) within the `AdventureWorks2008R2` database was right-clicked, as shown in Figure 17.7.

When you start the SQL Server PowerShell minishell by simply invoking `sqlps.exe` as seen earlier, a prompt opens at the root of the SQL Server provider.

NOTE

Some of the core cmdlets like `Get-Item`, `Remove-Item`, and `New-Item` are typically used within providers to retrieve, remove, and create items, respectively. Within the SQL Server provider, creating items using the `New-Item` cmdlet is currently not supported. Other methods are required to actually create items.

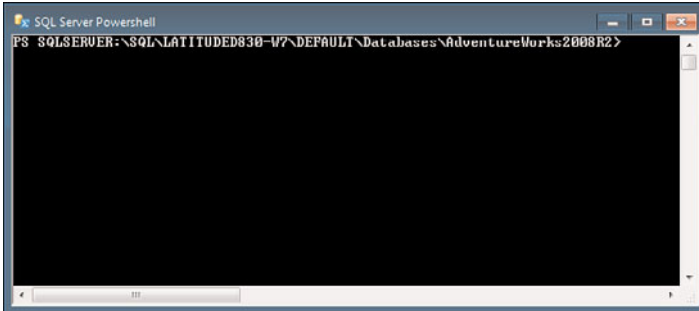

FIGURE 17.6 SQL Server provider at the database level.

FIGURE 17.7 SQL Server provider at the table level.

NOTE

Four SQL-based providers are actually available in SQL Server 2008 and six in SQL Server 2008 R2. We look only at the SQL provider that provides functionality for the database engine itself in any detail in this chapter. Refer to the SQL Server Books Online documentation for more information on the other providers (SQLPolicy, SQLRegistration, DataCollection, Utility, and DAC). The Utility and DAC providers are available only in SQL Server 2008 R2.

SQL Cmdlets

A number of cmdlets available in SQL Server PowerShell are part of the basic PowerShell functionality. However, within SQL Server PowerShell, five additional cmdlets are available only after the minishell is started (or if the snap-in is loaded manually, which is not covered in any detail here):

- ▶ **Invoke-PolicyEvaluation**—A cmdlet that evaluates a SQL Server Policy-Based Management policy (or policies) against a target server.
- ▶ **Invoke-SqlCmd**—A cmdlet that runs any regular T-SQL command and any languages and commands supported by the `sqlcmd` utility, which may be more familiar to most users.

- ▶ **Encode-SqlName**—A cmdlet that helps to encode SQL Server identifiers into a format that PowerShell can use.
- ▶ **Decode-SqlName**—A cmdlet that helps to return the original SQL Server identifiers from a value previously given by the Encode-SqlName cmdlet.
- ▶ **Convert-UrnToPath**—A cmdlet that converts the SMO Uniform Resource Name to a SQL Server provider path.

Later, examples of using the core cmdlets are provided, as well as the first two cmdlets introduced in the preceding list.

NOTE

For more details on the three other cmdlets not discussed here, see the built-in help for more information and examples.

NOTE

The intent is to ship more cmdlets as part of SQL-PowerShell in the future after more database users become more familiar with SQL Server PowerShell.

SQL Server Agent Support

PowerShell has been integrated into the SQL Server Agent subsystem. In other words, you can create jobs that call PowerShell-specific commands to run.

Consult SQL Server Books Online for more details on incorporating PowerShell into your SQL Server Agent job steps.

Step-By-Step Examples

The following sections provide examples of using PowerShell both for general tasks and for SQL Server 2008–specific tasks. We expand on some of the basic concepts introduced earlier with SQL Server 2008–specific examples.

General Tasks

Often you might be required to send out emails containing particular reports and/or output from commands run.

To do so, you use features from the .NET Framework via PowerShell to send out emails, as shown in here:

```
Function Send-Mail {
param([string]$To,[string]$From,[string]$Subject, `
```

```
[string]$Body,[string]$File,[string]$SmtpServer)
If($SmtpServer -eq ""){
    $SmtpServer = "FQDN of your SMTP server here"
}
$Smtp = New-Object System.Net.Mail.SMTPclient($SmtpServer)
$message = New-Object
System.Net.Mail.MailMessage($From,$To,$Subject,$Body)
If ($File -ne "") {
    $Attach = New-Object System.Net.Mail.Attachment $File
    $Message.Attachments.Add($Attach)
}
$smtp.Send($message)
}
```

You can enter the preceding code into a script or directly to the console. If you type the code in the console, you must press the Enter key twice (once to close the function and another time on an empty line) before the PowerShell prompt returns.

In the preceding code listing, functionality from the .NET Framework is used to get SMTP functionality. A function is used so that this code could be easily copied as required into new scripts, and so on. Calling the function is then easy, and passing the command-line arguments is shown here (the PowerShell prompt can vary depending on whether the default PowerShell is used or the new SQL minishell):

```
PS>Send-Mail -To "end_user@user.com" -From "user@user.com" -Subject
"Automated Email" -Body "Testing" -File "C:\reports\report.txt"
```

NOTE

You might need to configure some antivirus programs to allow the PowerShell.exe process (or sqlps.exe) to “talk” over the SMTP protocol port (TCP 25).

Scheduling Scripts

From time to time, it may be useful to have a method to schedule PowerShell scripts to run automatically based on a particular schedule (when the SQL Server Agent isn’t available locally, for example).

You can easily view the method to call PowerShell scripts by simply typing `powershell.exe /?` from a PowerShell session, as shown here:

```
PS>powershell.exe /?
...
PowerShell -Command "& {Get-EventLog -LogName security}"
...
```

Only a very small section of the text displayed is shown in this example. The powershell.exe can be used for scheduling regular PowerShell scripts. sqlps.exe works similarly, and you can also access its help by passing a slash and question mark (/?) to the command:

```
PS SQLSERVER:\> sqlps.exe /?
```

```
sqlps [ [ [-NoLogo] [-NoExit] [-NoProfile]
        [-OutputFormat {Text | XML}] [-InputFormat {Text | XML}]
      ]
      [-Command { -
                | <string> [ <command_parameters> ]
                | <script_block> [ -args <argument_array> ]
                }
      ]
      [ -Help | -?]
```

-NoLogo

Do not display the copyright banner on startup.

-NoExit

Keep running after completing all startup commands.

-NoProfile

Do not load a user profile.

-OutputFormat

Format the output of all objects as either text strings (Text) or in a serialized CLIXML format (XML).

-InputFormat

The input from stdin is formatted as either text strings (Text) or in a serialized CLIXML format (XML).

-Command

sqlps runs the commands specified and then exits, unless -NoExit is also specified. Do not specify other characters after the -Command switch, they will be read as command arguments.

-

Read input commands from the keyboard by using stdin.

<string> [<command_parameters>]

Specifies a string containing the PowerShell commands to be run. Use the format "&{<command>". The quotation marks identify a string and the invocation operator (&) causes sqlps to run the command.

<script_block> [-args <argument_array>]

Specifies a block of PowerShell commands to be run. Use the format {<script_block>}

-Help | -?

Show the syntax summary help.

NOTE

How do you know whether to use `powershell.exe` or `sqlps.exe` when scheduling jobs? If you're using anything relating to SMO and/or the SQL cmdlets in the script, `sqlps.exe` would seem to be easier to use because all the prerequisites to using SMO and the SQL cmdlets are already loaded, which can save several lines in a script. As a reminder, the SQL minishell is limited in its functionality, so `powershell.exe` may be required in particular if you need to load some PowerShell functionality from another application, such as Exchange.

As discussed briefly earlier, SQL Server Agent can also be used to run scheduled PowerShell commands.

Common OS-Related Tasks

Now let's look at some more OS-related tasks, while keeping our focus on SQL Server-related tasks.

Let's check the status of the SQL Server service using the `Get-Service` cmdlet in the regular PowerShell console:

```
PS>Get-Service "mssqlserver"
Status   Name           DisplayName
-----
Stopped MSSQLSERVER   SQL Server (MSSQLSERVER)
PS>
```

NOTE

When multiple instances are in use, the service name is something like `MSSQL$INSTANCE01`. To start such an instance from PowerShell or even the SQL minishell, you would have to use the following syntax for the service name: `MSSQL`$INSTANCE01`. The dollar sign (\$) character is escaped so that PowerShell doesn't try to interpret this as the beginning of a variable when the string is parsed.

The service is stopped. When you use the pipeline feature of PowerShell, the service is started:

```
PS>Get-Service "mssqlserver"|Start-Service
WARNING: Waiting for service 'SQL Server (SQLSERVER)'
```

```
(MSSQLSERVER)' to finish starting...
WARNING: Waiting for service 'SQL Server (SQLSERVER)
(MSSQLSERVER)' to finish starting...
PS>
```

This example demonstrates using the pipeline to chain commands together. Alternatively, you could use `Start-Service` directly:

```
PS>Start-Service "mssqlserver"
```

The difference between the two methods demonstrates some of the power in PowerShell. When you use `Get-Service`, a service object is retrieved. When you use the pipeline, this object is passed to `Start-Service`. `Start-Service` is built to basically accept input from the pipeline and autofills its parameters based on what was input; thus, it knows to start the SQL Server service.

NOTE

You could use SQL Server PowerShell, but because SQL Server wasn't started, Management Studio would not have been able to connect, and you could not open SQL Server PowerShell by right-clicking. You could use PowerShell to start `sqlps.exe`, though, and then you could use the `Get-Service` and `Start-Service` cmdlets to start SQL Server. If you use SQL Server PowerShell by calling `sqlps.exe` directly from within a default PowerShell console, the SQL Server could still be started, but a connection wouldn't be automatically made to the default instance of the database.

Most administrators have probably already used the Windows Task Manager to look at the SQL Server processes. Perhaps it was to determine whether SQL seemed to be using too much memory or some other issue. PowerShell provides the `Get-Process` cmdlet, shown here, to look at running processes:

```
PS>Get-Process sqlservr
Handles  NPM(K)  PM(K)      WS(K) VM(M)    CPU(s)
-----  -
Id ProcessName
-----
..
318    45      64156     44288  1554     2.03
572 sqlservr
PS>
```

Another common OS-related task is to look for events in the Windows application event log:

```
PS>Get-EventLog Application -New 10
PS>Get-EventLog Application -New 10| `
```

```
Where {$_.EntryType -eq "Error"}
PS>Get-EventLog Application -New 10| `
Where {$_.EntryType -eq "Error"}|Select-Object TimeWritten
```

The preceding example demonstrates another useful feature of the PowerShell pipeline where you can join several commands together to get specific results. First, only the 10 newest entries are retrieved; then a pipe is used to get only the entries classified as an error, and finally, only the `TimeWritten` property is displayed.

We mentioned WMI earlier in this chapter as a method for remote control and administration of servers. WMI is packed full of features that are useful for system administration. A few examples of using PowerShell's built-in WMI features are shown here.

- ▶ Getting a listing of all the fixed local logical drives:

```
PS>Get-WmiObject -query "select * from Win32_LogicalDisk where
DriveType='3'"
```

- ▶ Getting a listing of all the fixed remote logical drives:

```
PS>Get-WmiObject -computerName server -query
"select * from Win32_LogicalDisk where DriveType='3'"
```

- ▶ Getting a listing of all the local patches/hotfixes installed (the `-computerName` parameter could be used with a value to retrieve this information from a remote system):

```
PS>Get-WmiObject Win32_QuickFixEngineering
```

NOTE

Remote WMI connections may require that appropriate firewall rules be open in the network and also with a client firewall on the remote system. In addition, remote WMI queries must also be authenticated. By default, WMI queries use the current user's authentication credentials. In some scenarios WMI authentication can be more complicated.

The preceding examples show only the beginning of all the things WMI can provide quick access to. Another common task is trying to find files or folders. You can use the `Get-ChildItem` cmdlet to recursively search through a directory structure. The following example shows how to search for the location of the `powershell.exe` executable:

```
PS>Get-ChildItem c:\ -recurse powershell.exe
```

SQL Server–Specific Tasks

Before jumping into more hardcore SQL Server PowerShell features, let's briefly look at the SQL Server event log. Fortunately, the log simply contains text-based files, which PowerShell can read. You could use the `Get-Content` cmdlet to view the entire log, but

instead you can use the `Select-String` cmdlet to look for a specific string or pattern in the error log file. First, you change the current location to the SQL Server log directory:

```
PS>Set-Location "C:\Program Files\Microsoft SQL Server"
PS>Set-Location (join-path $pwd "MSSQL10_50.MSSQLSERVER\MSSQL\Log")
PS>Select-String "error" ERRORLOG
```

The PowerShell prompt in the preceding example is simply a generic one because the preceding commands would work both in the default PowerShell console and in the SQL Server PowerShell minishell.

An example of taking this further would be to retrieve all the errors in the `ERRORLOG` file. When you use `Get-Member` and `Format-List` to look at the object output by `Select-String`, the date is hidden inside a string in the `Line` property:

```
PS >
Select-String "error" ERRORLOG|foreach{$_}where{$_ -match "20*"}|
foreach{$date,$time=$_.split()[0],$.split()[1];[datetime]$(date+" "+$time) }
PS >
```

The preceding example demonstrates how to look for the string "error" in the current SQL Server `ERRORLOG` file. For all the lines that match, the `Line` property is passed along the pipeline. Next, based on some testing, it appears that you want to search only lines that start with "20* -". From that object, two values are retrieved: `$.split()[0]` and `$.split[1]`. These values are placed in the `$date` and `$time` variables, respectively. From there, they are recombined, and a type accelerator is used to indicate that this is a date/time object, so any calculations against this value will be simplified. What is finally output is the time stamp showing when the error occurred.

Using the Provider

Using the SQL Server provider can be very handy in navigating the system. Starting PowerShell from SSMS, DBAs can easily find their way through different objects as if working with files and directories.

When the SSMS is used to start PowerShell at the server level, the databases are down one level, and from there tables and users, for example, can also be easily accessed.

In the session shown in Figure 17.8, we navigated to a particular database and entered a `dir Tables` command. The output from the last command would scroll beyond the current screen, so only the first part of the output is displayed.

Creating a Database Table

Creating a database and a table are common tasks that a DBA may undertake. You can use T-SQL with the `Invoke-SqlCmd` cmdlet to do this, but a demonstration on how to do this with the SQL Server PowerShell minishell using SMO is presented here to help you better understand the new functionality that is available:

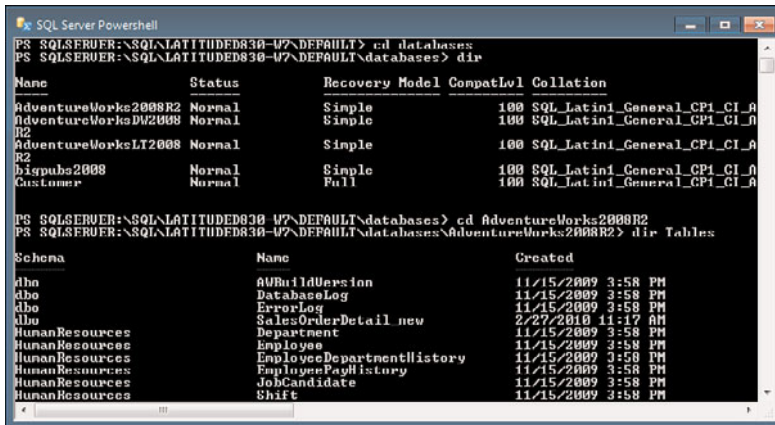

FIGURE 17.8 Navigating the SQL Server provider.

```

cd databases
$my_db=New-Object Microsoft.SqlServer.Management.Smo.Database
$my_db.Name="my_database"
$my_db.Parent=(Get-Item ..)
$my_db.Create()
cd my_database
cd tables
$my_tbl=New-Object Microsoft.SqlServer.Management.Smo.Table
$my_tbl.Name="my_table"
$my_tbl.Parent=(Get-Item ..)
$my_col=New-Object Microsoft.SqlServer.Management.Smo.Column
$my_col.Name="my_column"
$my_col.Parent=$my_tbl
$my_col.DataType= ([Microsoft.SqlServer.Management.Smo.DataType]::Int)
$my_tbl.Columns.Add($my_col)
$my_tbl.Create()

```

In the preceding example, some new objects are created, some of their properties are set, and some methods are called. You can search for the particular SMO classes used in this example to gain further information.

In the future, there may be something like `New-Database` and `New-Table` cmdlets that help to create a database and table, which would likely reduce the preceding code to fewer than five lines.

Performing a Database Backup

Another example that may be useful is performing a database backup using SMO. Using the AdventureWorks2008R2 database, you can back up the database using just a few lines:

```
$server=New-Object Microsoft.SqlServer.Management.Smo.Server
```

```
$backup=new-object Microsoft.SqlServer.Management.Smo.Backup
$file=new-object Microsoft.SqlServer.Management.Smo.BackupDeviceItem
$file.Name="C:\backup\AW_DB.bak"
$backup.Devices.Add($file)
$backup.Database="AdventureWorks2008R2"
$backup.SqlBackup($server)
```

The preceding code could be copied into a .ps1 file (for this example, assume it's copied to c:\temp\backup.ps1), and it could be changed to accept two arguments. The preceding code could be modified to the following code snippet so that it accepts parameters from the command line:

```
param([string]$device=$(throw Write-Host "Device required"), [string]
$dbase=$(throw Write-Host "Database required"))
Write-Host "backup of $dbase to $device starting..."
$server=New-Object Microsoft.SqlServer.Management.Smo.Server
$backup=new-object Microsoft.SqlServer.Management.Smo.Backup
$file=new-object Microsoft.SqlServer.Management.Smo.BackupDeviceItem
$file.Name=$device
$backup.Devices.Add($file)
$backup.Database=$dbase
$backup.SqlBackup($server)
Write-Host "backup complete"
Get-Item $device
```

The changes in the preceding example introduce a new keyword, `throw`. Without it, error messages would be thrown to the console, but this might not help the end user to understand why it failed. For the purpose of printing feedback to the console, the `Write-Host` and `Get-Item` cmdlets were also added to provide a limited amount of feedback and to finally provide the details of the final backup file.

Then to invoke the script, as shown in the following example, you simply need to pass two parameters to the script: the names of the file to back up to and the database to actually back up.

```
PS>$backup_to="C:\backup\AdventureWorks2008R2.bak"
PS>$db="AdventureWorks2008R2"
PS> c:\temp\backup.ps1 $backup_to $db
```

As an example of using a conditional statement in the preceding script, perhaps a check could be done to see whether a backup has already been completed within the past seven days. To accomplish this, you would add this particular section of code just before the line `Write-Host "backup of $dbase to $device starting...":`

```
If((Test-Path $device) -and (Get-Item $device).LastWriteTime `
-gt (Get-Date).AddDays(-7)){
    "Backup has been performed in last 7 days" Break
}
```

In the preceding code, a conditional statement is added to accomplish the check. The `AddDays()` method is passed a negative number which subtracts days from the current date..

NOTE

When you use the `param` keyword, this section of code must be on the first noncommented line in all scripts. Otherwise, the PowerShell parser returns an error.

Again, using SMO isn't necessarily for beginners, but the good thing is that scripts can easily be created and passed around. The preceding example shows the bare minimum required to do a database backup; several other options are available, and the preceding code would actually overwrite the backup each time it is run. There also isn't any error checking of any sort, which isn't the best way to develop scripts.

Along with the `New-Database` and `New-Table` cmdlets that may come in the future, maybe a `Start-DbBackup` will be another good cmdlet to have available.

Checking Server Settings

From the SSMS, by right-clicking on the SQL Server node and then starting a SQL Server PowerShell session, you can open a console directly in the root of the default SQL Server in the example.

From here, you can easily obtain information on the SQL Server. First, the location is set to the instance that is to be queried, and then an object representing the SQL Server is saved to a variable (this demonstrates the advanced features mentioned earlier where objects can be saved to variables). The properties of that variable can then be accessed as follows:

```
PS>Set-Location SQLSERVER:\SQL\\<instance_name>
PS>$sql_server=get-item .
PS>$sql_server.Information.VersionString
```

Using the `Get-Member` cmdlet discussed earlier, you can easily discover other members of the object contained in `$sql_server`, but this is left as an exercise for you to perform on your own.

NOTE

This example demonstrates an important feature of the SQL Server provider: context sensitivity. In the preceding example, the current location was in the root of the SQL Server provider or database, and the command `Get-Item .` was used. The dot in this command basically indicates that you want an object that represents the current location in the provider. If the dot were moved to a different location, this command would no longer work the same way.

Checking the Database Usage

Using the object retrieved in the `$sql_server` variable, you can create a quick report of database usage using the `databases` property of that object, as shown here:

```
PS SQLSERVER:\SQL\\<instancename>>
$sql_server.databases| Format-Table -autosize Name,@{
    Label= "% Used"
    Expression={[math]::round((($_.spaceavailable/1kb)/$.size),2)}
}Name                % Used
----                -
AdventureWorks2008R2  0.02
AdventureWorksDW2008R2  0
AdventureWorksLT2008R2 0.02
bigpubs2008           0.18
Customer              0.74
master                 0.24
model                  0.39
msdb                   0.02
my_database            0.38
tempdb                 0.8
```

Using the `Format-Table` cmdlet, you can easily and quickly create all kinds of reports. Some capabilities we haven't discussed yet were used to create this report:

- ▶ **Calculated properties**—The values displayed by `Format-Table` can be calculated using scriptblocks. That allows the logic to be highly customized. These scriptblocks are laid out as follows:

```
@{Label="some text value"
    Expression={the scriptblock to evaluate here}
}
```

- ▶ **Direct access to the .NET Framework**—The following line is directly from the .NET Framework:

```
"[math]::round(value,decimal)"
```

.NET functionality is being used to round out the numbers to the second decimal point.

PowerShell has special meaning for `1kb`, `1mb`, `1gb` and `1tb`, which all present the value of the counterpart in number of bytes—for example, `1kb=1024`. The values can also be uppercase.

Getting Table Properties

Another common task is to get a row count of the tables in a particular database:

```
PS SQLSERVER:\SQL\<servername>\<instancename>\Databases\
AdventureWorks2008R2\Tables> Get-ChildItem .| Sort-Object -descending|Select-
Object -First 10| Format-Table -autosize Name,RowCountNote
```

NOTE

An easy-to-remember alias for `Get-ChildItem` is basically `dir`.

In the preceding example using the `AdventureWorks2008R2` database, the top 10 tables with the highest row count value are returned.

NOTE

The preceding example shows how many features are packaged within PowerShell, which applies not only to SQL tables, but also to all .NET objects. Simply using `Get-Item` on a particular table returns only the default properties of `Schema`, `Name`, and `Created`. Piping something like `Get-Item [table_name]` to either `Format-Table *` or `Get-Member` exposes all the properties available for a particular object.

Cmdlet Example: Invoke-SqlCmd

The `Invoke-SqlCmd` cmdlet was mentioned earlier. It will likely be the most commonly used cmdlet currently provided. Here is a simple example using this cmdlet:

```
Invoke-sqlcmd -query "exec sp_help"
```

Using `Invoke-SqlCmd`, you can simply pass any T-SQL–based query as a value to the cmdlet. The preceding basic example is provided by running a basic built-in stored procedure: `sp_help`.

This example demonstrates several important issues, especially how powerful the provider can be. Based on the location in the SQL provider, some of the values passed to the cmdlet are automatically provided to the cmdlet by the provider itself: the server and database to query aren't required in the command line.

Let's consider this example a bit further and do a few extra things with it.

First, this cmdlet can accept input from the pipeline:

```
"exec sp_help"|ForEach-Object{Invoke-SqlCmd $_}
```

The preceding line demonstrates a few more issues that have already been discussed: the `ForEach-Object` cmdlet, the special variable `$_`, and also the way parameters can automat-

ically match values to parameters even when the parameter name isn't explicitly added to the command entered.

The `sp_help` stored procedure provides a lot of information. What if only the extended stored procedures were required?

When `Get-Member` is used, the members from this particular query are inspected, and it is determined that the `Object_type` property is the value that indicates what kind of stored procedure is being dealt with.

The query to get only extended stored procedures is now the following:

```
"exec sp_help"|ForEach-Object{Invoke-SqlCmd $_}| `
  Where{$_Object_type -eq "extended stored proc"}|Select Name
```

Finally, the output consists only of extended stored procedures.

Cmdlet Example: Invoke-PolicyEvaluation

Another one of the provided cmdlets is `Invoke-PolicyEvaluation`. This cmdlet is used to specify a SQL Server Policy-Based Management policy (or policies) that will be evaluated against the target server. You can easily cycle through all the available policies and evaluate each one, or simply provide a list of policies to evaluate separated by a comma. Consider this example:

```
sl "C:\Program Files\Microsoft SQL Server\100\Tools\Policies\DatabaseEngine\1033"
Invoke-PolicyEvaluation -Policy "Database Auto Shrink.xml" -TargetServerName
"MSSQLSERVER"
```

The preceding command returns the output to the console of the result of the policy evaluation. By default, the particular policy passed to the cmdlet is only checked. In other words, by default, properties are actually changed so that they are now compliant with the policy.

Joining Columns

Quite often, databases provide a table for users. Frequently, these users have their last name and first name in separate columns. Because these are typically simple strings, a feature, already discussed, allows two strings to be easily joined together.

The following code snippet shows how two columns from the `AdventureWorks2008R2` database are easily joined together from within the SQL minishell:

```
PS SQLSERVER:\SQL\D830\DEFAULT\databases\adventureworks2008r2> Invoke-SqlCmd
  "Select * from Person.Person"| `
>>  Select-Object -First 10|ForEach-Object{$_.LastName + ", " + $_.FirstName}
Sánchez, Ken
Duffy, Terri
Tamburello, Roberto
Walters, Rob
```

Erickson, Gail
 Goldberg, Jossef
 Miller, Dylan
 Margheim, Diane
 Matthew, Gigi
 Raheem, Michael

Here, the first 10 records are selected, and then the `LastName` and `FirstName` values are combined together.

Retrieving an Entry

On occasion, you might need to get a particular entry from a table. When the following code snippet is run, an array is automatically returned:

```
PS SQLSERVER:\SQL\D830\DEFAULT\databases\adventureworks2008r2> Invoke-SqlCmd
"Select * from Person.Person"
```

PowerShell provides a simple way to look at particular elements within an array. In the following example, entry 100 is returned and then entries 95 to 105:

```
PS SQLSERVER:\SQL\D830\DEFAULT\databases\adventureworks2008r2> (Invoke-SqlCmd
"Select * from Person.Person")[100]
PS SQLSERVER:\SQL\D830\DEFAULT\databases\adventureworks2008r2> (Invoke-SqlCmd
"Select * from Person.Person")[95..105]
```

NOTE

The first element of an array is the element zero; therefore, the first record in an array is retrieved by referencing the element `id [0]`.

Summary

This chapter provides an overview of PowerShell and how it has been specifically implemented in SQL Server 2008. Microsoft is putting a lot of effort into integrating PowerShell into all its server-based products, including SQL Server. Support for PowerShell in SQL Server 2008 still has a way to go before it could ever be considered the main scripting language, but the functionality available now is worth looking at.

The next chapter delves into high availability and the options available in SQL Server 2008.

CHAPTER 18

SQL Server High Availability

With SQL Server 2008, Microsoft continues to push the high availability (HA) bar higher and higher. Extensive high-availability options, coupled with a variety of Windows server family enhancements, provide almost everyone with a chance at achieving the mythical “five-nines” (that is, 99.999% uptime).

Understanding your high-availability requirements is only the first step in implementing a successful high-availability application. Knowing what technical options exist is equally as important. Then, by following a few basic design guidelines, you can match your requirements to the best high-availability technical solution.

This chapter introduces a variety of fundamental HA options—such as redundant hardware configurations, RAID, and MSCS clustering—as well as more high-level options—such as SQL clustering, data replication, and database mirroring—that should lead you to a solid high-availability foundation. Microsoft has slowly been moving in the direction of trying to make SQL Server (and the Windows operating systems) as continuously available as possible for as many of its options as possible. Remember that Microsoft is competing with the UNIX/Linux-based worlds that have offered (and achieved) much higher uptime levels for years. The SQL Server RDBMS engine itself and the surrounding services, such as Analysis Services, Integration Services, Notification Services, and Reporting Services, have all taken big steps toward higher availability.

IN THIS CHAPTER

- ▶ What's New in High Availability144
- ▶ What Is High Availability?145
- ▶ The Fundamentals of HA147
- ▶ Building Solutions with One or More HA Options150
- ▶ Other HA Techniques That Yield Great Results159
- ▶ High Availability from the Windows Server Family Side162

What's New in High Availability

In general, a couple of Microsoft SQL Server 2008 configuration options offer a very strong database engine foundation that can be highly available (7 days a week, 365 days a year). Microsoft's sights are set on being able to achieve five-nines reliability with almost everything it builds. An internal breakthrough introduced with SQL Server 2005 called "copy-on-write" technology, has enabled Microsoft to greatly enhance several of its database high availability options.

Here are a few of the most significant enhancements and new features that have direct or indirect effects on increasing high availability for a SQL Server 2008-based implementation:

- ▶ **Increased number of nodes in a SQL cluster**—You can create a SQL cluster of up to 64 nodes on Windows Server Data Center 2008.
- ▶ **Enhancements to do unattended cluster setup**—Instead of having to use wizards to set up SQL clustering, you can use the Unattended Cluster Setup mode. This is very useful for fast re-creation or remote creation of SQL clustering configurations.
- ▶ **All SQL Server 2008 services as cluster managed resources**—All SQL Server 2008 services are now cluster aware.
- ▶ **SQL Server 2008 database mirroring**—Database mirroring creates an automatic failover capability to a "hot" standby server. (Chapter 20, "Database Mirroring," covers this topic in detail.)
- ▶ **SQL Server 2008 peer-to-peer replication**—This option of data replication uses a publisher-to-publisher model (hence peer-to-peer).
- ▶ **SQL Server 2008 automatic corruption recovery from mirror**—This enhancement in database mirroring recognizes and corrects corrupt pages during mirroring.
- ▶ **SQL Server 2008 mirroring transaction record compression**—This feature allows for compression of the transaction log records used in database mirroring to increase the speed of transmission to the mirror.
- ▶ **SQL Server 2008 fast recovery**—Administrators can reconnect to a recovering database after the transaction log has been rolled forward (and before the rollback processing has finished).
- ▶ **Online restore**—Database administrators can perform a restore operation while the database is still online.
- ▶ **Online indexing**—The online index option allows concurrent modifications (updates, deletes, and inserts) to the underlying table or clustered index data and any associated indexes during index creation time.
- ▶ **Database snapshot**—SQL Server 2008 allows for the generation and use of a read-only, stable view of a database. The database snapshot is created without the overhead of creating a complete copy of the database or having completely redundant storage.

- ▶ **Hot additions**—This feature allows for hot additions to memory and CPU.
- ▶ **Addition of a snapshot isolation level**—A new snapshot isolation (SI) level is being provided at the database level. With SI, users can access the last committed row, using a transactionally consistent view of the database.
- ▶ **Dedicated administrator connection**—SQL Server 2008 supports a dedicated administrator connection that administrators can use to access a running server even if the server is locked or otherwise unavailable. This capability enables administrators to troubleshoot problems on a server by executing diagnostic functions or Transact-SQL statements without having to take down the server.

At the operating system (OS) level, Virtual Server 2005 has firmly established virtualization for both development and production environments and allows entire application and database stacks to run on a completely virtual operating system footprint that will never bring down the physical server.

NOTE

Microsoft has announced that log shipping will be deprecated soon. Although it has been functionally replaced with database mirroring, log shipping remains available in SQL Server 2008. However, you should plan to move off log shipping as soon as you can.

Keep in mind that Microsoft already has an extensive capability in support of high availability. The new HA features add significant gains to the already feature-rich offering.

What Is High Availability?

The availability continuum depicted in Figure 18.1 shows a general classification of availability based on the amount of downtime an application can tolerate without impacting the business. You would write your service-level agreements (SLAs) to support and try to achieve one of these continuum categories.

Topping the chart is the category extreme availability, so named to indicate that this is the least tolerant category and is essentially a zero (or near zero) downtime requirement (that is, sustained 99.5% to 100% availability). The mythical five-nines falls at the high end of this category. Next is the high availability category, which has a minimal tolerance for downtime (that is, sustained 95% to 99.4% availability). Most “critical” applications would fit into this category of availability need. Then comes the standard availability category, with a more normal type of operation (that is, sustained 83% to 94% availability). The acceptable availability category is for applications that are deemed noncritical to a company’s business, such as online employee benefit package self-service applications. These applications can tolerate much lower availability ranges (sustained 70% to 82% availability) than the more critical services. Finally, the marginal availability category is for nonproduction custom applications, such as marketing mailing label applications that can tolerate significant downtime (that is, sustained 0% to 69% availability). Again, remember that availability is measured by the planned operation times of the application.

Availability Continuum

	Characteristic	Availability Range
Extreme Availability	Near zero downtime!	(99.5%-100%) 1.8 days/yr–5.26 min/yr
High Availability	Minimal downtime	(95%-99.4%) 18 days/yr–2.0 days/yr
Standard Availability	With some downtime tolerance	(83%-94%)
Acceptable Availability	Non-critical Applications	(70%-82%)
Marginal Availability	Non-production Applications	(up to 69%)

Availability Range describes the percentage of time relative to the “planned” hours of operations

8,760 hours/year | 168 hours/week | 24 hours/day
 525,600 minutes/year | 7,200 minutes/week | 1,440 minutes/day

FIGURE 18.1 Availability continuum.

NOTE

Another featured book from Sams Publishing, called *Microsoft SQL Server High Availability*, can take you to the depths of high availability from every angle. This landmark offering provides a complete guide to high availability, beginning with ways to gather and understand your HA requirements, assess your HA needs, and completely build out high-availability implementations for the most common business scenarios in the industry. Pick up this book if you are serious about achieving five-nines of reliability.

Achieving the mythical five-nines (that is, a sustained 99.999% availability) falls into the extreme availability category (which tolerates between 5.26 minutes and 1.8 days of down time per year). In general, the computer industry calls this high availability, but we push this type of near-zero downtime requirement into its own extreme category, all by itself. Most applications can only dream about this level of availability because of the costs involved, the high level of operational support required, the specialized hardware that must be in place, and many other extreme factors.

The Fundamentals of HA

Every minute of downtime you have today translates into losses that you cannot well afford. You must fully understand how the hardware and software components work together and how, if one component fails, the others will be affected. High availability of

an application is a function of all the components together, not just one by itself. Therefore, the best approach for moving into supporting high availability is to work on shoring up the basic foundation components of hardware, backup/recovery, operating system upgrading, ample vendor agreements, sufficient training, extensive quality assurance/testing, rigorous standards and procedures, and some overall risk-mitigating strategies, such as spreading out critical applications over multiple servers. By addressing these first, you add a significant amount of stability and high-availability capability across your hardware/system stack. In other words, you are moving up to a necessary level before you completely jump into a particular high-availability solution. If you do nothing further from this point, you have already achieved a portion of your high-availability goals.

Hardware Factors

You need to start by addressing your basic hardware issues for high availability and fault tolerance. This includes redundant power supplies, UPS systems, redundant network connections, and ECC memory (error correcting). Also available are “hot-swappable” components, such as disks, CPUs, and memory. In addition, most servers are now using multiple CPUs, fault-tolerant disk systems such as RAID, mirrored disks, storage area networks (SANs), Network Attached Storage (NAS), redundant fans, and so on.

Cost may drive the full extent of what you choose to build out. However, you should start with the following:

- ▶ Redundant power supplies (and UPSs)
- ▶ Redundant fan systems
- ▶ Fault-tolerant disks, such as RAID (1 through 10), preferably “hot swappable”
- ▶ ECC memory
- ▶ Redundant Ethernet connections

Backup Considerations

After you consider hardware, you need to look at the basic techniques and frequency of your disk backups and database backups. For many companies, the backup plan isn’t what it needs to be to guarantee recoverability and even the basic level of high availability. At many sites, database backups are not being run, are corrupted, or aren’t even considered necessary. You would be shocked by the list of Fortune 1000 companies where this occurs.

Operating System Upgrades

You need to make sure that all upgrades to your OS are applied and also that the configuration of all options is correct. This includes making sure you have antivirus software installed (if applicable), along with the appropriate firewalls for external-facing systems.

Vendor Agreements Followed

Vendor agreements come in the form of software licenses, software support agreements, hardware service agreements, and both hardware and software service-level agreements. Essentially, you are trying to make sure you can get all software upgrades and patches for your OS and for your application software at any time, as well as get software support, hardware support agreements, and both software and hardware SLAs in place to guarantee a level of service within a defined period of time.

Training Kept Up to Date

Training is multifaceted in that it can be for software developers to guarantee that the code they write is optimal, for system administrators who need to administer applications, and even for end users themselves to make sure they use the system correctly. All these types of training play into the ultimate goal of achieving high availability.

Quality Assurance Done Well

Testing as much as possible—and doing it in a very formal way—is a great way to guarantee a system’s availability. Dozens of studies over the years have clearly shown that the more thoroughly you test (and the more formal your QA procedures), the fewer software problems you will have. Many companies foolishly skimp on testing, which has a huge impact on system reliability and availability.

Standards/Procedures Followed

Standards and procedures are interlaced tightly with training and QA. Coding standards, code walkthroughs, naming standards, formal system development life cycles, protection of tables from being dropped, use of governors, and so on all contribute to more stable and potentially more highly available systems.

Server Instance Isolation

By design, you may want to isolate applications (such as SQL Server’s applications and their databases) away from each other to mitigate the risk of such an application causing another to fail.

Plain and simple, you should never put applications in each other’s way if you don’t have to. The only things that might force you to load up a single server with all your applications would be expensive licensing costs for each server’s software and perhaps hardware scarcity (strict limitations to the number of servers available for all applications). A classic example occurs when a company loads up a single SQL Server instance with between two and eight applications and their associated databases. The problem is that the applications are sharing memory, CPUs, and internal work areas, such as `tempdb`. Figure 18.2 shows an overloaded SQL Server instance that is being asked to service seven major applications (Appl 1 DB through Appl 7 DB).

The single SQL Server instance in Figure 18.2 is sharing memory (cache) and critical internal working areas, such as `tempdb`, with all seven major applications. Everything runs fine

High Risk: Single SQL Server Instance

FIGURE 18.2 High risk: Many applications sharing a single SQL Server 2008 instance.

until one of these applications submits a runaway query, and all other applications being serviced by that SQL Server instance come to a grinding halt. Most of this built-in risk could be avoided by simply putting each application (or perhaps two applications) onto their own SQL Server instance, as shown in Figure 18.3. This fundamental design approach greatly reduces the risk of one application affecting another.

FIGURE 18.3 Mitigated risk: Isolating critical applications away from each other.

Many companies make this fundamental error. The trouble is that they keep adding new applications to their existing server instance without a full understanding of the shared resources that underpin the environment. It is often too late when they finally realize that they are hurting themselves “by design.” You have now been given proper warning of the risks. If other factors, such as cost or hardware availability, dictate otherwise, then at least it is a calculated risk that is entered into knowingly (and is properly documented as well).

Building Solutions with One or More HA Options

When you have the fundamental foundation in place, as described in the preceding section, you can move on to building a tailored software-driven high-availability solution. Which HA option(s) you should be using really depends on your HA requirements. The following high-availability options are used both individually and, very often, together to achieve different levels of HA:

- ▶ Microsoft Cluster Services (non-SQL Server based)
- ▶ SQL clustering
- ▶ Data replication (including peer-to-peer configurations)
- ▶ Log shipping
- ▶ Database mirroring

All these options are readily available “out of the box” from Microsoft, from the Windows Server family of products and from Microsoft SQL Server 2008.

It is important to understand that some of these options can be used together, but not all go together. For example, you might use Microsoft Cluster Services (MSCS) along with Microsoft SQL Server 2008’s SQL Clustering to implement the SQL clustering database configuration, whereas, you wouldn’t necessarily need to use MSCS with database mirroring.

Microsoft Cluster Services (MSCS)

MSCS could actually be considered a part of the basic HA foundation components described earlier, except that it’s possible to build a high-availability system without it (for example, a system that uses numerous redundant hardware components and disk mirroring or RAID for its disk subsystem). Microsoft has made MSCS the cornerstone of its clustering capabilities, and MSCS is utilized by applications that are cluster enabled. A prime example of a cluster-enabled technology is Microsoft SQL Server 2008.

MSCS is the advanced Windows operating system configuration that defines and manages between 2 and 16 servers as “nodes” in a cluster. These nodes are aware of each other and can be set up to take over cluster-aware applications from any node that fails (for example, a failed server). This cluster configuration also shares and controls one or more disk subsystems as part of its high-availability capability. Figure 18.4 illustrates a basic two-node MSCS configuration.

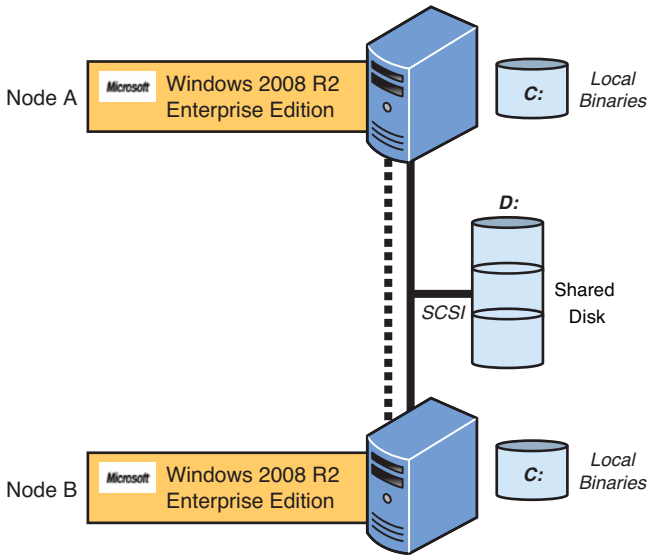

FIGURE 18.4 Basic two-node MSCS configuration.

MSCS is available only with Microsoft Windows Enterprise Edition and Data Center operating system products. Don't be alarmed, though. If you are looking at a high-availability system to begin with, there is a great probability that your applications are already running with these enterprise-level OS versions.

MSCS can be set up in an active/passive or active/active mode. Essentially, in an active/passive mode, one server sits idle (that is, is passive) while the other is doing the work (that is, is active). If the active server fails, the passive one takes over the shared disk and the cluster-aware applications instantaneously.

SQL Clustering

If you want a SQL Server instance to be clustered for high availability, you are essentially asking that this SQL Server instance (and the database) be completely resilient to a server failure and completely available to the application without the end user ever even noticing that there was a failure (or at least with minimal interruption). Microsoft provides this capability through the SQL Clustering option. SQL Clustering is built on top of MSCS for its underlying detection of a failed server and for its availability of the databases on the shared disk (which is controlled by MSCS). SQL Server is said to be a “cluster-aware/enabled” technology.

A SQL Server instance that is clustered can be created by actually creating a virtual SQL Server instance that is known to the application (the constant in the equation) and then

two physical SQL Server instances that share one set of databases. In an active/passive configuration, only one SQL Server instance is active at a time and just goes along and does its work. If that active server fails (and with it, the physical SQL Server instance), the passive server (and the physical SQL Server instance on that server) simply takes over instantaneously. This is possible because MSCS also controls the shared disk where the databases are. The end user and application never really know which physical SQL Server instance they are on or whether one failed. Figure 18.5 illustrates a typical SQL Clustering configuration built on top of MSCS.

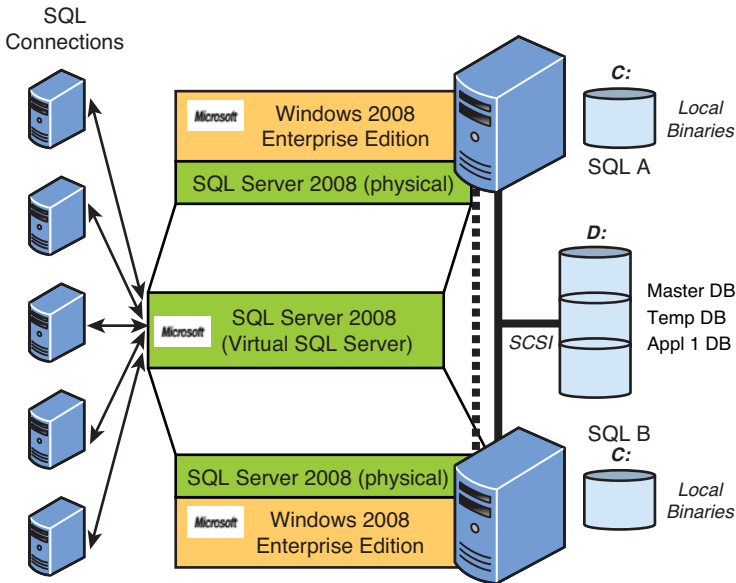

FIGURE 18.5 Basic SQL Clustering two-node configuration (active/passive).

Setup and management of this type of configuration are much easier than you might think. More and more often, SQL Clustering is the method chosen for most high-availability solutions. Later in this chapter, you see that other methods may also be viable for achieving high availability (based on the application's HA requirements). Chapter 21, "SQL Server Clustering," covers this topic in more detail.

Extending the clustering model to include Network Load Balancing (NLB) pushes this particular solution even further into higher availability—from client traffic high availability to back-end SQL Server high availability. Figure 18.6 shows a four-host NLB cluster architecture acting as a virtual server to handle the network traffic coupled with a two-node SQL cluster on the back end. This setup is resilient from top to bottom.

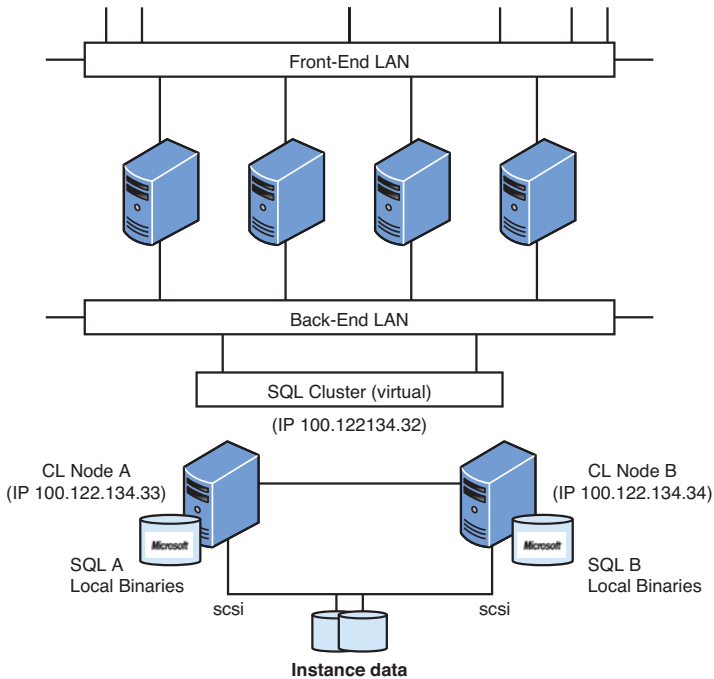

FIGURE 18.6 An NLB host cluster with a two-node server cluster.

The four NLB hosts work together, distributing the work efficiently. NLB automatically detects the failure of a server and repartitions client traffic among the remaining servers.

The following apply to SQL Clustering in SQL Server 2008:

- ▶ **Full SQL Server 2008 Services as cluster-managed resources**—All SQL Server 2008 services, including the following, are cluster aware:
 - ▶ SQL Server DBMS engine
 - ▶ SQL Server Agent
 - ▶ SQL Server Full-Text Search
 - ▶ Analysis Services
 - ▶ Integration Services
 - ▶ Notification Services
 - ▶ Reporting Services
 - ▶ Service Broker

Now, you can extend this fault-tolerant solution to embrace more SQL Server instances and *all* of SQL Server's related services. This is a big deal because things like Analysis Services previously had to be handled with separate techniques to achieve near high availability. Not anymore; each SQL Server service is now cluster aware.

Data Replication

The next technology option that can be utilized to achieve high availability is data replication. Originally, data replication was created to offload processing from a very busy server (such as an OLTP application that must also support a big reporting workload) or to geographically distribute data for different, very distinct user bases (such as worldwide product ordering applications). As data replication (transactional replication) became more stable and reliable, it started to be used to create “warm” (almost “hot”) standby SQL Servers that could also be used to fulfill basic reporting needs. If the primary server ever failed, the reporting users would still be able to work (hence a higher degree of availability achieved for them), and the replicated reporting database could be used as a substitute for the primary server, if needed (hence a warm-standby SQL Server). When doing transactional replication in the “instantaneous replication” mode, all data changes were replicated to the replicate servers extremely quickly. With SQL Server 2000, updating subscribers allowed for even greater distribution of the workload and, overall, increased the availability of the primary data and distributed the update load across the replication topology. There are plenty of issues and complications involved in using the updating subscribers approach (for example, conflict handlers, queues).

With SQL Server 2005, Microsoft introduced peer-to-peer replication, which is not a publisher/subscription model, but a publisher-to-publisher model (hence peer-to-peer). It is a lot easier to configure and manage than other replication topologies, but it still has its nuances to deal with. This peer-to-peer model allows excellent availability for this data and great distribution of workload along geographic (or other) lines. This may fit some companies' availability requirements and also fulfill their distributed reporting requirements as well.

The top of Figure 18.7 shows a typical SQL data replication configuration of a central publisher/subscriber using continuous transactional replication. This can serve as a basis for high availability and also fulfills a reporting server requirement at the same time. The bottom of Figure 18.7 shows a typical peer-to-peer continuous transactional replication model that is also viable.

The downside of peer-to-peer replication comes into play if ever the subscriber (or the other peer) needs to become the primary server (that is, take over the work from the original server). This takes a bit of administration that is *not* transparent to the end user. Connection strings have to be changed, ODBC data sources need to be updated, and so on. But this process may take minutes as opposed to hours of database recovery time, and it may well be tolerable to end users. Peer-to-peer configurations handle recovery a bit better in that much of the workload is already distributed to either of the nodes. So, at most, only part of the user base will be affected if one node goes down. Those users can easily be redirected to the other node (peer), with the same type of connection changes described earlier.

FIGURE 18.7 Basic data replication configurations for HA.

With either the publisher/subscriber or peer-to-peer replication approach, there is a risk of not having all the transactions from the publishing server. However, often, a company is willing to live with this small risk in favor of availability. Remember that a replicated database is an approximate image of the primary database (up to the point of the last update that was successfully distributed), which makes it very attractive as a warm standby. For publishing databases that are primarily read-only, using a warm standby is a great way to distribute the load and mitigate the risk of any one server failing. Chapter 19, “Replication,” covers data replication and all the various implementation scenarios that you might ever need to use.

Log Shipping

Another, more direct, method of creating a completely redundant database image is to utilize log shipping. Microsoft “certifies” log shipping as a method of creating an “almost hot” spare. Some folks even use log shipping as an alternative to data replication (it has been referred to as “the poor man’s data replication”). There’s just one problem: Microsoft has formally announced that log shipping (as we know and love it) will be deprecated in the near future. The reasons are many, but the primary one is that it is being replaced by database mirroring (referred to as *real-time log shipping*, when it was first being conceived). If you still want to use log shipping, it is perfectly viable—for now.

Log shipping does three primary things:

- ▶ Makes an exact image copy of a database on one server from a database dump
- ▶ Creates a copy of that database on one or more other servers from that dump

- ▶ Continuously applies transaction log dumps from the original database to the copy

In other words, log shipping effectively replicates the data of one server to one or more other servers via transaction log dumps. Figure 18.8 shows a source/destination SQL Server pair that has been configured for log shipping.

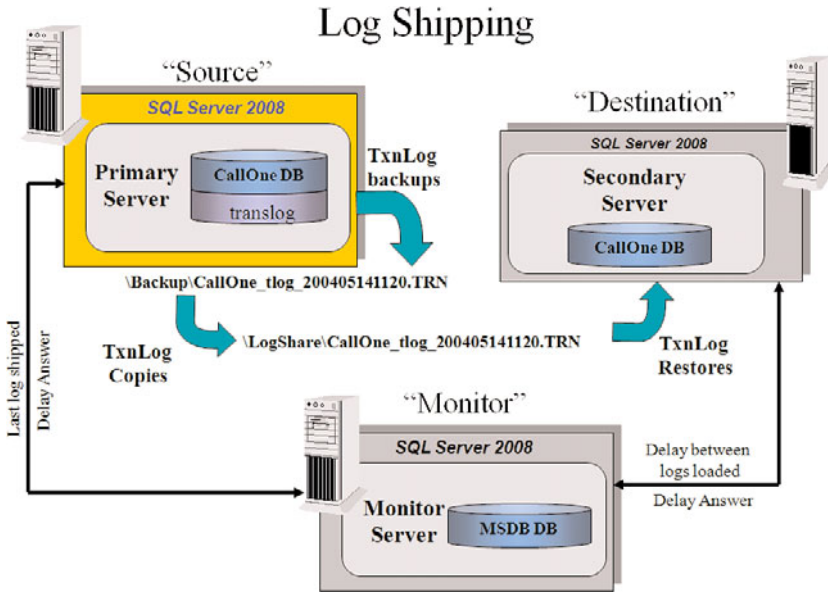

FIGURE 18.8 Log shipping in support of high availability.

Log shipping is a great solution when you have to create one or more failover servers. It turns out that, to some degree, log shipping fits the requirement of creating a read-only subscriber as well. The following are the gating factors for using log shipping as a method of creating and maintaining a redundant database image:

- ▶ Data latency lag is the time that exists between the transaction log dumps on the source database and when these dumps are applied to the destination databases.
- ▶ Sources and destinations must be the same SQL Server version.
- ▶ Data is read-only on the destination SQL Server until the log shipping pairing is broken (as it should be to guarantee that the transaction logs can be applied to the destination SQL Server).

The data latency restriction might quickly disqualify log shipping as an instantaneous high-availability solution (if you need rapid availability of the failover server). However, log shipping might be adequate for certain situations. If a failure ever occurs on the primary SQL Server, a destination SQL Server that was created and maintained via log shipping can be swapped into use fairly quickly. The destination SQL Server would contain exactly what was on the source SQL Server (right down to every user ID, table, index, and file allocation map, except for any changes to the source database that

occurred after the last log dump was applied). This directly achieves a level of high availability. It is still not completely transparent, though, because the SQL Server instance names are different, and the end user may be required to log in again to the new server instance.

NOTE

Log shipping is not covered further in this book because of its limited life going forward. The *SQL Server 2000 Unleashed* version of this book covers log shipping in extensive detail. Remember that log shipping is not data replication and uses a completely different technology than data replication.

Database Mirroring

Another failover option with SQL Server is database mirroring. Database mirroring essentially extends the old log shipping feature of SQL Server and creates an automatic failover capability to a “hot” standby server. Database mirroring is being billed as creating a fault-tolerant database that is an “instant” standby (ready for use in less than three seconds).

At the heart of database mirroring is the “copy-on-write” technology. Copy-on-write means that transactional changes are shipped to another server as the logs are written. All logged changes to the database instance become immediately available for copying to another location. As you can see in Figure 18.9, database mirroring utilizes a witness server as well as client components to insulate the client applications from any knowledge of a server failure.

FIGURE 18.9 SQL Server 2008 database mirroring high-availability configuration.

Chapter 20 dives much more deeply into database mirroring setup, configuration, and architecture. It is sufficient to say here that with database mirroring, an application can possibly be failed over to the mirrored database in 3 seconds or less, with nearly complete client transparency. You can also leverage this mirrored database for offloading reporting by creating a snapshot from it. Again, this topic is covered in Chapter 20.

Combining Failover with Scale-Out Options

SQL Server 2008 pushes combinations of options to achieve higher availability levels. A prime example would be combining data replication with database mirroring to provide maximum availability of data, scalability to users, and fault tolerance via failover, potentially at each node in the replication topology. By starting with the publisher and perhaps the distributor, you make them both database mirror failover configurations.

Building up a combination of both options together is essentially the best of both worlds: the super-low latency of database mirroring for fault tolerance and high availability (and scalability) of data through replication. Check out Chapter 20 for more details on this creative configuration.

Other HA Techniques That Yield Great Results

Microsoft has been revisiting (and architecting) several operations that previously required a table or whole database to be offline. For several critical database operations (such as recovery operations, restores, indexing, and others), Microsoft has either made the data in the database available earlier in the execution of the operation or made the data in the database completely available simultaneously with the operation. The following primary areas are now addressed:

- ▶ **Fast recovery**—This faster recovery option directly improves the availability of SQL Server databases. Administrators can reconnect to a recovering database after the transaction log has been rolled forward (and before the rollback processing has finished). Figure 18.10 illustrates how Microsoft makes a SQL Server 2008 database available earlier than would SQL Server 2000.

In particular, a database in SQL Server 2008 becomes available when committed transaction log entries are rolled forward (termed *redo*) and no longer have to wait for the “in flight” transactions to be rolled back (termed *undo*).

- ▶ **Online restore**—Database administrators can perform a restore operation while the database is still online. Online restore improves the availability of SQL Server because only the data being restored is unavailable; the rest of the database remains online and available to users. In addition, the granularity of the restore has changed to be at the filegroup level and even at the page level, if needed. The remainder of the database remains available.
- ▶ **Online indexing**—Concurrent modifications (updates, deletes, and inserts) to the underlying table or clustered index data and any associated indexes can now be done during index creation time. For example, while a clustered index is being

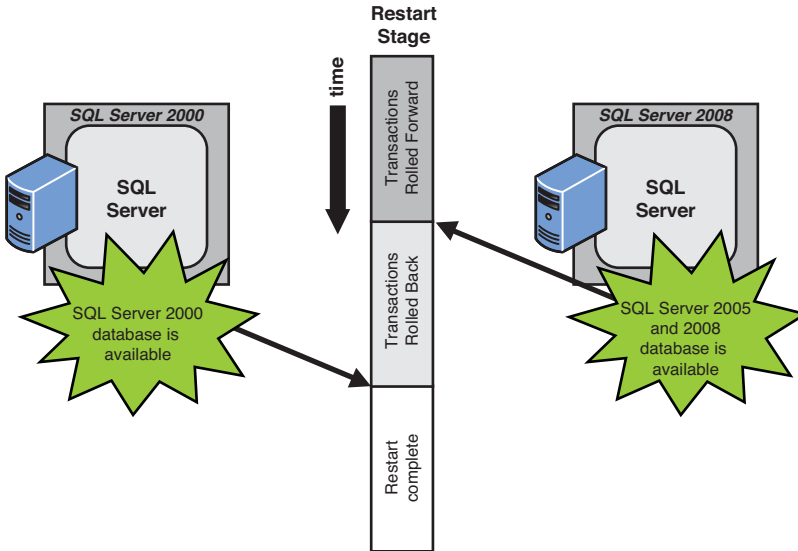

FIGURE 18.10 SQL Server 2008 databases become available earlier than databases with SQL Server 2000 database recovery (fast recovery).

rebuilt, you can continue to make updates to the underlying data and perform queries against the data.

- ▶ **Database snapshots**—You can now create a read-only, stable view of a database. A database snapshot is created without the overhead of creating a complete copy of the database or having completely redundant storage. A database snapshot is simply a reference point of the pages used in the database (that is defined in the system catalog). When pages are updated, a new page chain is started that contains the data pages changed since the database snapshot was taken, as illustrated in Figure 18.11.

As the original database diverges from the snapshot, the snapshot gets its own copy of original pages when they are modified. The snapshot can even be used to recover an accidental change to a database by simply reapplying the pages from the snapshot back to the original database.

The copy-on-write technology used for database mirroring also enables database snapshots. When a database snapshot is created on a database, all writes check the system catalog of “changed pages” first; if not there, the original page is copied (using the copy-on-write technique) and is put in a place for reference by the database snapshot (because this snapshot must be kept intact). In this way, the database snapshot and the original database share the data pages that have not changed.

- ▶ **Data partitioning improvements**—Data partitioning has been enhanced with native table and index partitioning. It essentially allows you to manage large tables and indexes at a lower level of granularity. In other words, a table can be defined to identify distinct partitions (such as by date or by a range of key values). This approach effectively defines a group of data rows that are unique to a partition.

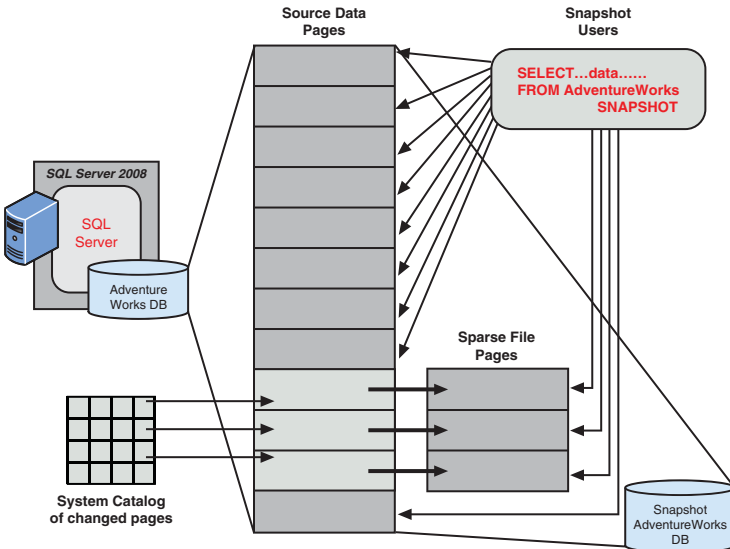

FIGURE 18.11 Database snapshots and the original database share pages and are managed within the system catalog of SQL Server 2008.

These partitions can be taken offline, restored, or loaded independently while the rest of the table is available.

- ▶ **Addition of a snapshot isolation level**—This snapshot isolation (SI) level is a database-level capability that allows users to access the last committed row, using a transactionally consistent view of the database. This capability provides improved scalability and availability by not blocking data access of this previously unavailable data state. This new isolation level essentially allows data reading requests to see the last committed version of data rows, even if they are currently being updated as part of a transaction (for example, they see the rows as they were at the start of the transaction without being blocked by the writers, and the writers are not blocked by readers because the readers do not lock the data). This isolation level is probably best used for databases that are read-mostly (with few writes/updates) due to the potential overhead in maintaining this isolation level.
- ▶ **Dedicated administrator connection**—This feature introduces a dedicated administrator connection that administrators can use to access a running server even if the server is locked or otherwise unavailable. This capability enables administrators to troubleshoot problems on a server by executing diagnostic functions or Transact-SQL statements without having to take down the server.

High Availability from the Windows Server Family Side

To enhance system uptimes, numerous system architecture enhancements that directly reduce unplanned downtime, such as improved memory management and driver verification, were made in Windows 2000, 2003, and 2008 R2. New file protection capabilities

prevent new software installations from replacing essential system files and causing failures. In addition, device driver signatures identify drivers that may destabilize a system. And, perhaps another major step toward stabilization is the use of virtual servers.

Microsoft Virtual Server 2005

Virtual Server 2005 is a much more cost-effective virtual machine solution designed on top of Windows Server 2008 to increase operational efficiency in software testing and development, application migration, and server consolidation scenarios. Virtual Server 2005 is designed to increase hardware efficiency and help boost administrator productivity, and it is a key Microsoft deliverable toward the Dynamic Systems Initiative (eliminating reboots of servers, which directly affects downtime!). As shown in Figure 18.12, the host operating system—Windows Server 2008 in this case—manages the host system (at the bottom of the stack).

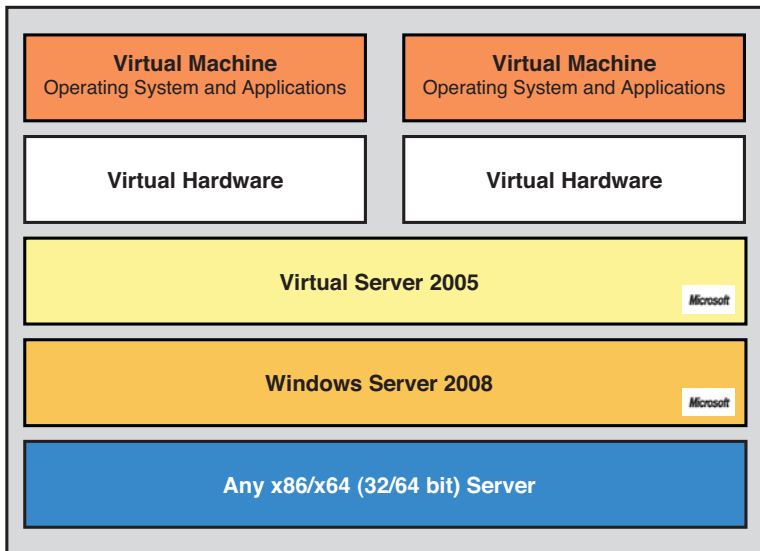

FIGURE 18.12 Microsoft Virtual Server 2005 server architecture.

Virtual Server 2005 provides a Virtual Machine Monitor (VMM) virtualization layer that manages virtual machines and provides the software infrastructure for hardware emulation. As you move up the stack, each virtual machine consists of a set of virtualized devices, the virtual hardware for each virtual machine.

A guest operating system and applications run in the virtual machine—unaware, for example, that the network adapter they interact with through Virtual Server is only a software simulation of a physical Ethernet device. When a guest operating system is running, the special-purpose VMM kernel takes mediated control over the CPU and hardware during virtual machine operations, creating an isolated environment in which the guest

operating system and applications run close to the hardware at the highest possible performance.

Virtual Server 2005 is a multithreaded application that runs as a system service, with each virtual machine running in its own thread of execution; I/O occurs in child threads. Virtual Server derives two core functions from the host operating system: the underlying host operating system kernel schedules CPU resources, and the device drivers of the host operating system provide access to system devices. The Virtual Server VMM provides the software infrastructure to create virtual machines, manage instances, and interact with guest operating systems. An often-discussed example of leveraging Virtual Server 2005 capabilities would be to use it in conjunction with a disaster recovery implementation.

Virtual Server 2005 and Disaster Recovery

Virtual Server 2005 enables a form of server consolidation for disaster recovery. Rather than maintaining redundancy with costly physical servers, customers can use Virtual Server 2005 to back up their mission-critical functionality in a cost-effective way by means of virtual machines. The Virtual Machine Monitor (VMM) and Virtual Hard Disk (VHD) technologies in Virtual Server 2005, coupled with the comprehensive COM API, can be used to create similar failover functionality as standard, hardware-driven disaster recovery solutions. Customers can then use the Virtual Server COM API to script periodic duplication of physical hard disks containing vital business applications to virtual machine VHDs. Additional scripts can switch to the virtual machine backup in the event of catastrophic failure. In this way, a failing device can be taken offline to troubleshoot, or the application or database can be moved to another physical or virtual machine. Moreover, because VHDs are a core Virtual Server technology, they can be used as a disaster recovery agent, wherein business functionality and data can be easily archived, duplicated, or moved to other physical machines.

Summary

As you come to completely understand and assess your application's high-availability requirements, you can create a matching high-availability solution that will serve you well for years to come. The crux of high availability is laying a fundamentally sound foundation that you can count on when failures occur and then, when failures do occur, determining how much data loss you can tolerate, how much downtime is possible, and what the downtime is costing you.

The overall future seems to be improving greatly in all the basic areas of your Microsoft platform footprint, including

- ▶ Cheaper and more reliable hardware components that are highly swappable
- ▶ The advent of virtual server capabilities (with Windows Virtual Server 2005) to insulate software failures from affecting hardware
- ▶ Enhancements that Microsoft is making to SQL Server 2008 that address availability

The critical enhancements to the cornerstone availability capabilities of SQL Clustering will help this fault-tolerant architecture grow more reliable for years to come. The big bonuses come with the features of database mirroring as another fault-tolerant solution at the database level and the database snapshots feature to make data more available to more users more quickly than the older method of log shipping.

To top it all off, Microsoft is making great strides in the areas of online maintenance operations (online restores, online index creates, and so on) and leaping into the realm of one or more virtual server machines (with Virtual Server 2005) that will not bring down a physical server that houses them (which is very UNIX-like).

Chapter 19 delves into the complexities of the major data replication options available with SQL Server 2008.

CHAPTER 19

Replication

There is no such thing as a typical configuration or application anymore. Companies now have to support numerous hardware and software configurations in multitiered, distributed environments. These diverse configurations and applications (and users of the applications) come in all sizes and shapes. And, of course, you need a way to deal with varied data access requirements for these different physical locations; these remote or mobile users over a local area network, wide area network, wireless connections, and dial-up connections; and any needs over the Internet. Microsoft's data replication facility allows for a great breadth of capability to deal with many of these demands. However, to build a proper data replication implementation that meets many of these user requirements, you must have a thorough understanding of the business requirements and technical capabilities of data replication. Data replication is a set of technologies for storing and forwarding data and database objects from one database to another and then synchronizing this data between databases to maintain consistency. With SQL Server 2008, the data replication feature set offers numerous improvements in manageability, availability, programmability, mobility, scalability, and performance.

This chapter does the following:

- ▶ Helps you understand what data replication is
- ▶ Shows you how to understand and analyze user requirements of data
- ▶ Allows you to choose which replication configuration best meets these requirements (if any)

IN THIS CHAPTER

- ▶ What's New in Data Replication
- ▶ What Is Replication?
- ▶ The Publisher, Distributor, and Subscriber "Magazine" Metaphor
- ▶ Replication Scenarios
- ▶ Subscriptions
- ▶ Replication Agents
- ▶ Planning for SQL Server Data Replication
- ▶ SQL Server Replication Types
- ▶ Basing the Replication Design on User Requirements
- ▶ Setting Up Replication
- ▶ Scripting Replication
- ▶ Monitoring Replication

- ▶ Demonstrates how to implement a replication configuration
- ▶ Describes how to administer and monitor a data replication implementation

What's New in Data Replication

Much of what's new for Microsoft SQL Server data replication revolves around simplifying setup, administration, and monitoring of a data replication topology. This is the result of years of practical experience and thousands of production replication implementations around the globe. The overall data replication approach that Microsoft has developed (since replication's inception back in SQL Server 6.5 days) has been so solid that competitors, such as Oracle (with its Oracle Streams technology), have tried to mimic this architectural approach.

Among many others, the following are some of the new replications features and enhancements that make SQL Server 2008 data replication one of the best data distributions tools on the market:

- ▶ **Highly available replication node additions**—SQL Server 2008 offers the capability to add nodes to a replication topology without quiescing the topology.
- ▶ **Topology Viewer**—Enhancements have been made to the Peer-to-Peer Topology Wizard so that you can now visually see what the peer-to-peer topology looks like with the Topology Viewer.
- ▶ **Capability to centrally monitor all agents and jobs at the Publisher**—You are able to view information about all the agents and jobs associated with publications at the selected Publisher.
- ▶ **Minor Replication Monitor enhancements**—Replication Monitor has undergone slight tweaks to make it easier to monitor your full replication topologies. It allows you to monitor the overall health of a replication topology and provides detailed information about the status and performance of publications and subscriptions.
- ▶ **Capability to replicate switch partition ALTER**—Enhanced Transactional Replication Support for Partitioned Tables is now available, including the capability to replicate the switch partition ALTER for Tables.
- ▶ **Scripting integrated into wizards**—You can almost completely script your replication setup or breakdown during or after wizard executions.
- ▶ **Conflict Viewer**—This feature helps you view and resolve any conflicts that occurred during the synchronization of a merge subscription or queued updating subscription.
- ▶ **Peer-to-peer transactional replication**—Further enhancements have been introduced to the peer-to-peer replication model. They allow replication between identical participants in the topology (a master/master or symmetric publisher concept).
- ▶ **Peer-to-peer conflict detection**—The capability to detect conflicts during synchronization in a peer-to-peer replication topology has been added.

- ▶ **More replication mobility**—Merge replication provides the capability to replicate data over HTTPS with the web synchronization option, which is useful for synchronizing data from mobile users over the Internet or synchronizing data between Microsoft SQL Server databases across a corporate firewall.
- ▶ **Microsoft Sync Framework**—This comprehensive synchronization platform enables collaboration and offline access for applications, services, and devices. It features technologies and tools that enable roaming, sharing, and taking data offline. By using Sync Framework, developers can build sync ecosystems that integrate any application with any data from any store that uses any protocol over any network. We mention it here because of its replication-like behavior for “occasionally connected” applications.

Many of these terms and references might be new or foreign to you now, but they are all explained in this chapter. At the end of this chapter, when you review these new features, you’ll be able to appreciate much more readily their significance.

What Is Replication?

Long before you ever start setting up and using SQL Server data replication, you need to have a solid grasp of what data replication is and how it can be used to meet your company’s needs. In its classic definition, data replication is based on the “store-and-forward” data distribution model, as shown in Figure 19.1. In other words, data that is inserted, updated, or deleted in one location (stored) is automatically distributed (forwarded) to one or more locations.

FIGURE 19.1 The store-and-forward data distribution model.

Of course, the data distribution model addresses all the other complexities of updates, deletes, data latency, autonomy, and so on. It is this data distribution model that Microsoft’s data replication facility serves to implement. It has come a long way since the early days of Microsoft SQL Server replication (earlier than 6.5) and is now easily categorized as “production worthy.” Numerous worldwide data replication scenarios have been implemented for some of the biggest companies in the world without a hitch. These scenarios fall into five major types:

- ▶ **Offloading**—You might need to deliver data to different locations to eliminate network traffic and unnecessary load on a single server (for example, when you need to isolate reporting activity away from your online transaction processing). The industry trend is to create an operational data store (ODS) data architecture that replicates core transactional data to a separate platform in real-time and delivers the data to the reporting systems, web services, and other data consumers without impacting the transactional systems in any way.
- ▶ **Enabling**—You might need to enable a group of users with a copy of data or a subset of data (vertically or horizontally) for their private use.
- ▶ **Partitioning**—You might need to move data off a single server onto several other servers to provide for high availability and decentralization of data (or partitioning of data). This might be the basis of serving customer call centers around the globe that must service “active” support calls (partitioned on active versus closed service requests).
- ▶ **Regionalization**—You might have regional ownership of data (for example, regional customers and their orders). In this case, it is possible to set up data replication to replicate data bidirectionally from two or more publishers of the same data.
- ▶ **Failover**—You could be replicating all data on a server to another server (that is, a failover server) so that if the primary server crashes, users can switch to the failover server quickly and continue to work with little downtime or data loss.

Figure 19.2 illustrates the topology of some of these replication variations.

FIGURE 19.2 Data replication scenarios.

As you may notice, you can use data replication for many reasons. Many of these reasons are discussed later in this chapter. First, however, you need to understand some of the common terms and metaphors Microsoft uses in relationship to data replication. They started with the “magazine” concept as the basis of the metaphor. A magazine is created by a publisher, distributed via the mail, and delivered to only those who have a subscription to the magazine. The frequency of the magazine publication can vary, as can the frequency of the subscription (depending on how often the subscriber wants to receive a new magazine). The publication (magazine) consists of one or more articles. One or more articles can be subscribed to.

The Publisher, Distributor, and Subscriber Magazine Metaphor

Any SQL Server can play up to three distinct roles in a data replication environment:

- ▶ **Publication server**—The publication server (or publisher) contains the database or databases that will be published (the magazine!). This is the source of the data that is to be replicated to other servers. In Figure 19.3, the Customer table (an article in the magazine) in the AdventureWorks2008 database is the data to be published. To publish data, the database that contains the data that will be published must first be enabled for publishing. Full publishing configuration requirements are discussed later in this chapter, in the section “Setting Up Replication.”

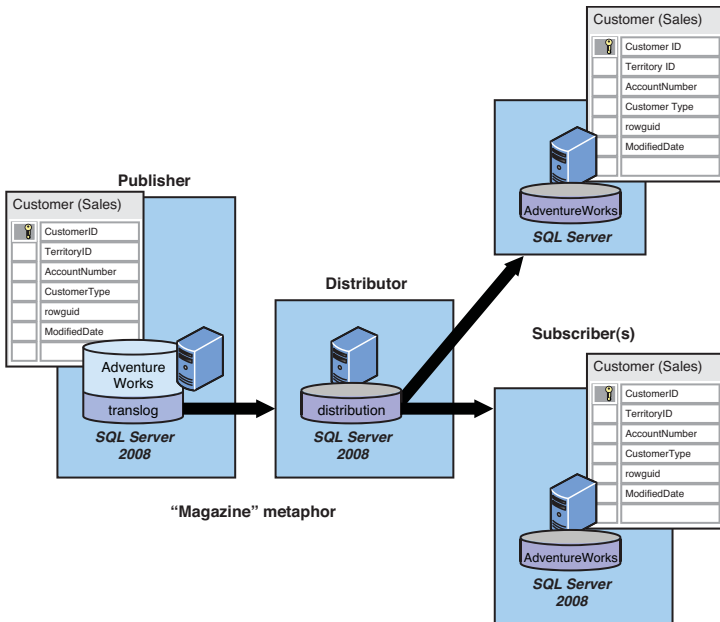

FIGURE 19.3 The publisher, distributor, and one or more subscribers.

- ▶ **Distribution server**—The distribution server (or distributor) can either be on the same server as the publication server or on a different server (in which case it is a remote distribution server). This server contains the distribution database. This database, also called the store-and-forward database, holds all the data changes that are to be forwarded from the published database to any subscription servers that subscribe to the data. A single distribution server can support several publication servers. The distribution server is truly the workhorse of data replication; it is essentially the mail system that picks up the magazine and delivers it to the subscription holder.
- ▶ **Subscription server**—The subscription server (or subscriber) contains a copy of the database or portions of the database being published (for example, the Customer table in the AdventureWorks2008 database). The distribution server sends any changes made to this table (in the published database) to the subscription server's copy of the Customer table. This is known as *store-and-forward*. Some data replication configurations send the data to the subscription server, and then the data is read-only. It is also possible for subscribers (known as updating subscribers) to make updates, which are sent back to the publisher. More on this in the Updating Subscribers Replication Model section.

There are now new variations of this update subscriber option called *peer-to-peer replication*. Peer-to-peer allows for more than one publisher of the same data (table) at the same time! Essentially, each publisher is also a subscriber at the same time (hence, peer-to-peer). This chapter provides more information on updating subscribers and peer-to-peer configurations in the “The Updating Subscribers Replication Model” section, later.

Along with enabling distinct server roles (publisher, distributor, and subscriber), Microsoft utilizes a few more magazine metaphors, including publications and articles. A *publication* is a group of one or more *articles* and is the basic unit of data replication. An *article* is simply a pointer to a single table, or a subset of rows or columns out of a table, that will be made available for replication.

Publications and Articles

A single database can contain more than one publication. You can publish data from tables, from database objects, from the execution of stored procedures, and even from schema objects, such as referential integrity constraints, clustered indexes, nonclustered indexes, user triggers, extended properties, and collation. Regardless of what you plan to replicate, all articles in a publication are synchronized at the same time. Figure 19.4 shows an example of a publication (named Cust_Orders publication) with three articles (three tables from the AdventureWorks2008 database). You can also choose to replicate whole tables or just parts of tables via filtering.

Filtering Articles

You can create articles within a publication in several different ways. The basic way to create an article is to publish all the columns and rows contained in a table. Although this is the easiest way to create articles, your business needs might require that you publish only specific columns or certain rows of a table. This is referred to as *filtering vertically* or

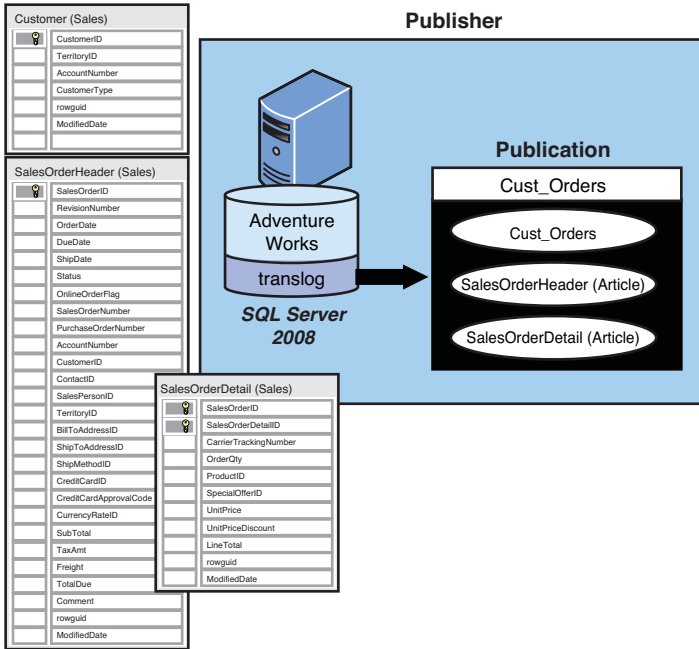

FIGURE 19.4 The **Cust_Orders** publication (in the **AdventureWorks2008** database).

horizontally. When you filter vertically, you filter only specific columns, whereas with horizontal filtering, you filter only specific rows. In addition, SQL Server 2008 provides the added functionality of join filters and dynamic filters.

As Figure 19.5 shows, you might need to replicate only a customer's **CustomerID**, **TerritoryID**, and **CustomerType** to various subscribing servers around your company. In your company, the other data, such as **AccountNumber**, may be restricted information that should not be replicated for general use. For that reason, you simply create an article for data replication that contains a subset of the **Customer** table that will be replicated to these other locations and excludes **AccountNumber** (and **rowguid** and **ModifiedDate** as well).

As another example, you might need to publish only the **Customer** table data for a specific customer type, such as "individual" customers (**CustomerType = 'I'**) or customers that are "stores" (**CustomerType = 'S'**). This process, as shown in Figure 19.6, is known as horizontal filtering.

It is possible to combine horizontal and vertical filtering, as shown in Figure 19.7. This way, you can weed out unneeded columns *and* rows that aren't required for replication (that is, are not needed by the subscribers). For example, you might need only the customers that are stores and need only **CustomerID**, **TerritoryID**, and **CustomerType** data to be published.

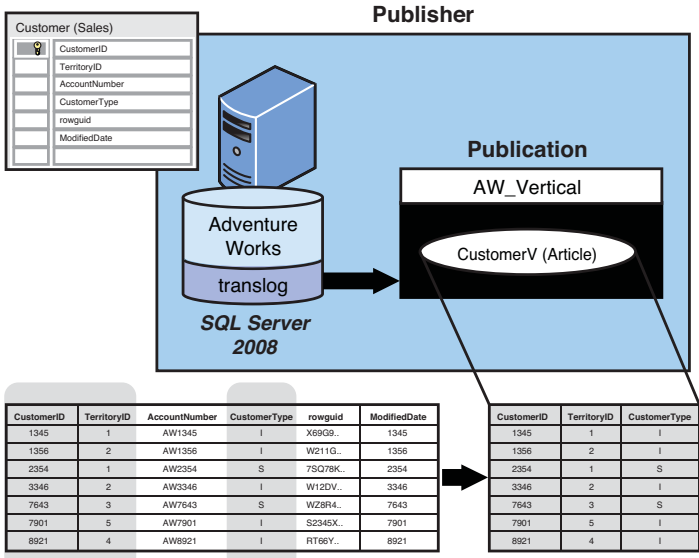

FIGURE 19.5 Vertical filtering creates a subset of columns from a table to be replicated to subscribers.

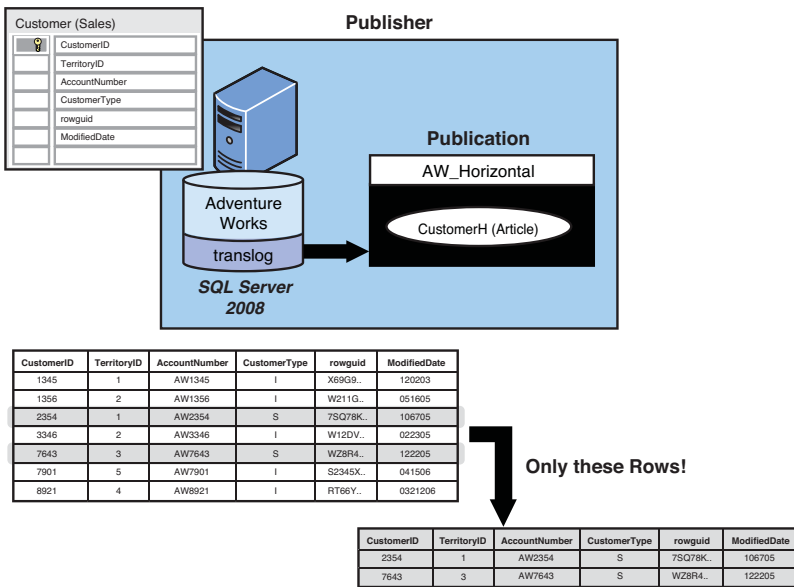

FIGURE 19.6 Horizontal filtering creates a subset of rows from a table to be replicated to subscribers.

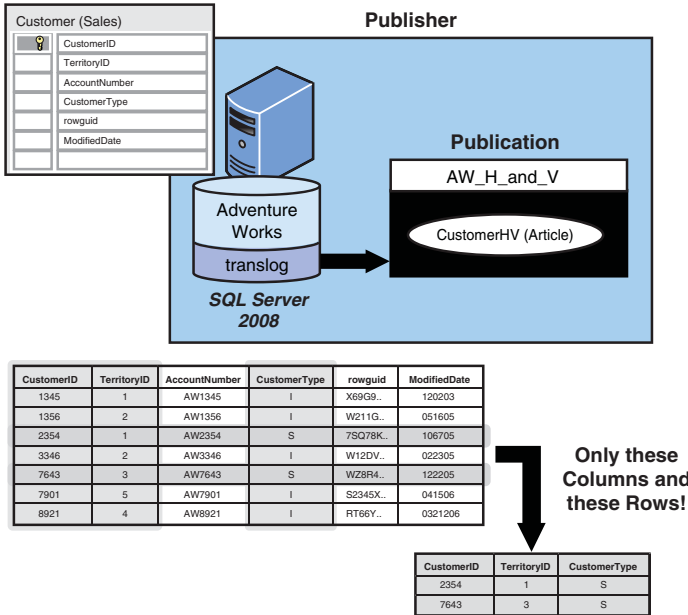

FIGURE 19.7 Combining horizontal and vertical filtering allows you to pare down the information in an article to only the important information needed by the subscribers.

As mentioned earlier, it is now possible to use join filters. Join filters enable you to use the values of one article (that is, values from a table) to determine what gets replicated from another article (that is, what values can be associated with another table) via a join. In other words, if you are publishing the Customer table data based on the customers that are stores, you can extend filtering (that is, a join filter) to replicate only those orders for these types of customers (as shown in Figure 19.8). This way, you replicate only orders for customers that are stores to a subscriber that needs to see only this filtered data. This type of replication can be efficient if it is done well.

You also can publish stored procedure executions, along with their parameters, as articles. This can be either a standard procedure execution article or a serializable procedure execution article. The difference is that the latter is executed as a serializable transaction; the serializable option is recommended because it replicates the procedure execution only if the procedure is executed within the context of a serializable transaction. If that same stored procedure is executed from outside a serializable transaction, changes to data in published tables are replicated as a series of DML statements. In general, replicating stored procedure executions gives you a major reduction in the number of SQL statements being replicated across the network versus standard DML statements.

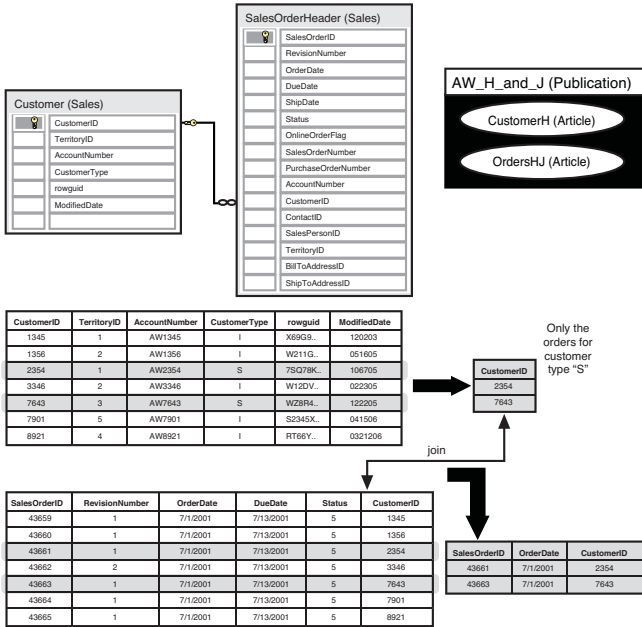

FIGURE 19.8 Horizontal and Join publication: Joining customers that are stores (type “S”) to corresponding **SalesOrderHeader** rows.

For instance, if you wanted to update the Customer table for every customer via an UPDATE SQL statement, the resulting Customer table updates would be replicated as a large multi-step transaction involving at least 5,000 separate UPDATE statements at a minimum. This number of statements would significantly bog down your network. However, with stored procedure execution articles, only the execution of the stored procedure is replicated to the subscription server, and the stored procedure—not the numerous update statements—is executed on that subscription server. Figure 19.9 illustrates the difference in execution described earlier. Some subtleties when utilizing this type of data replication processing can't be overlooked, such as making sure the published stored procedure behaves the same on the subscribing server side.

Many more data replication terms are presented in this chapter, but it is essential that you first learn about the different types of replication scenarios that can be built and the reasons any of them would be desired over the others. It is also worth noting that Microsoft SQL Server 2008 supports replication to and from many different “heterogeneous” data sources. In other words, OLE DB and ODBC data sources can subscribe to SQL Server publications, and they can receive data replicated from a number of data sources, including Microsoft Exchange, Microsoft Access, Oracle, and DB2.

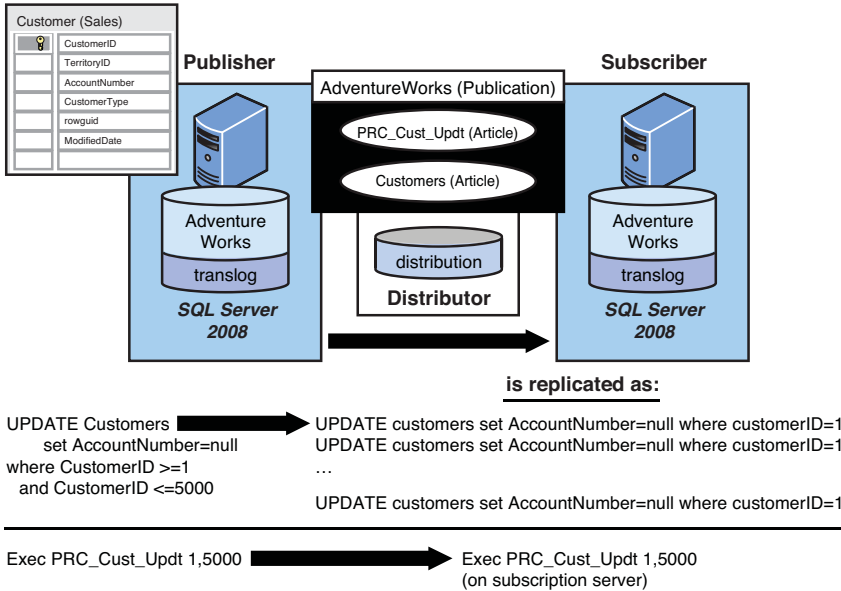

FIGURE 19.9 Comparison of stored procedure execution and standard SQL statement replication.

Replication Scenarios

In general, depending on your business requirements and hardware or network constraints, one of several different data replication models can be implemented, including the following:

- ▶ Central publisher
- ▶ Central publisher with a remote distributor
- ▶ Publishing subscriber
- ▶ Central subscriber
- ▶ Multiple publishers with multiple subscribers
- ▶ Updating subscribers
- ▶ Peer-to-peer

The Central Publisher Replication Model

The central publisher replication model, shown in Figure 19.10, is Microsoft’s default scenario and a common model used if your primary server has plenty of spare CPU cycles and you want a simple replication model. In this scenario, one SQL Server performs the function of both publisher and distributor. The publisher/distributor can have any number

of subscribers. These subscribers can come in many different varieties, such as SQL Server 2008, SQL Server 2005, SQL Server 2000, SQL Server 7.0, and Oracle.

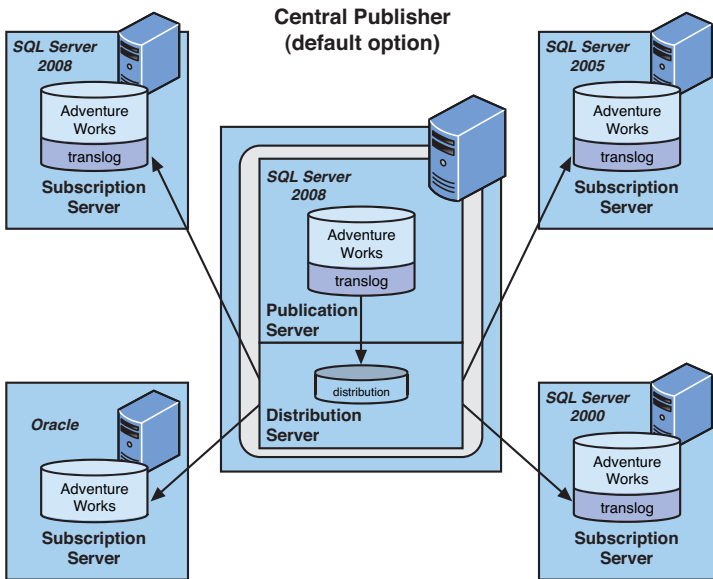

FIGURE 19.10 The central publisher scenario is fairly simple and is a replication model used often.

The central publisher scenario can be used in the following situations:

- ▶ Creation of a copy of a database for ad hoc queries and report generation (classic use)
- ▶ Publication of master lists to remote locations, such as master customer lists or master price lists
- ▶ Maintenance of a remote copy of an online transaction processing (OLTP) database that could be used by the remote sites during communication outages
- ▶ Maintenance of a spare copy of an OLTP database that could be used as a “hot spare” in case of server failure

However, it’s important to consider the following for this replication model:

- ▶ If your OLTP server’s activity is substantial and affects greater than 10% of your total data per day, this scenario is not for you. Other scenarios or configurations will better fit your needs.
- ▶ If your OLTP server is maximized on CPU, memory, and disk utilization, you should also consider another data replication scenario because this one is not for you either.

The Central Publisher with Remote Distributor Replication Model

The central publisher with remote distributor scenario, as shown in Figure 19.11, is similar to the central publisher scenario and would be used in the same general situations. The major difference between the two is that in the central publisher with remote distributor scenario, a second server is used to perform the role of distributor. This is highly desirable when you need to free the publishing server from having to perform the distribution task from a CPU, disk, and memory point of view. This is also the best scenario from which to expand the number of publishers and subscribers. Remember that a single distribution server can distribute changes for several publishers. The publisher and distributor must be connected to each other via a reliable, high-speed data link. This remote distributor scenario is proving to be one of the best data replication configurations due to its minimal impact on the publication server and maximum distribution capability to any number of subscribers.

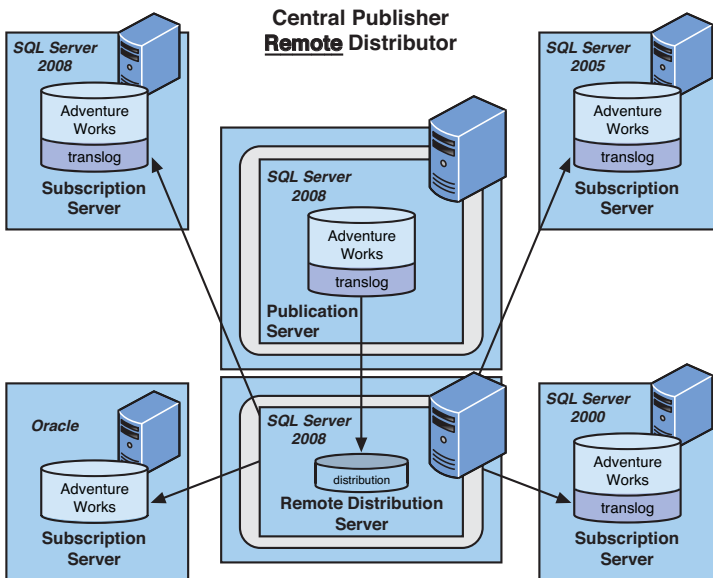

FIGURE 19.11 You use the central publisher with remote distributor scenario when you need to offload the distribution work to another server (to minimize the impact to the publishing server).

As mentioned previously, the central publisher/remote distributor approach can be used for all the same purposes as the central publisher scenario, and it also provides the added benefit of having minimal resource impact on the publication servers. If your OLTP server's activity affects more than 10% of your total data per day, this scenario can usually handle it without much issue. If your OLTP server has overburdened CPU, memory, and disk utilization, implementing this model easily solves these issues as well. The central

publisher/remote distribution model is useful for the vast majority of all the data replication configurations due to its optimal characteristics. Nine out of ten replication scenarios that this author has implemented used the remote distributor replication model.

The Publishing Subscriber Replication Model

In the publishing subscriber scenario, as shown in Figure 19.12, the publication server also has to act as a distribution server to one subscriber. This subscriber, in turn, immediately publishes the data to any number of other subscribers. The configuration depicted here does not use a remote distribution configuration option but serves the same distribution model purpose. This scenario is best used when a slow or expensive network link exists between the original publishing server and all the other potential subscribers. This allows the initial (critical) publication of the data to be distributed from the original publishing server to that single subscriber across the slow, unpredictable, or expensive network line. Then, each of the many other subscribers can subscribe to the data, using faster, more predictable, “local” network lines than they would have with the publishing subscriber server.

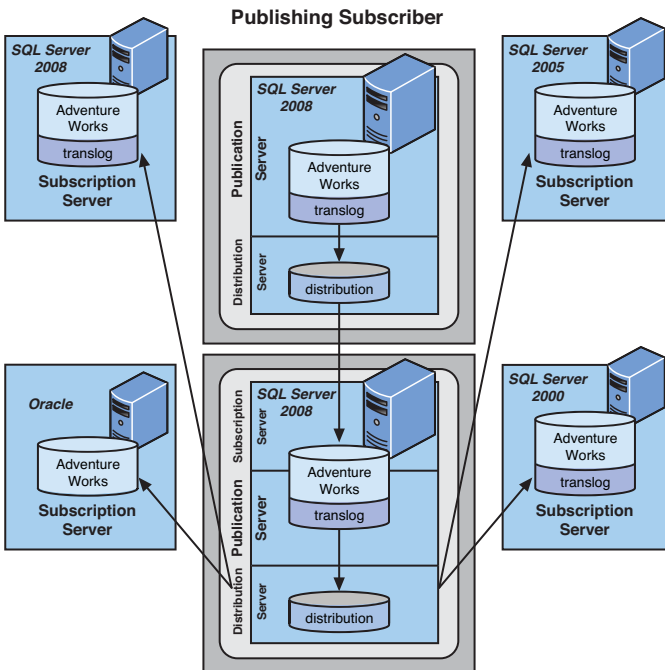

FIGURE 19.12 The publishing subscriber scenario works well when you have to deal with slow, unpredictable, or expensive network links in diverse geographic situations.

A classic example of this model is a company whose main office is in San Francisco and has several branch offices in Europe. Instead of replicating changes to all the branch offices in Europe, it replicates the updates to a single publishing subscriber server in Paris. This publishing subscriber server in Paris then replicates the updates to all other subscriber servers around Europe.

The Central Subscriber Replication Model

In the central subscriber scenario, as shown in Figure 19.13, several publishers replicate data to a single, central subscriber. Basically, this supports the concept of consolidating data at a central site. An example of this might be consolidating all new orders from regional sales offices to company headquarters. In such a situation, you now have several publishers of the Orders table, and you need to take some form of precaution, such as filtering by region. This would guarantee that no one publisher could update another region's orders.

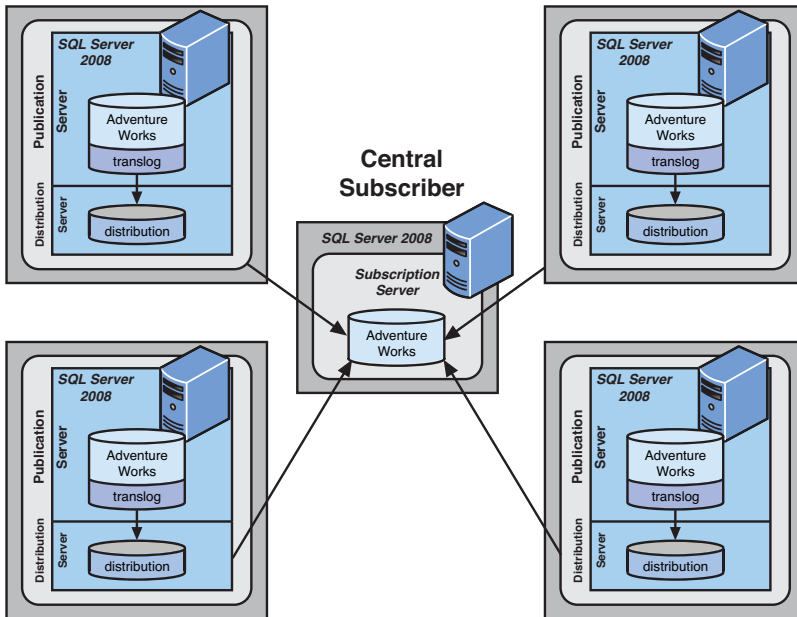

FIGURE 19.13 With the central subscriber scenario, several publishers send data to a single, central subscriber.

The Multiple Publishers with Multiple Subscribers Replication Model

In the multiple publishers with multiple subscribers scenario, as shown in Figure 19.14, a common table (such as the Customer table) is maintained on every server participating in the scenario. Each server publishes a particular set of rows (for example, the customer rows in a customer's own territory) that pertain to it—usually via filtering on something that identifies that site to the data rows it owns—and subscribes to the rows that all the other servers are publishing. The result is that each server has all the data at all times and can make changes to its data only. You must be careful when implementing this scenario to ensure that all sites remain synchronized. The most frequently used applications of this system are regional order processing systems and reservation tracking systems. When setting up this type of system, you need to make sure that only local users update local

data. This check can be implemented through the use of stored procedures, restrictive views, or a check constraint.

Multiple Publishers of a Single Table

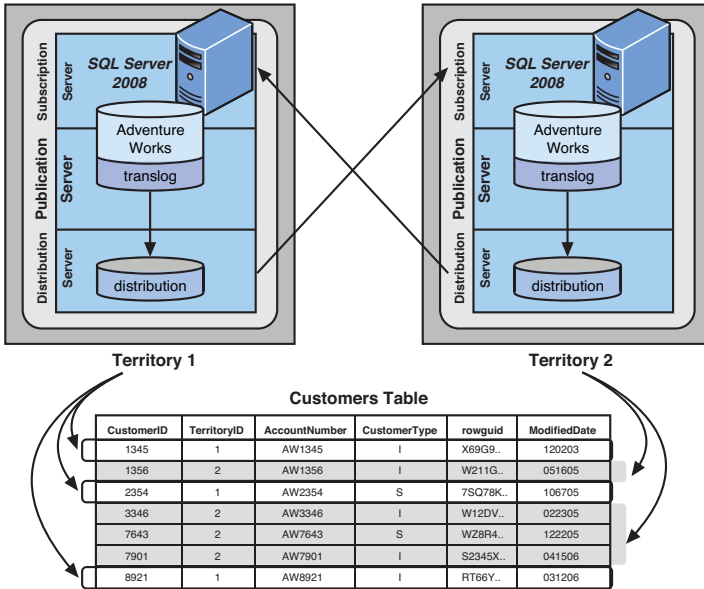

FIGURE 19.14 In the multiple publishers of a single table scenario, every server in the scenario maintains a common table.

The Updating Subscribers Replication Model

SQL Server 2008 has built-in functionality that allows the subscriber to update data in a table to which it subscribes and have those updates automatically made back to the publisher through either immediate or queued updates. This model, called the updating subscribers model, utilizes a two-phase commit process to update the publishing server as the changes are made on the subscribing server. These updates are then replicated to any other subscribers, but not to the subscriber that made the update.

Immediate updating allows subscribers to update data only if the publisher will accept these updates immediately. If the changes are accepted at the publisher, they are propagated to the other subscribers. The subscribers must be continuously and reliably connected to the publisher to make changes at the subscriber.

Queued updating allows subscribers to update data and then store those updates in a queue while disconnected from the publisher. When the subscriber reconnects to the publisher, the updates are propagated to the publisher. This functionality utilizes SQL Server 2008 queues and the queue reader agent or Microsoft Message Queuing (MSMQ).

A combination of immediate updating with queued updating allows the subscriber to use immediate updating but switch to queued updating if a connection cannot be maintained

between the publisher and subscribers. After switching to queued updating, reconnecting to the publisher, and emptying the queue, the subscriber can switch back to immediate updating mode. An updating subscriber is shown in Figure 19.15.

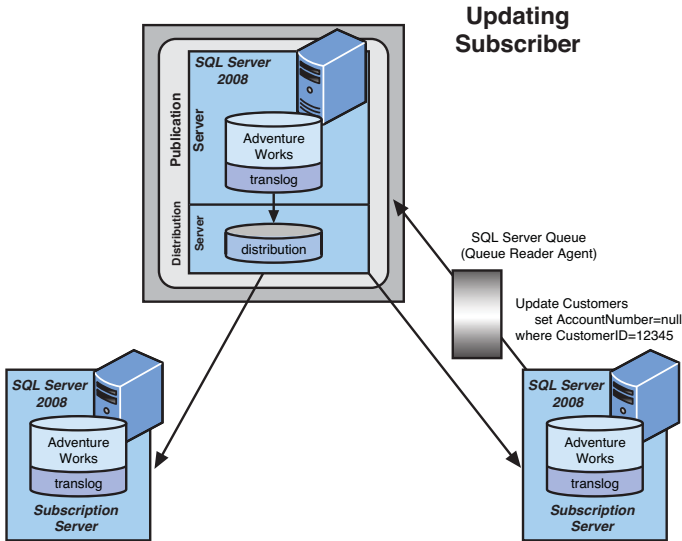

FIGURE 19.15 An updating subscriber updating its copy of a customer table and queuing the changes back to the publisher.

The Peer-to-Peer Replication Model

In SQL Server 2008, the peer-to-peer replication model can provide a simpler way for all nodes to have the same data and also gives them the capability to update this data independently. Peer-to-peer replication is different from subscriber updating in that there is no publisher/subscriber hierarchical relationship. Each peer is equal in level. They establish peer originator IDs so that each can keep track of where updates are coming from and can be utilized if conflicts arise. Peers do not subscribe to each other's data; they share each other's data. There are several limitations with peer-to-peer replication, most of which are to protect this peer-to-peer relationship from being corrupted or from having major data conflicts arise. There are no queues or immediate updating mechanisms involved, thus making this approach very useful when you need to have the same data in more than one place and need to update your local data to your heart's content. If your peers typically do not update the same rows (as in regional data peer-to-peers), this replication model can be very reliable with minimal issues. This type of replication model also allows for any number of peers and provides a separate, very graphic wizard to configure each node in the topology.

NOTE

New peer nodes can also be added to the topology without having to quiesce the topology, thus increasing the availability of the entire replication model.

Figure 19.16 illustrates a typical peer-to-peer configuration with each peer using a remote distribution server. Also note that with peer-to-peer replication, you might decide to prohibit updates to the other nodes' data by putting into place some type of stored procedure or view restrictions that allow the local node to update only its own local data. The example in Figure 19.16 shows that North American users can update customers with customer IDs between 1 and 3000, whereas Asian users can update customers with customer IDs between 3001 and 9000.

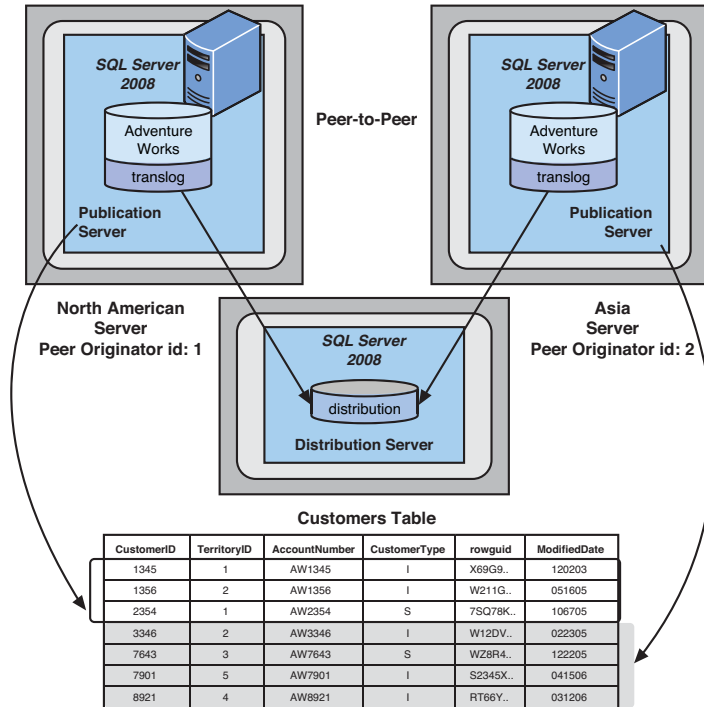

FIGURE 19.16 Peer-to-peer replication.

Subscriptions

A *subscription* is essentially a formal request and registration of that request for data that is being published. By definition, you subscribe to all articles of a publication.

When a subscription is being set up, you have the option of either having the data “pushed” to the subscriber server or “pulling” the data to the subscription server when it is needed. This is referred to as either a *push subscription* or *pull subscription*.

As shown in Figure 19.17, a pull subscription is set up and managed by the subscription server. The biggest advantage here is that pull subscriptions allow the system administrators of the subscription servers to choose what publications they will receive and when they receive them. With pull subscriptions, publishing and subscribing are separate acts and are not necessarily performed by the same user. In general, pull subscriptions are best

when the publication does not require high security or if subscribing is done intermittently when the subscriber's data needs to be periodically brought up to date.

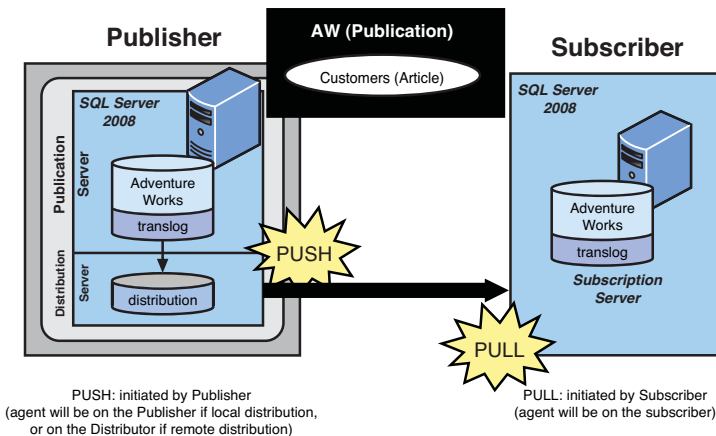

FIGURE 19.17 Push or pull subscriptions.

As you can also see in Figure 19.17, a push subscription is created and managed by the publication and distribution server. In effect, the distribution server and all the agents that do the work are pushing the publication to the subscription server. The advantage of using push subscriptions is that all the administration takes place in a central location (on the publication/distribution server side). In addition, publishing and subscribing happen at the same time, and many subscribers can be set up at once. This type of subscription is also recommended when dealing with heterogeneous subscribers because of the lack of pull capability on the subscription server side.

Anonymous Subscriptions (Pull Subscriptions)

It is possible to have “anonymous” subscriptions. An anonymous subscription is a special type of pull subscription that can be used in the following circumstances:

- ▶ When you are publishing data to the Internet
- ▶ When you have a huge number of subscribers
- ▶ When you don't want the overhead of maintaining extra information at the publisher or distributor
- ▶ When all the rules of your pull subscriptions apply to all your anonymous subscribers

Normally, information about all the subscribers, including performance data, is stored on the distribution server. Therefore, if you have a large number of subscribers or you do not want to track detailed information about the subscribers, you might want to allow anonymous subscriptions to a publication. Then little is kept at the distribution server, but it then becomes the responsibility of the subscriber to initiate the subscription and to keep synchronized.

The Distribution Database

The distribution database is a special type of database installed on the distribution server. This database, which is as a store-and-forward database, holds all transactions waiting to be distributed to any subscribers. This database receives transactions from any published databases that have designated it as their distributor. The transactions are held here until they are sent to the subscribers successfully. After a period of time, these transactions are purged from the distribution database. In some special situations, the transactions might not be purged for a longer period, enabling anonymous subscribers ample time to synchronize. The distribution database is the heart of the data replication facility. As you can see in Figure 19.18, the distribution database has several MS tables, such as MSarticles. These tables contain all the necessary information for the distribution server to fulfill the distribution role. Following are some of these tables:

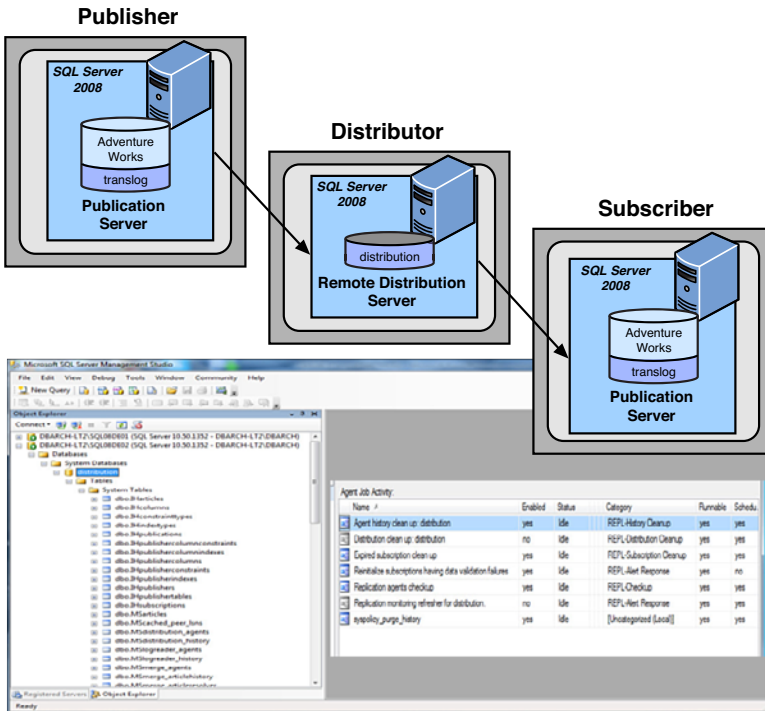

FIGURE 19.18 Tables of the distribution database and the distribution agents.

- ▶ All the different publishers who will use this distribution server—Stored in the MSpublisher_databases and MSPublication_access tables.
- ▶ The publications and articles that will be distributed—Stored in the MSPublications and MSArticles tables.
- ▶ The complete information for all the distribution agents to perform their tasks—Stored in the MSdistribution_agents table.
- ▶ The complete information of the executions of these agents—Stored in the MSdistribution_history table.

- ▶ **The subscribers**—Stored in `MSsubscriber_info`, `MSsubscriptions`, and other related tables.
- ▶ **Any errors that occur during replication and synchronization states**—Stored in `MSrepl_errors`, `MSsync_state`, and related tables.
- ▶ **The actual commands and transactions that are to be replicated**—Stored in the `MSrepl_commands` and `MSrepl_transactions` tables.
- ▶ **Heterogeneous (non-SQL Server) publishers' or subscribers' information**—Kept in the tables whose names begin with `IH`, such as `IHpublishers`, that will contain one row for each non-SQL Server publisher for which this distribution server distributes information.

Replication Agents

SQL Server utilizes replication agents to do different tasks during the replication process. These agents are constantly waking up at some frequency and fulfilling specific jobs. As you can see in Figure 19.19, several replication agent categories are listed under the Job Activity Monitor when you expand the SQL Server Agents branch (SQL Server Agent, Jobs, Job Activity Monitor branch).

Name	Enabled	Status	L	L	N	Category	R/r
Agent history clean up: distribution	yes	Idle	5	5	5	REPL-History Cleanup	yes
DBARCH-LT2\SQLO8DE01-AdventureWorks2008-4	yes	Execut.	L	n	n	REPL-LogReader	yes
DBARCH-LT2\SQLO8DE01-AdventureWorks2008-PUBLISH AdventureWork-DBARCH-LT2\SQLO8DE00-9	yes	Execut.	L	n	n	REPL-Distribution	yes
DBARCH-LT2\SQLO8DE01-AdventureWorks2008-PUBLISH AdventureWorks2008-3	yes	Idle	5	5	n	REPL-Snapshot	yes
Distribution clean up: distribution	yes	Idle	5	5	5	REPL-Distribution Cleanup	yes
Expired subscription clean up	yes	Idle	L	n	n	REPL-Subscription Cleanup	yes
Reinitialize subscriptions having data validation failures	yes	Idle	L	n	n	REPL-Alert Response	yes
Replication agents checkup	yes	Idle	5	5	5	REPL-Checkup	yes
Manual	no	Idle	L	n	n	REPL-Alert Response	yes
sysoption_purge_history	yes	Idle	5	5	5	[Uncategorized (Local)]	yes

FIGURE 19.19 Replication agent jobs. Replication job category entries are prefixed with **REPL-**.

Here are the main replication agent categories:

- ▶ Snapshot Agent
- ▶ Log Reader Agent
- ▶ Distribution Agent
- ▶ Merge Agent (for updating subscribers)
- ▶ History Cleanup Agent
- ▶ Distribution Cleanup Agent
- ▶ Expired Subscription Cleanup Agent

- ▶ Reinitialize Subscriptions Having Data Validation Failures Agent
- ▶ Replication Monitoring Refresher for Distribution Agent
- ▶ Replication Agent Cleanup Agent

The Snapshot Agent

The snapshot agent is responsible for preparing the schema and initial data files of published tables and stored procedures, storing the snapshot on the distribution server, and recording information about the synchronization status in the distribution database. Each publication has its own snapshot agent that runs on the distribution server. It takes on the name of the publication within the publishing database within the machine on which it executes (that is, `[Machine][Publishing database][Publication Name]`).

Figure 19.19 shows what this snapshot agent looks like under the SQL Server Agent, Job Activity Monitor branch in SQL Server Management Studio (SSMS). The snapshot agent (REPL-Snapshot category name) is named `DBARCH-LT2\SQL08DE01-AdventureWorks2008-PUBLISH AdventureWorks2008 - Tra-1`. In addition, these agents can be referenced from the Replication Monitor option (when you launch the Replication Monitor by right-clicking from the Replication branch in SQL Server Management Studio). Most often you are likely to use the SQL Server Agent path to these agents though.

It's worth noting that the snapshot agent might not even be used if the initialization of the subscriber's schema and data is done manually.

The Snapshot Agent Synchronization

The snapshot agent is the process that ensures both databases start on an even playing field. This process is known as *synchronization*. The synchronization process is performed whenever a publication has a new subscriber. Synchronization happens only one time for each new subscriber. It ensures that database schema and data are exact replicas on both servers. After the initial synchronization, all updates are made via replication.

When a new server subscribes to a publication, synchronization is performed. When synchronization begins, a copy of the table schema is copied to a file with the `.sch` extension. This file contains all the information necessary to create the table and any indexes on the tables, if they are requested. Next, a copy is made of the data in the table to be synchronized and written to a file (or several files) with the `.bcp` extension. The data file is a BCP, or bulk copy file. Both files are stored in the temporary working directory on the distribution server.

After the synchronization process has started and the data files have been created, any inserts, updates, and deletes are stored in the distribution database. These changes are not replicated to the subscription database until the synchronization process is complete.

When the synchronization process starts, only new subscribers are affected. Any subscriber that has been synchronized already and has been receiving modifications is unaffected. The synchronization set is applied to all servers waiting for initial synchronization. After the schema and data have been re-created, all transactions that have been stored in the distribution server are sent to the subscriber.

When you set up a subscription, it is possible to manually load the initial snapshot onto the server. This is known as *manual synchronization*. For extremely large databases, it is frequently easier to dump the database and then reload the database on the subscription server. If you load the snapshot this way, SQL Server assumes that the databases are already synchronized and automatically begins sending data modifications.

Snapshot Agent Processing

Figure 19.20 shows the details of the snapshot agent execution for a typical push subscription. You can see the execution history by simply right-clicking the snapshot job and choosing View History.

FIGURE 19.20 Snapshot agent execution job history.

The following sequence of tasks occurs with the snapshot agent:

1. The snapshot agent is initialized. This initialization can be immediate or at a designated time in the company's nightly processing window.
2. The agent connects to the publisher.
3. The agent generates schema files with the .sch file extension for each article in the publication. These schema files are written to a temporary working directory on the distribution server. These are the create table statements and such that will be used to create all objects needed on the subscription server side. They exist only for the duration of the snapshot processing.
4. All the tables in the publication are locked (held). The lock is required to ensure that no data modifications are made during the snapshot process.
5. The agent extracts a copy of the data in the publication and writes it to the temporary working directory on the distribution server. If all the subscribers are SQL Server machines, the data is written using a SQL Server native format, with the .bcp file extension. If you are replicating to databases other than SQL Server, the data is stored in standard text files with the .txt file extension. The .sch file and .txt

files/.bmp files are known as a *synchronization set*. Every table or article has a synchronization set.

CAUTION

It's important to make sure you have enough disk space on the drive that contains the temporary working directory. The snapshot data files will potentially be huge, and this size is the most common reason for snapshot failure.

- As you can see in Figure 19.21, the agent executes the object creations and bulk copy processing at the subscription server side in the order in which they were generated (or it skips the object creation part if the objects have already been created on the subscription server side and you have indicated this during setup). This process takes awhile, so it is best to do this in an off time so as not to impact the normal processing day. Network connectivity is critical here. Snapshots often fail at this point.

FIGURE 19.21 Snapshot agent delivering the snapshot to the subscriber (most recent operation on the top).

- The snapshot agent posts the fact that a snapshot has occurred and what articles/publications were part of the snapshot to the distribution database. This is the only information sent to the distribution database.
- When all the synchronization sets are finished being executed, the agent releases the locks on all the tables of this publication. The snapshot is now considered finished.

The Log Reader Agent

The log reader agent is responsible for moving transactions marked for replication from the transaction log of the published database to the distribution database. Each database published using transactional replication has its own log reader agent that runs on the distribution server. It is easy to find because it takes on the name of the publishing database whose transaction log it is reading (*[Machine name][Publishing DB name]*) and the REPL-LogReader category. Figure 19.19 shows the log reader agent (REPL-LogReader category name) for the AdventureWorks2008 database. It is named DBARCH-LT2\SQL08DE01-AdventureWorks2008-4.

After initial synchronization has taken place, the log reader agent begins to move transactions from the publication server to the distribution server. All actions that modify data in a database are logged to the transaction log in that database. This log is used not only in the automatic recovery process, but also in the replication process. When an article is created for publication and the subscription is activated, all entries about that article are marked in the transaction log. For each publication in a database, a log reader agent reads the transaction log and looks for any marked transactions. When the log reader agent finds a change in the log, it reads the changes and converts them to SQL statements that correspond to the action taken in the article. The SQL statements are then stored in a table on the distribution server, waiting to be distributed to subscribers.

Because replication is based on the transaction log, several changes are made in the way the transaction log works. During normal processing, any transaction that has either been successfully completed or rolled back is marked inactive. When you are performing replication, completed transactions are not marked inactive until the log reader process has read them and sent them to the distribution server.

Truncating and fast bulk-copying into a table are nonlogged processes. In tables marked for publication, you cannot perform nonlogged operations unless you temporarily turn off replication.

NOTE

One of the major changes in the transaction log comes when you have the Truncate Log on Checkpoint option turned on. When this option is on, SQL Server truncates the transaction log every time a checkpoint is performed, which can be as often as every several seconds. With replication, the inactive portion of the log is not truncated until the log reader process has read the transaction.

The Distribution Agent

A distribution agent moves transactions and snapshot jobs held in the distribution database out to the subscribers. This agent isn't created until a push subscription is defined for a subscriber. The distribution agent takes on the name of the publication database along with the subscriber information (*[Machine name][Publication DB name][Subscriber machine name]*). If you look back at Figure 19.19, you see a distribution agent (the *REPL-Distribution category* name) for the AdventureWorks2008 database to a subscriber. It is

named DBARCH-LT2\SQL08DE01--AdventureWorks2008 - PUBLISH AdventureWork - DBARCH-LT2\SQL08DE03-9, where SQL08DE01 is the publisher and SQL08DE03 is the subscriber.

Those not set up for immediate synchronization share a distribution agent that runs on the distribution server. Pull subscriptions, to either snapshot or transactional publications, have a distribution agent that runs on the subscriber. Merge publications do not have a distribution agent at all. Rather, they rely on the merge agent, discussed next.

In transactional replication, the transactions have been moved into the distribution database, and the distribution agent either pushes out the changes to the subscribers or pulls them from the distributor, depending on how the servers are set up. All actions that change data on the publishing server are applied to the subscribing servers in the same order they were incurred. Figure 19.22 shows the latest history of the distribution agent and the total duration of the current subscription (11:20:56:4830000 hours, minutes, seconds, milliseconds in this example).

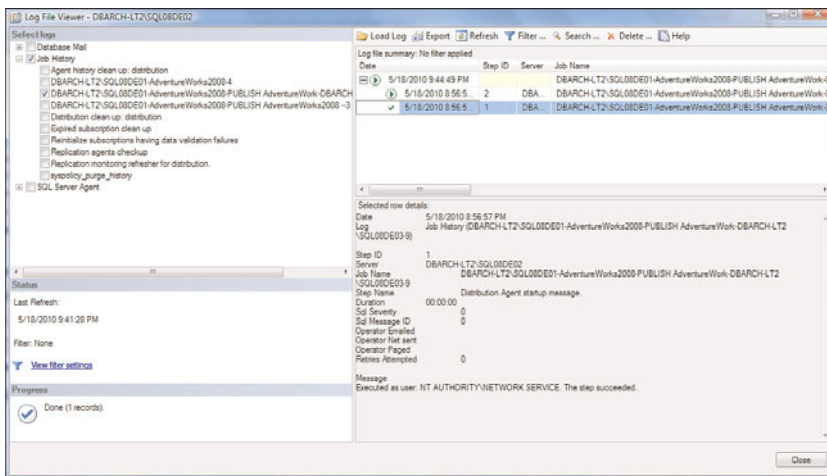

FIGURE 19.22 Distribution agent job history.

The Merge Agent

When you are dealing with merge publications, the merge agent moves and reconciles incremental data changes that occur after the initial snapshot was created. Each merge publication has a merge agent that connects to the publishing server and the subscribing server and updates both as changes are made. In a full merge scenario, the agent first uploads all changes from the subscriber where the generation is 0 or greater than the last

generation sent to the publisher. The agent gathers the rows in which changes were made, and the rows without conflicts are applied to the publishing database.

A conflict can arise when changes are made at both the publishing server and subscription server to a particular row(s) of data. A conflict resolver handles these conflicts. Conflict resolvers are associated with an article in the publication definition. These conflict resolvers are sets of rules or custom scripts that can handle any complex conflict situation that might occur. The agent then reverses the process by downloading any changes from the publisher to the subscriber. Push subscriptions have merge agents that run on the publication server, whereas pull subscriptions have merge agents that run on the subscription server. Snapshot and transactional publications do not use merge agents.

Other Specialized Agents

In Figure 19.19, you can see that several other agents have been set up to do house cleaning around the replication configuration:

- ▶ **Agent history clean up: Distribution**—This agent clears out agent history from the distribution database every 10 minutes (by default). Depending on the size of the distribution, you might want to vary the frequency of this agent.
- ▶ **Distribution clean up: Distribution**—This agent clears out replicated transactions from the distribution database every 72 hours by default. This agent is used for snapshot and transactional publications only. If the volume of transactions is high, the frequency of this agent should be adjusted downward so you don't have too large of a distribution database. However, the frequency of synchronization with subscribers drives this frequency adjustment.
- ▶ **Expired subscription clean up**—This agent detects and removes expired subscriptions from the published databases. As part of the subscription setup, an expiration date is set. This agent usually runs once per day by default. You don't need to change this frequency.
- ▶ **Reinitialize subscriptions having data validation failures**—This agent is manually invoked. It is not on a schedule, but it could be. It automatically detects the subscriptions that failed data validation and marks them for re-initialization. This can then potentially lead to a new snapshot being applied to a subscriber that had data validation failures.
- ▶ **Replication monitoring refresher for distribution**—Microsoft SQL Server Replication Monitor is designed to efficiently monitor a large number of computers. The queries that Replication Monitor uses to perform calculations and gather data are cached and refreshed on a periodic basis. Caching reduces the number of queries and calculations required as you view different pages in Replication Monitor and allows monitoring to scale well for multiple users. Cache refresh is handled by the Replication monitoring refresher for distribution agent. This job runs continuously,

but the cache refresh schedule is based on waiting a certain amount of time after the previous refresh:

If there were agent history changes since the cache was last created, the wait time is a minimum of 4 seconds or the amount of time taken to create the previous cache.

If there were no agent history changes since the cache was last created, the wait time is a maximum of 30 seconds or the amount of time taken to create the previous cache. You don't need to change this frequency.

- ▶ **Replication agents checkup**—This agent detects replication agents that are not actively logging history. This checkup is critical because debugging replication errors is often dependent on an agent's history that has been logged.

Planning for SQL Server Data Replication

You must consider many factors when choosing a method to distribute data. Your business requirements determine which is the right method for you. In general, you need to understand the timing and latency of your data, its independence at each site, and your specific need to filter or partition the data.

Autonomy, Timing, and Latency of Data

Distributed data implementations can be accomplished using a few different facilities in Microsoft: Integration Services (IS), Distributed Transaction Coordinator (DTC), and Data Replication. The trick is to match the right facility to the type of data distribution you need to get done.

In some applications, such as online transaction processing and inventory control systems, data must be synchronized at all times. This requirement, called *immediate transactional consistency*, was known as tight consistency in previous versions of SQL Server.

SQL Server implements immediate transactional consistency data distribution in the form of two-phase commit processing. A *two-phase commit*, sometimes known as *2PC*, ensures that transactions are committed on all servers, or the transaction is rolled back on all servers. This ensures that all data on all servers is 100% in sync at all times. One of the main drawbacks of immediate transactional consistency is that it requires a high-speed LAN to work. This type of solution might not be feasible for large environments with many servers because occasional network outages can occur. These types of implementations can be built with DTC and IS.

In other applications, such as decision support and report generation systems, 100% data synchronization all the time is not terribly important. This requirement, called *latent transactional consistency*, was known as loose consistency in previous versions of SQL Server.

Latent transactional consistency is implemented in SQL Server via data replication. Replication allows data to be updated on all servers, but the process is not a simultaneous one. The result is "real-enough-time" data. This is known as latent transactional consistency because a lag exists between the data updated on the main server and the replicated

data. In this scenario, if you could stop all data modifications from occurring on all servers, all the servers would eventually have the same data. Unlike the two-phase consistency model, replication works over both LANs and WANs, as well as slow or fast links.

When planning a distributed application, you must consider the effect of one site's operation on another. This is known as *site autonomy*. A site with complete autonomy can continue to function without being connected to any other site. A site with no autonomy cannot function without being connected to all other sites. For example, applications that utilize two-phase commits rely on all other sites being able to immediately accept changes sent to them. In the event that any one site is unavailable, no transactions on any server can be committed. In contrast, sites using merge replication can be completely disconnected from all other sites and continue to work effectively, not guaranteeing data consistency. Luckily, some solutions combine both high data consistency and site autonomy.

Methods of Data Distribution

After you have determined the amount of transactional latency and site autonomy needed, based on your business requirements, you need to select the data distribution method that corresponds. Each different type of data distribution has a different amount of site autonomy and latency. With these distributed data systems, you can choose from several methods:

- ▶ **Distributed transactions**—Distributed transactions ensure that all sites have the same data at all times. You pay a certain amount of overhead cost to maintain this consistency. (We do not discuss this nondata replication method here.)
- ▶ **Transactional replication with updating subscribers**—Users can change data at the local location, and those changes are applied to the source database at the same time. The changes are then eventually replicated to other sites. This type of data distribution combines replication and distributed transactions because data is changed at both the local site and source database.
- ▶ **Peer-to-peer replication**—A variation on the Transactional replication with updating subscribers theme is peer-to-peer replication, which is essentially full transactional replication between two (or more) sites, but is publisher-to-publisher (not update subscriber). There is no hierarchy—publisher (parent) and subscriber (child).
- ▶ **Transactional replication**—With transactional replication, data is changed only at the source location and is sent out to the subscribers. Because data is changed at only a single location, conflicts cannot occur.
- ▶ **Snapshot replication with updating subscribers**—This method is much like transactional replication with updating subscribers; users can change data at the local location, and those changes are applied to the source database at the same time. The entire changed publication is then replicated to all subscribers. This type of replication provides higher autonomy than transactional replication.

- ▶ **Snapshot replication**—A complete copy of the publication is sent out to all subscribers. This includes both changed and unchanged data.
- ▶ **Merge replication**—All sites make changes to local data independently and then update the publisher. It is possible for conflicts to occur, but they can be resolved.

SQL Server Replication Types

Microsoft has narrowed the field to three major types of data replication approaches within SQL Server: snapshot, transactional, and merge. Each replication type applies to only a single publication. However, it is possible to have multiple replication types per database.

Snapshot Replication

Snapshot replication makes an image of all the tables in a publication at a single moment in time and then moves that entire image to the subscribers. Little overhead on the server is incurred because snapshot replication does not track data modifications as the other forms of replication do. It is possible, however, for snapshot replication to require large amounts of network bandwidth, especially if the articles being replicated are large. Snapshot replication is the easiest form of replication to set up and is used primarily with smaller tables for which subscribers do not have to perform updates. An example of this might be a phone list that is to be replicated to many subscribers. This phone list is not considered to be critical data, and the frequency of it being refreshed is more than enough to satisfy all its users.

The primary agents used for snapshot replication are the snapshot agent and distribution agent.

- ▶ The snapshot agent creates files that contain the schema of the publication and the data. The files are temporarily stored in the snapshot folder of the distribution server, and then the distribution jobs are recorded in the distribution database.
- ▶ The distribution agent is responsible for moving the schema and data from the distributor to the subscribers.

A few other agents are also used; they deal with other needed tasks for replication, such as cleanup of files and history. In snapshot replication, after the snapshot has been delivered to all the subscribers, these agents delete the associated `.bcp` and `.sch` files from the distributor's working directory.

Transactional Replication

Transactional replication is the process of capturing transactions from the transaction log of the published database and applying them to the subscription databases. With SQL Server transactional replication, you can publish all or part of a table, views, or one or more stored procedures as an article. All data updates are then stored in the distribution database and sent and applied to any number of subscribing servers. Obtaining these updates from the publishing database's transaction log is extremely efficient. No direct reading of tables is required except during initial snapshot, and only the minimal amount

of traffic is generated over the network. This has made transactional replication the most often used method.

As data changes are made, they are propagated to the other sites at nearly real-time; you determine the frequency of this propagation. Because changes are usually made only at the publishing server, data conflicts are avoided for the most part. As an example, push subscribers usually receive updates from the publisher in a minute or less, depending on the speed and availability of the network. Subscribers also can be set up for pull subscriptions. This capability is useful for disconnected users who are not connected to the network at all times.

The primary agents used for transactional replication are the snapshot agent, log agent, and distribution agent:

- ▶ The snapshot agent creates files that contain the schema of the publication and the data. The files are stored in the snapshot folder of the distribution server, and the distribution jobs are recorded in the distribution database.
- ▶ The log reader agent monitors the transaction log of the database that it is set up to service. Each database published has its own log reader agent set up for replication, and it will copy the transactions from the transaction log of that published database into the distribution database.
- ▶ The distribution agent is responsible for moving the schema and data from the distributor to the subscribers for the initial synchronization and then moving all the subsequent transactions from the published database to each subscriber as they come in. These transactions are stored in the distribution database for a certain length of time and are eventually purged.

A few other agents deal with the other housekeeping issues surrounding data replication, such as schema files cleanup, history cleanup, and transaction cleanup.

Merge Replication

Merge replication involves getting the publisher and all subscribers initialized and then allowing data to be changed at all sites involved in the merge replication at the publisher and at all subscribers. All these changes to the data are subsequently merged at certain intervals so that, again, all copies of the database have identical data.

Occasionally, data conflicts have to be resolved. The publisher does not always win in a conflict resolution. Instead, the winner is determined by whatever criteria you establish.

The primary agents used for merge replication are the snapshot agent and merge agent:

- ▶ The snapshot agent creates files that contain the schema of the publication and the data. The files are stored in the snapshot folder of the distribution server, and the distribution jobs are recorded in the distribution database. This is essentially the same behavior as with all other types of replication methods.

- ▶ The merge agent takes the initial snapshot and applies it to all the subscribers. It then reconciles all changes made on all the servers, based on the rules you configure.

Preparing for Merge Replication

When you set up a table for merge replication, SQL Server performs three schema changes to the database. First, it must either identify or create a unique column for each row that will be replicated. This column is used to identify the different rows across all the different copies of the table. If the table already contains a column with the `ROWGUIDCOL` property, SQL Server automatically uses that column for the row identifier. If not, SQL Server adds a column called `rowguid` to the table. SQL Server also places an index on this `rowguid` column.

Next, SQL Server adds triggers to the table to track changes that occur to the data in the table and record them in the merge system tables. The triggers can track changes at either the row or column level, depending on how you set it up. SQL Server supports multiple triggers of the same type on a table, so merge triggers do not interfere with user-defined triggers on the table.

Finally, SQL Server adds new system tables to the database that contains the replicated tables. The `MSMerge_contents` and `MSMerge_tombstone` tables track the updates, inserts, and deletes. These tables rely on `rowguid` to track which rows have actually been changed.

The merge agent is responsible for moving changed data from the site where it was changed to all other sites in the replication scenario. When a row is updated, the triggers added by SQL Server fire off and update the new system tables, setting the generation column equal to 0 for the corresponding `rowguid`. When the merge agent runs, it collects the data from the rows where the generation column is 0 and then resets the generation values to values higher than the previous generation numbers. This allows the merge agent to look for data that has already been shared with other sites without having to look through all the data. The merge agent then sends the changed data to the other sites.

When the data reaches the other sites, the data is merged with existing data according to rules you have defined. These rules are flexible and highly extensible. The merge agent evaluates existing and new data and resolves conflicts based on priorities or which data was changed first. Another available option is that you can create custom resolution strategies using the Component Object Model (COM) and custom stored procedures. After conflicts have been handled, synchronization occurs to ensure that all sites have the same data.

The merge agent identifies conflicts using the `MSMerge_contents` table. In this table, a column called `lineage` is used to track the history of changes to a row. The agent updates the `lineage` value whenever a user makes changes to the data in a row. The entry into this column is a combination of a site identifier and the last version of the row created at the site. As the merge agent is merging all the changes that have occurred, it examines each site's information to see whether a conflict has occurred. If a conflict has occurred, the agent initiates conflict resolution based on the criteria mentioned earlier.

Basing the Replication Design on User Requirements

As mentioned earlier, business requirements drive your replication configuration and method. In addition, nailing down all the details of the business requirements is the hardest part of a data replication design process. After you have completed the requirements gathering, the replication design usually just falls into place from it easily. The requirements gathering is highly recommended to get a prototype up and running as quickly as possible to measure the effectiveness of one approach over the other. You must understand several key aspects to make the right design decisions, including the following:

- ▶ What is the number of sites, and what is the site autonomy in the scope (location)?
- ▶ Which sites have the master data (data ownership)?
- ▶ What is the data latency requirement (by site)?
- ▶ What types of data accesses are being made (by site)?
 - ▶ Reads
 - ▶ Writes
 - ▶ Updates
 - ▶ Deletes

This information needs to include exactly what data and data subsets that drive filtering are needed for the data accesses (by site).

- ▶ What is the volume of activity/transactions, including the number of users (by site)?
- ▶ How many machines do you have to work with (by site)?
- ▶ What are the available processing power (CPU and memory) and disk space on each of these machines (by site)?
- ▶ What are the stability, speed, and saturation level of the network connections between machines (by site)?
- ▶ What is the dial-in, Internet, or other access mechanism requirement for the data?
- ▶ What potential subscriber or publisher database engines are involved?

Figure 19.23 shows the factors that contribute to replication designs and the possible data replication configuration that would best be used. It is only a partial table because of the numerous factors and many replication configuration options available. However, it gives a good idea of the general design approach described here. Perhaps 95% of user requirements can be classified fairly easily. The other 5% might take some imagination in determining the best overall solution. Depending on the requirements that need to be

supported, you might even end up with a solution using something like database mirroring or other distribution techniques.

Data Access	Latency	Autonomy	Sites (locations)	Frequency	Network	Machines	Owner	Other	REPLICATION
Read Only Reporting	short	high	many	high	fast/stable	1 server/site	1 OLTP site	Each site only needs regional data	Central Publisher Transactional repl filter by region
Read Only Reporting	long	high	many	low	fast/stable	1 server/site	1 OLTP site	Each site only needs regional data	Central Publisher Snapshot repl filter by region
Read Mostly A few updates	short	high	<10	medium	fast/stable	1 server/site	1 OLTP site	Regional updates on one table	Central Publisher Transactional repl Updating Subs
Read Mostly A few updates	medium	high	<10	medium	slow/unreliab	1 server/site	All update	Regional update all tables	Central Publisher Merge repl
Read equal Equal updates	short	high	<10	medium	fast/stable	n server/site	All update	Regional update all tables	Peer-to-Peer Transactional repl
Inserts (new orders)	short	high	many	high	fast/stable	1 server/site	n update sites	Each site only needs regional data	Central Subscriber Transactional repl
Hot/Warm Spare	Very short	high	<2	high	fast/stable	1 server/site	1 OLTP site	Fail-over	Central Publisher Remote Distributor Transactional repl

FIGURE 19.23 Replication design factors.

Data Characteristics

You need to analyze the underlying data types and characteristics thoroughly. Issues such as collation or character set and data sorting come into play. You must be aware of what they are set to on all nodes of your replication configuration. SQL Server 2008 does not convert the replicated data and might even mistranslate the data as it is replicated because it is impossible to map all characters between character sets. It is best to look up the character set “mapping chart” for SQL Server replication to all other data target environments. Most are covered well, but problems arise with certain data types, such as `image`, `timestamp`, and `identity`. Sometimes, using the Unicode data types at all sites is best for consistency. Following is a general list of issues to watch out for in this regard:

- ▶ Collation consistency across all nodes of replication.
- ▶ Time stamp column data in replication. It might not be what you think.
- ▶ `identity`, `uniqueidentifier`, and `guid` column behavior with data replication.
- ▶ text or `image` data types to heterogeneous subscribers.
- ▶ Missing or unsupported data types because of prior versions of SQL Server or heterogeneous subscribers as part of the replication configuration.

- ▶ Maximum row size limitations between merge replication and transactional replication.

Figure 19.24 lists further SQL Server 2008 replication object limitations.

Microsoft SQL Server 2008 Replication object	Maximum sizes/numbers (32-bit)	Maximum sizes/numbers (64-bit)
Articles (merge publication)	256	256
Articles (snapshot or transactional publication)	32,767	32,767
Columns in a table (merge publication)	246	246
Columns in a table (SQL Server snapshot or transactional publication)	1000	1000
Columns in a table (Oracle snapshot or transactional publication)	995	995
Bytes for a column used in a row filter (merge publication)	1024	1024
Bytes for a column used in a row filter (snapshot or transactional publication)	8000	8000

FIGURE 19.24 SQL Server 2008 replication object limitations.

NOTE

If you have triggers on your tables and you want them to be replicated along with your table, you might want to add the line of code `NOT FOR REPLICATION` so that the trigger code isn't executed redundantly on the subscriber side.

Setting Up Replication

In general, SQL Server 2008 data replication is exceptionally easy to set up via SQL Server Management Studio wizards. However, if you use the wizards, you need to be sure to generate SQL scripts for every phase of replication configuration. In a production environment, you are likely to rely heavily on scripts and not have the luxury of having much time to set up and break down production replication configurations via wizards. Generating SQL scripts also eases the setup/breakdown process in development, test, and user acceptance environments.

You always have to define any data replication configuration in the following order:

1. Create or enable a distributor to enable publishing.
2. Enable publishing. (A distributor must be designated for a publisher.)
3. Create a publication and define articles within the publication.
4. Define subscribers and subscribe to a publication.

Figure 19.25 shows SQL Server Management Studio Object Explorer with three separate server connections. These three servers represent a possible replication topology.

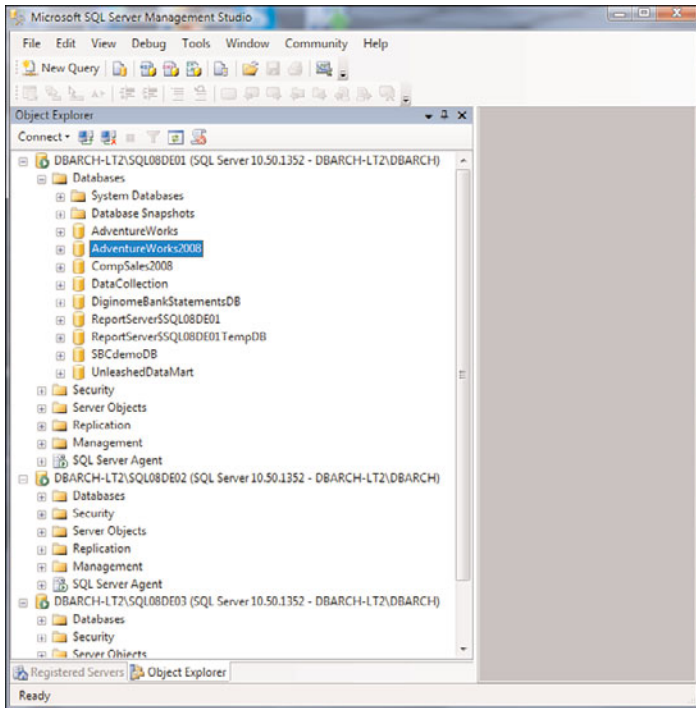

FIGURE 19.25 Three servers to be used in the replication topology (central publisher, remote distributor, and subscriber).

The following section takes you through the process of building up a typical central publisher/remote distribution data replication configuration. The following SQL Server named instances are used for different purposes (as shown in Figure 19.25):

- ▶ **Publisher**—A SQL08DE01 named instance
- ▶ **Distributor**—A SQL08DE02 named instance (REMOTE distributor)
- ▶ **Subscriber**—A SQL08DE03 named instance

The following section highlights the different areas in SQL Server Management Studio that are needed to create this replication configuration.

Creating a Distributor and Enabling Publishing

Before setting up a publisher, you have to designate a distribution server to be used by that publisher. As discussed earlier, you can either configure the local server as the distribution server or choose a remote server as the distributor (not on the same machine as the

publication server). You can configure the server as a distributor and publisher at the same time, or you can configure the server as a dedicated distributor on the remote server separately. In the sample topology described here, you start by creating a remote distributor separately so you can orient yourself to what is happening on each server in the topology as it is being built up. You are also able to enable a specific SQL Server instance as the publisher that will use this distributor (all in one wizard sequence). This method is very efficient.

Before you can configure replication, you must be a member of the `sysadmin` server role, so you should ensure that now. Then you use the following steps to configure a server as a distributor (remote distributor):

1. In SQL Server Management Studio, locate the `Replication` node under the server that will be the distributor (under the `SQL08DE02` named instance node). Right-click the `Replication` node and choose `Configure Distribution`. This starts you through the wizard, which provides three options:
 - ▶ Configure this server to be a distributor.
 - ▶ Configure this server to be both a publisher and distributor.
 - ▶ Configure this server to be a publisher that uses another server as its distributor.
2. When the wizard starts, click past the initial `Configure Distribution Wizard` splash page. Then choose the first radio button, which should say `'DBARCH-LT2\SQL08DE02' Will Act as Its Own Distributor` (as shown in Figure 19.26). This designates this server as a distributor for one or more publishers. The distribution database and log are created here as well (and not on the publication server).

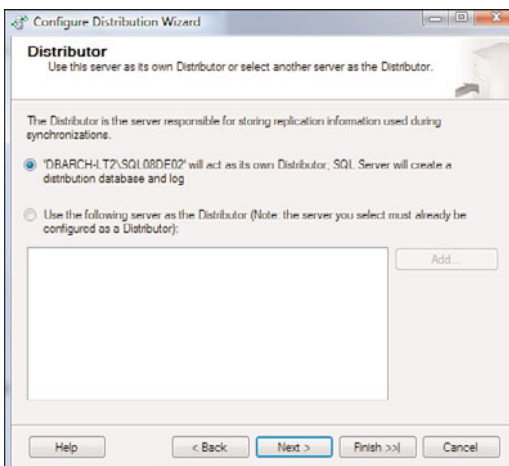

FIGURE 19.26 Configuring a separate distributor (REMOTE) wizard.

3. You are then asked how you want the replication agents to be started. Select the agents to be started automatically (the Yes option).
4. Next comes the location for the snapshot folder. Give it the proper network full pathname. Remember that potentially a large amount of data will be coming here, and it should be on a drive that can support the snapshot concept without filling up the drive.
5. When you are asked to configure the distribution database, select the default settings. Figure 19.27 shows all the distribution database name and location information.

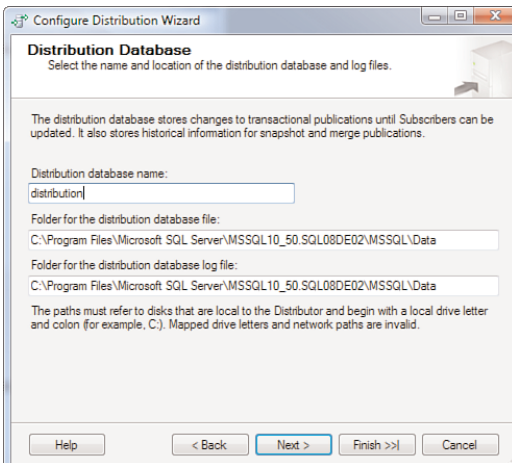

FIGURE 19.27 Specification of the distribution database name and location.

6. Identify the publisher if you know which SQL Server instance will be publishing the data that this distributor will distribute for. To do this, click the Add button at the bottom-left corner of the Publishers page to enable servers to use this distributor when they become publishers. You are prompted for the server name and authentication method for the distributor to reach this publisher. Specify DBARCH-LT2\SQL08DE01 as a publisher that will use this distributor. The end result, as shown in Figure 19.28, is DBARCH-LT2\SQL08DE01 designated (checked) as a publisher that will use this distribution database (distributor). Remember to uncheck the SQL Server named instance of the distribution server if you don't want to publish from that server (the SQL08DE02 named instance).
7. Specify a distributor password. This is the password that will be used by publishers to connect to the distributor. You will be able to administer this password through SQL Server Management Studio directly. The wizard then summarizes what actions you want to take place, such as configure the distribution server or generate a script file with steps to configure distribution. Choose both. It's always good to have the scripts created now so you can start script-based configurations immediately. A

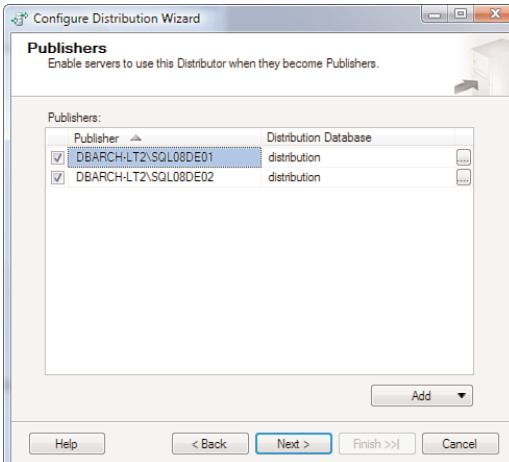

FIGURE 19.28 Designate the publisher that will use this remote distributor.

Complete the Wizard page is displayed, describing all the tasks that are about to happen, along with their configuration specifications. Figure 19.29 shows this summary.

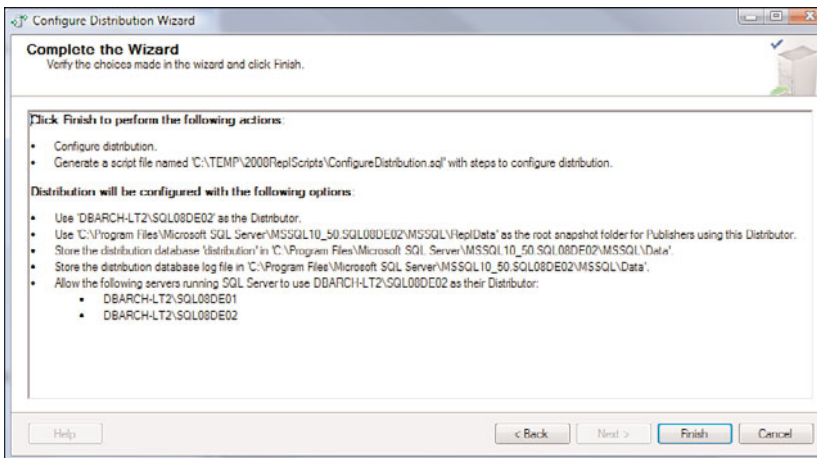

FIGURE 19.29 Completing the configuration of the distributor and enabling the publisher.

When you click Finish, several things begin to occur. First, a configuring dialog page comes up and spins its wheels through each step you have requested (as shown in Figure 19.30). A summary of steps, errors, and warnings is displayed on this page. When it completes, you can explore any issues (errors or warnings) by drilling down in the Report

option (lower-right side of this dialog). Make sure you see Success after each step of this configuration.

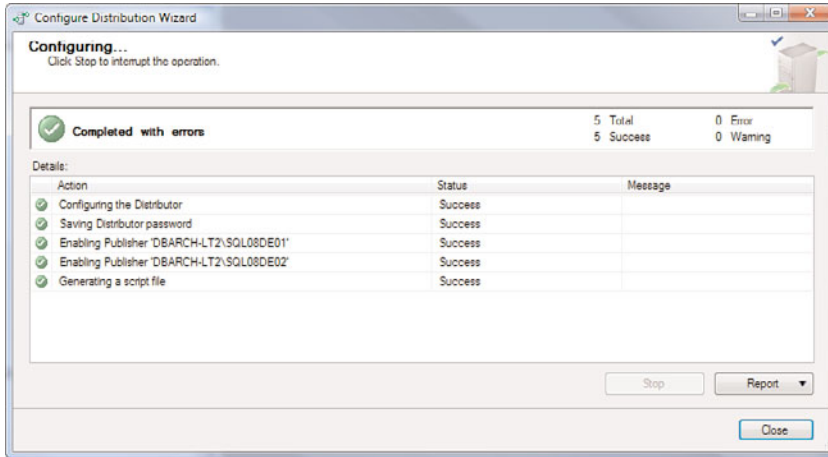

FIGURE 19.30 Configuring the distributor and enabling a publisher in progress.

Now is probably a good time to locate that distributor setup and enabling publication script and drop it into your replication administrator folder that you keep in a safe place. Figure 19.31 shows what this script looks like. Notice that the password is not displayed. The details of these scripts are described later in this chapter, in the “Scripting Replication” section.

When the distributor is configured and the distribution database is created, a series of replication agents (managed by SQL Server Agent) are created, with various duties, as described earlier in this chapter. Figure 19.32 shows the initial set of agents created on the distribution server (as seen from the Job Activity Monitor under the SQL Server Agent). No agents exist yet that actually publish data or distribute data. Those agents are created later, as you start publishing and subscribing.

Creating a Publication

When the distribution database has been created and publishing has been enabled on the server, you can create and configure a publication. In SQL Server Management Studio, you start by locating the **Replication** node under the publication server from which you want to publish data (the `DBARCH-LT2\SQL08DE01` named instance in this example). Figure 19.33 shows the program item option when you right-click the **Replication** node under what will be the publication server. As you can see, there are three options; one to create a new publication, one to create a new Oracle publication, and one to create a new subscription.

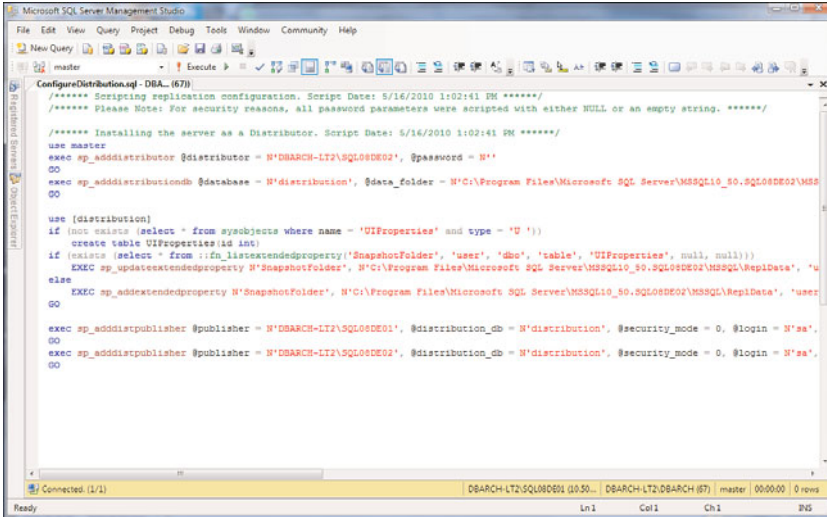

FIGURE 19.31 The script generated for creating the distributor and enabling a publisher.

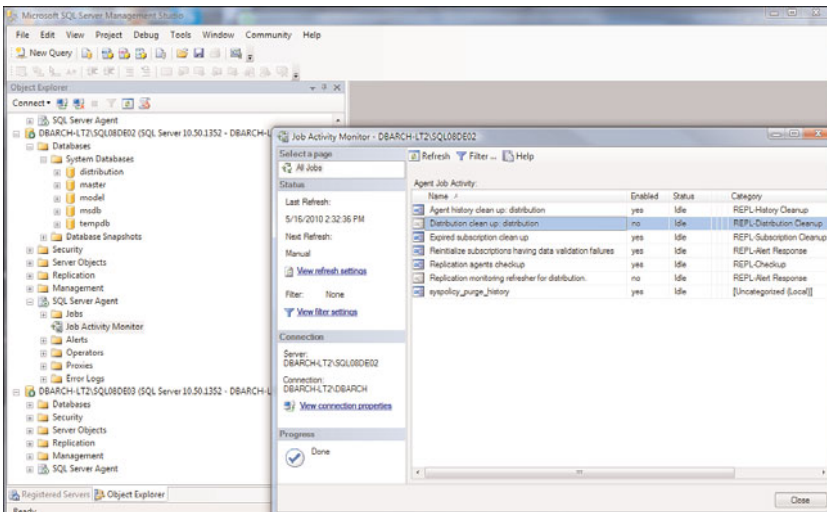

FIGURE 19.32 Initial replication agents on the distributor.

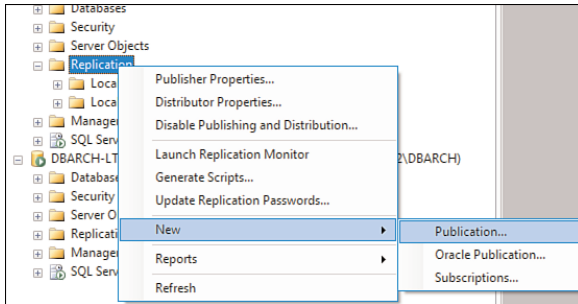

FIGURE 19.33 The New Publication item option on the server that will be the publisher.

You should choose to create a new publication (the first option). When you do, the New Publication Wizard is launched.

Here's how you create a new publication:

1. The first New Publication Wizard page outlines the two things that can be done with this wizard. The options are "Select the data and database objects you want to replicate" and "Filter the published data so that subscribers receive only the data they need." After this splash page, you need to specify how you want to distribute the data for this new publication. As you can see in Figure 19.34, you should use a remote distributor (the DBARCH-LT2\SQL08DE02 named instance) to distribute data for this new publication you are defining.
2. When you are asked to provide a password that will be used to establish the administrative link to the distributor, supply it. It should be the same one you specified earlier when setting up the distribution server.
3. Identify the database on which you are going to set up a publication (see Figure 19.35). For this example, choose to create a publication on the AdventureWorks2008 database.
4. Choose the type of replication method for this publication: Snapshot Publication, Transactional Publication, Transactional Publication with Updateable Subscriptions, or Merge Publication Method of Replication. For this example, select Transactional Publication.

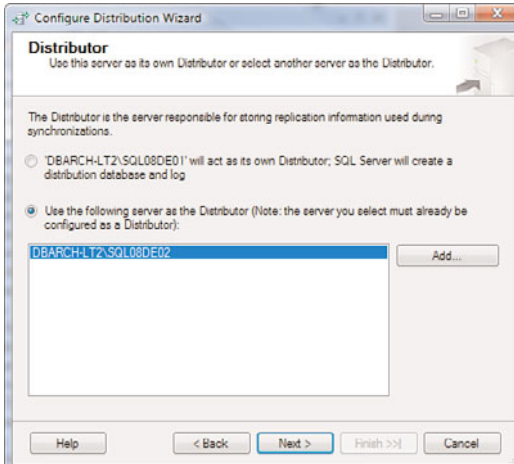

FIGURE 19.34 Specifying the remote distribution server for the new publication.

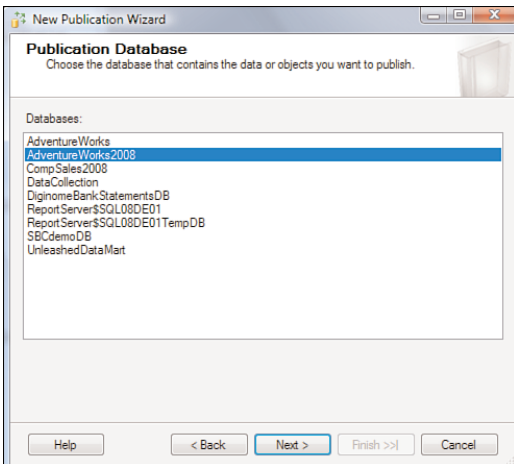

FIGURE 19.35 Choosing the database that contains the data or objects you want to publish.

5. Next, you are presented with the place where you specify what tables and other objects to publish. These will become your articles. You can specify filtering of any selected articles, where appropriate. To keep this simple, just choose the primary stored procedures, views, indexed views, user-defined functions, and tables of the AdventureWorks2008 database for this publication. (You do not select any filtering at this time.) Figure 19.36 shows the Articles specification page. Also in Figure 19.36, you can view the article properties that dictate how all article objects should be handled by replication (via the Article Properties button in the upper-right corner of this wizard screen). An example of this is specifying the delete delivery format behavior for this publication (for all tables) to be Do Not Replication Delete Statements or Use Stored Procedures to Do the Deletes and not individual delete statements.

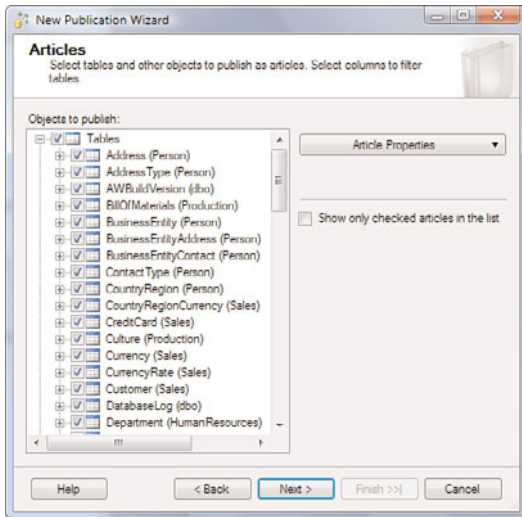

FIGURE 19.36 Choosing the tables and other objects that determine the articles to publish.

The next wizard screen carefully analyzes what you are asking to become articles and highlights any dependencies that must be considered as part of replication. A good example of an article issue is that indexed views require the tables to which they are bound to be part of the replication.

6. When the Snapshot Agent wizard configuration screen prompts you to either create a snapshot immediately or at some scheduled time and to keep the snapshot available to initialize subscriptions, select to create a snapshot immediately and keep it available to initialize the subscription. As part of this snapshot agent creation, you have to specify under what security credentials you want the agent security to run. In addition, you can specify if you want the log reader agent to use the same security settings as the snapshot agent. The rule of thumb here is to keep it simple and let these agents use the same security settings (as shown in Figure 19.37).
7. The wizard now has enough information to create the publication. When the wizard actions are summarized for you, choose to create the publication and generate a script file with all the steps to create the publication in it. Again, this script generation part is highly recommended. You certainly don't want to have to go through this wizard over and over. Once is enough.
8. When the summary of all choices made in the creation of a new publication is listed in the Complete the Wizard screen, name the publication appropriately. Your publication names should contain the type of publication method being used (for example, Snapshot, Transactional, Merge) and any other identifying qualifier that seems appropriate (usually reflecting the scope of the publication). Figure 19.38 shows this summary of actions and the publication name PUBLISH AdventureWorks2008 - Transactional.

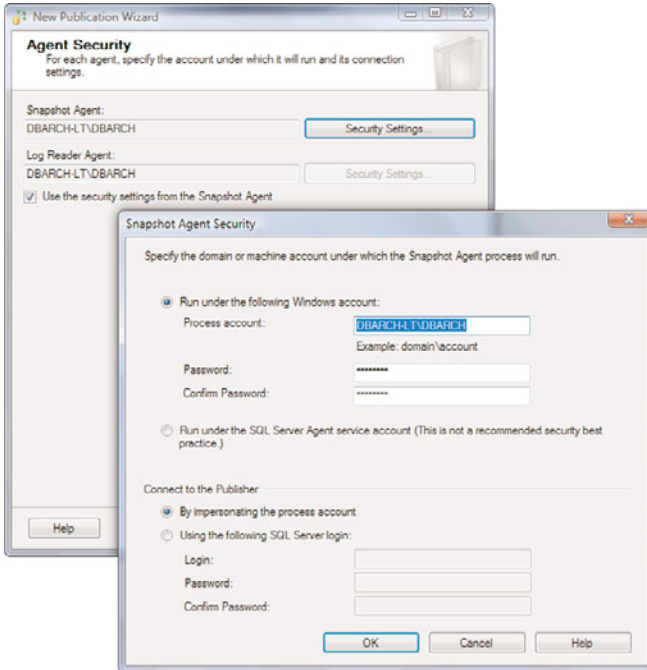

FIGURE 19.37 Agent security for snapshot agent and log reader agent.

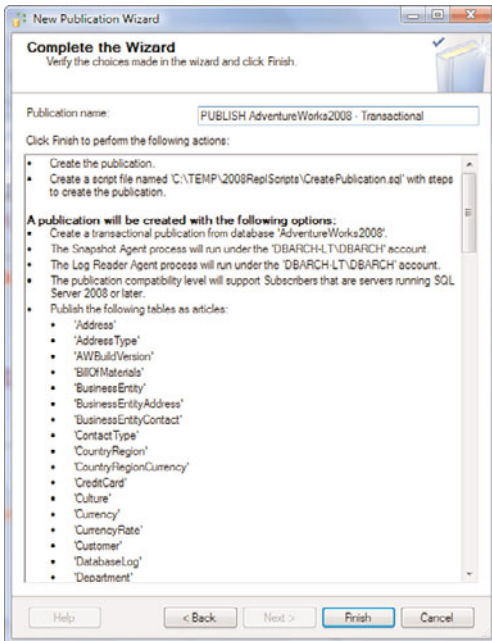

FIGURE 19.38 Publication action summary and naming the publication before it is created.

The actual creation of the publication is next. An action progress screen appears, showing each step (action) and indicating any errors or warnings occurring in the publication creation process. To view any errors or warnings, you simply click the Report button in the lower-right side after the processing completes. As you can see in Figure 19.39, this report lists, by name, all articles created and that the snapshot agent is starting. This is where all the initial action takes place.

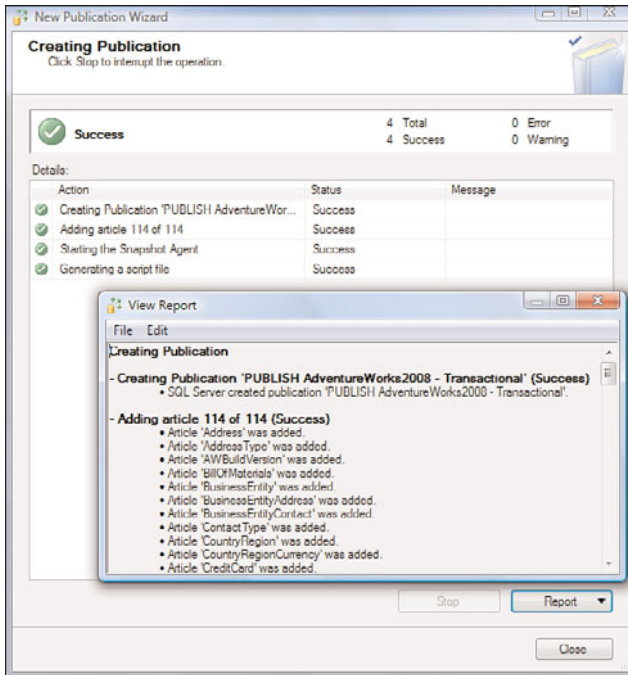

FIGURE 19.39 The publication steps and status, along with the report generated during this process.

As part of this process, several new agents (jobs) are added; they implement this publication using the designated distributor. There are no subscribers yet; they come later. Figure 19.40 shows the new jobs (agents) and publication entries. You are now ready to create subscriptions against this publication.

As you can see in Figure 19.41, if you launch Replication Monitor (from the Replication node under the publication server), you can see the newly created publication and its status, and you have access to any servers subscribing to it (none yet), along with the common replication jobs that are servicing this publication.

Because you chose to execute the snapshot immediately, the snapshot executes and utilizes the snapshot folder to generate the schema files (.sch files), data snapshot files

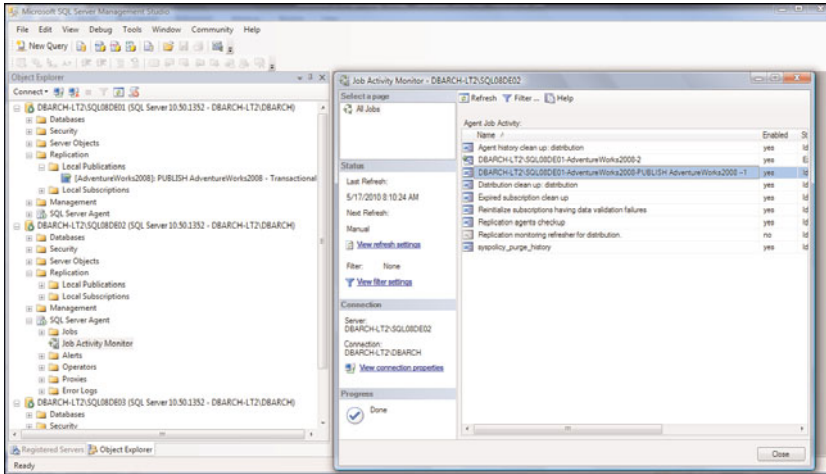

FIGURE 19.40 SQL Server Management Studio and the new publication agents (snapshot agent, distribution agent, and so on) and the new local publication.

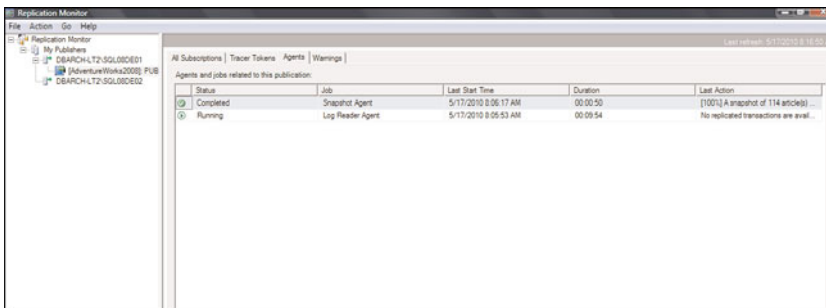

FIGURE 19.41 Replication Monitor, viewing the status of the newly created publication (from the publisher).

(.bcp), and so on to fully enable a subscription when one is created. Figure 19.42 shows the contents of the snapshot folder being used for the publication of the AdventureWorks2008 publication. Remember that this folder must be located in a place that is big enough to contain all the data that will be extracted and used for the snapshot; plan ahead.

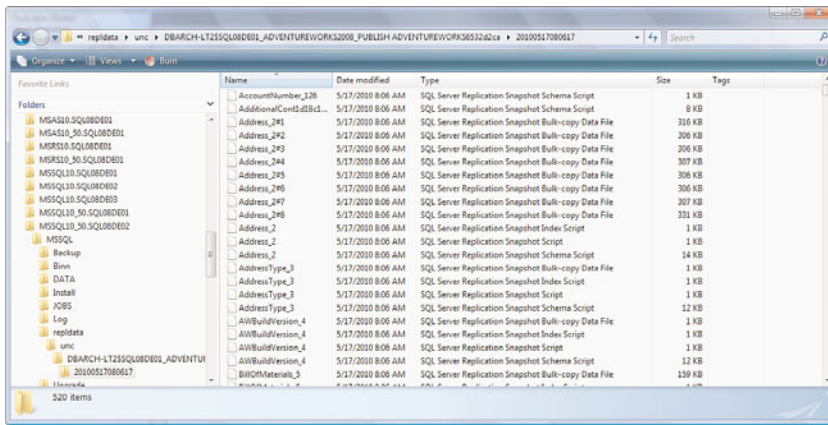

FIGURE 19.42 Contents of the snapshot folder produced for the publication.

Horizontal and Vertical Filtering

During the publication creation process, you could have done some filtering of the data, either horizontally or vertically (or both at the same time). The concept of filtering was covered earlier in this chapter. Figure 19.43 illustrates all you need to do to vertically filter (in terms of limiting what gets published to a subset of columns of a table). As you can see, you uncheck the AccountNumber column for the Customer table so that it isn't included in the article for that object in this publication. This might be done because account number information needs to be more tightly controlled within your company and shouldn't be part of what is viewed by any subscribing systems.

In addition, you can specify horizontal filters by using the Filter Rows option on a publication (publication properties). This allows you to specify horizontal filtering on any table you publish. Figure 19.44 shows a typical row filter on the Customer table that results in publishing North East Territory customers only (that is, those with TerritoryID values of 1 or 2).

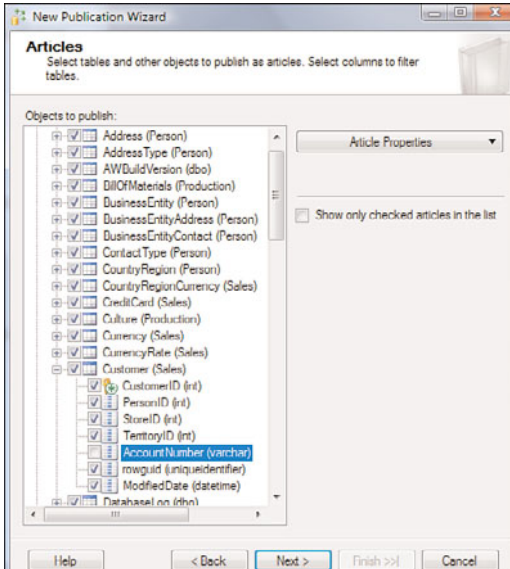

FIGURE 19.43 Specifying a vertical filter on the Customer table (limiting the columns to be published).

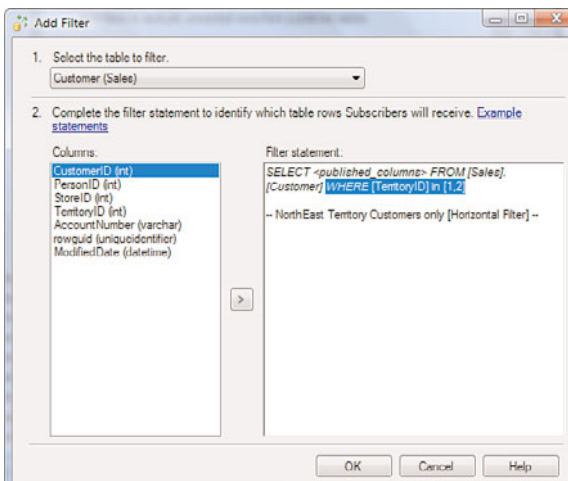

FIGURE 19.44 Specifying a horizontal filter on the **Customer** table (limiting the rows to be published).

Join filtering allows you to limit the rows you will publish, via join criteria, to another table. Figure 19.45 shows a complex join that filters `SalesOrderHeader` rows that correspond to North East Territory customers only (that is, those with `TerritoryID` values of 1 or 2).

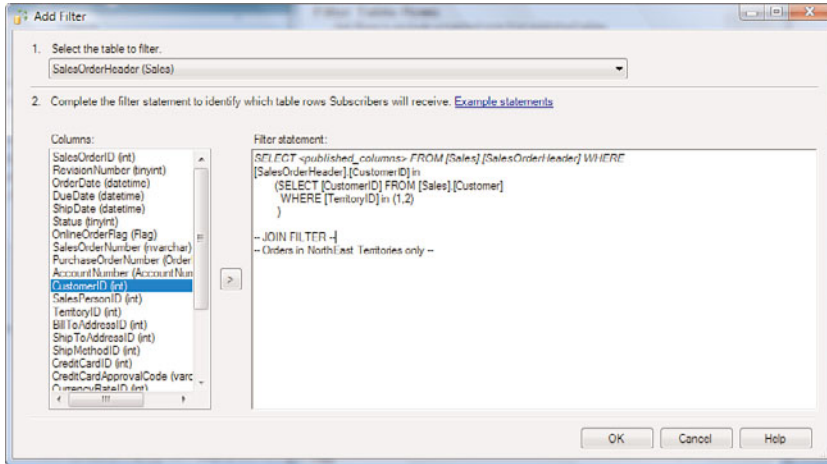

FIGURE 19.45 Specifying a join filter on the `SalesOrderHeader` table (limiting the sales rows that will be published by joining for the North East customers only).

Creating Subscriptions

Now that you have installed and configured the distributor, enabled publishing, and created a publication, you can create subscriptions.

Remember that two types of subscriptions can be created: push or pull. Pull subscriptions allow remote sites to subscribe to any publication that they are allowed to, but for this to work, you must be confident that the administrators at the other sites have properly configured the subscriptions at their sites. Push subscriptions are easier to create because all the subscription processes are performed and administered from the publication/distributor point of view. This also makes using them the most common approach.

For this example, we use the New Subscription Wizard to create a *push* subscription:

1. In SQL Server Management Studio, locate the Replication node under the publication server (the `DBARCH-LT2\SQL08DE01` named instance in this example) or the Replication node under the subscription server (the `DBARCH-LT2\SQL08DE03` named instance in this example). You can create a push subscription from either (but we use the subscription server here). Open the Replication node, navigate to the Local Subscription branch, right-click, and choose the New Subscriptions option. As you can see in Figure 19.46, choosing this option launches the New Subscription Wizard, where you can create one or more subscriptions to a publication and specify where and when to run the agents that synchronize the subscription.

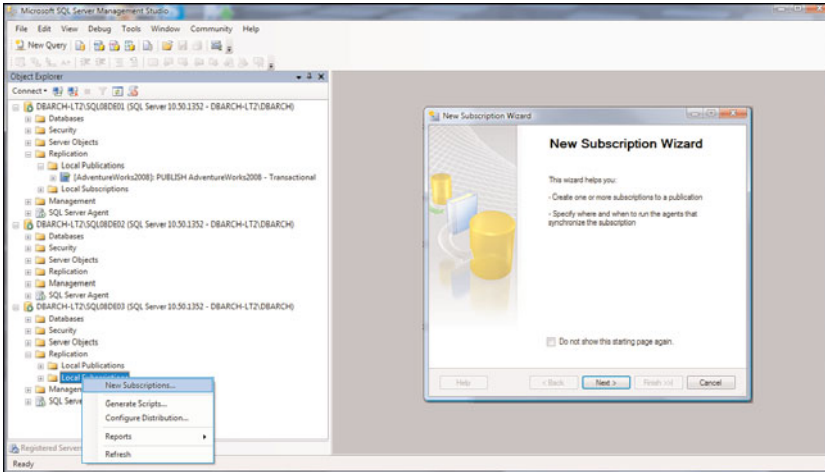

FIGURE 19.46 Launching the New Subscription Wizard from SQL Server Management Studio.

2. You first need to identify the publisher and publication from which you want to create one or more subscriptions. As you can see in Figure 19.47, we have specified the publisher (DBARCH-LT2\SQL08DE01) and the publication that has been created for the AdventureWorks2008 database.

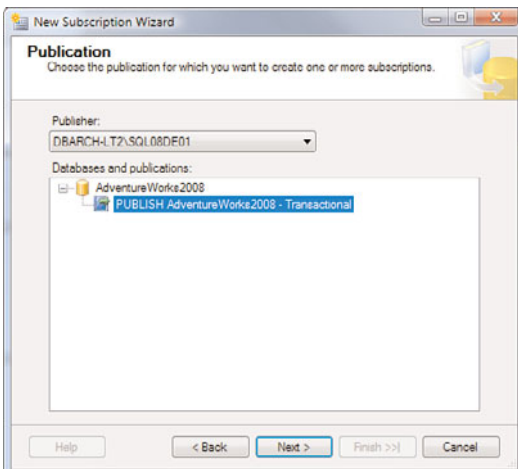

FIGURE 19.47 Identifying the publication from which to subscribe.

- When you are presented with the option of where the replication agents will be run for the subscription, choose the first option—having the agents run at the distributor. This makes it a push subscription, which is much easier to control and manage centrally than a pull subscription (as shown in Figure 19.48).

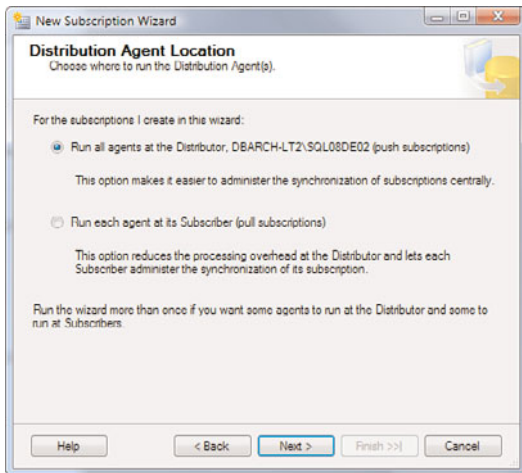

FIGURE 19.48 Run all agents at the Distributor (push subscriptions).

- Next, the New Database dialog appears, asking you to identify the database target for the subscription and the physical database files for its allocation (assuming that you want to create this from scratch using this wizard process). Figure 19.49 shows this New Database dialog, with the target database named `AdventureWorks2008ODS`. Essentially, we have decided to create a subscription that will continuously flow data from the publisher to the subscriber for all tables in the publication. This continuous replication at the transactional level effectively creates a mirror image of the data for operational usage. That's why we have used the suffix ODS, for Operational Data Store, for the new database. This is a typical industry usage of replication that takes all read-only access to OLTP data and offloads it to the ODS copy of the same data (which is as close to up-to-date as the last transaction that was replicated to it).
- In the Subscribers screen, with the new entry for the target subscriber server (the `DBARCH-LT2\SQL08DE03` named instance in this example), check the box for the target subscription server. Figure 19.50 shows this subscriber server and the subscription database target.
- Specify the process account and connection options for the distribution agent (to connect to the subscription server). Typically, you choose the option to use a domain account or choose to impersonate the process account (shown in Figure 19.51).
- Specify the synchronization schedule for each agent. You want the distribution agent to run continuously, but you also have the options to run on a schedule and on demand (as shown in Figure 19.51).

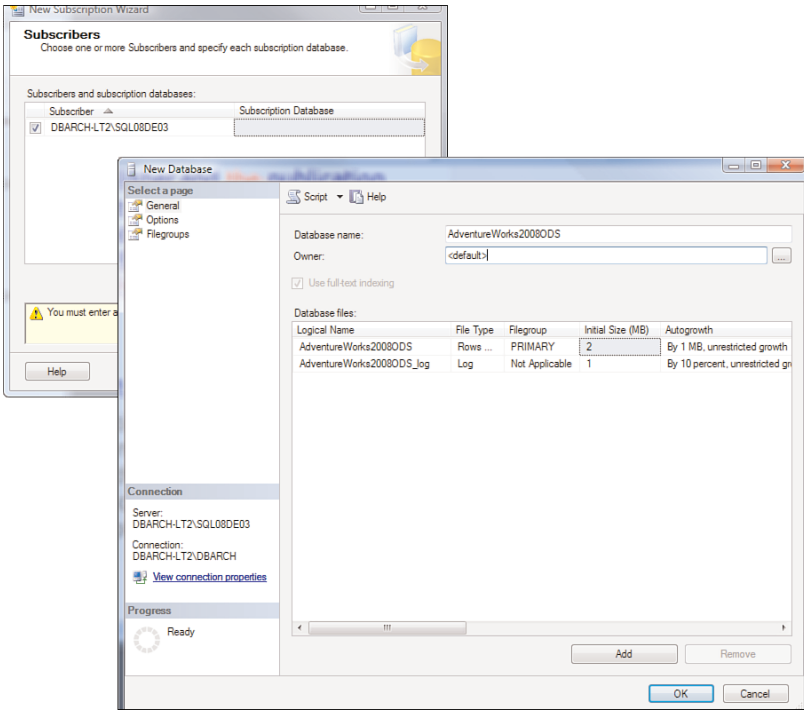

FIGURE 19.49 The New Database dialog specifying the target database (AdventureWorks2008ODS).

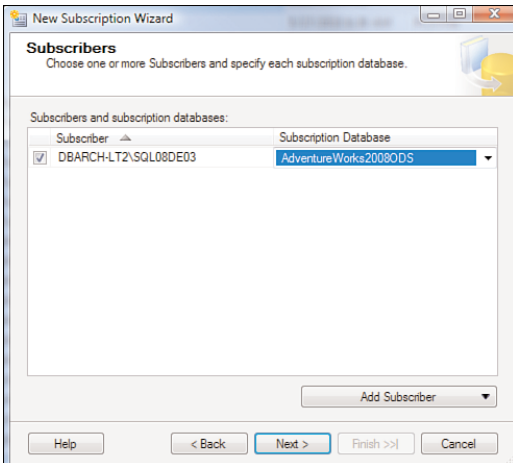

FIGURE 19.50 Specifying the subscription server target database.

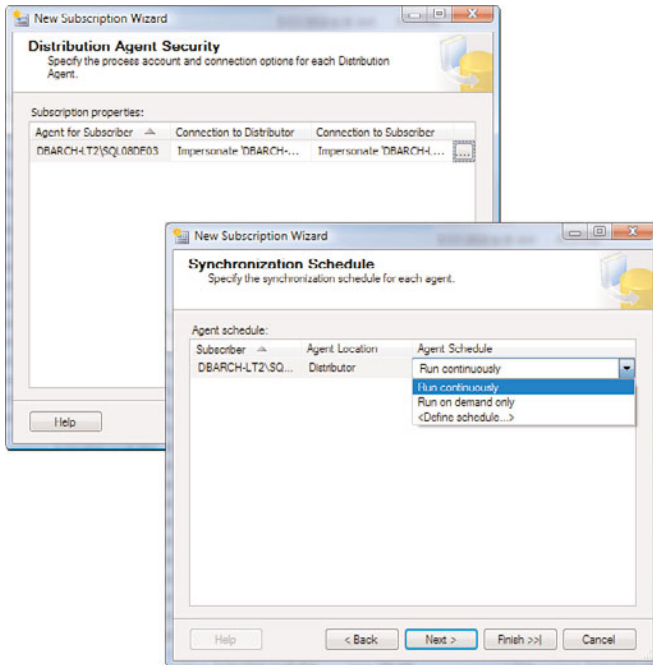

FIGURE 19.51 Distribution Agent Security and Synchronization Schedule for the subscription (Run Continuously).

8. Specify the initialization of the subscription. You want the subscription to be initialized immediately, but, depending on the size of the database, this might be accomplished manually with a database backup of the publication database.
9. On the next screen, which lists the New Subscription Wizard actions, choose to create the subscription and generate a script file with all the steps to create the subscription for use later.
10. On the next wizard dialog, identify the location of the script to be generated. As shown in Figure 19.52, you are presented with the final wizard summary screen. Click Finish to create your subscription, initialize the subscription database, and enjoy a full transactional replication implementation.

After you click Finish, the create subscription process starts and goes through each step. Remember to check for errors or warnings if any errors occur. When this process completes, you wait for the agents to initialize the target database and start replication to the subscriber. If you have specified that the schema and data be created immediately, things start happening quickly. The distribution agent finishes the job. As you can see in Figure 19.53, the distribution agent applies the schemas to the subscriber (as viewed from the Replication Monitor's Distributor to Subscriber History tab). The bulk copying of the data into the tables on the subscriber side follows accordingly. After this bulk copying is done, the initialization step is completed, and active replication begins.

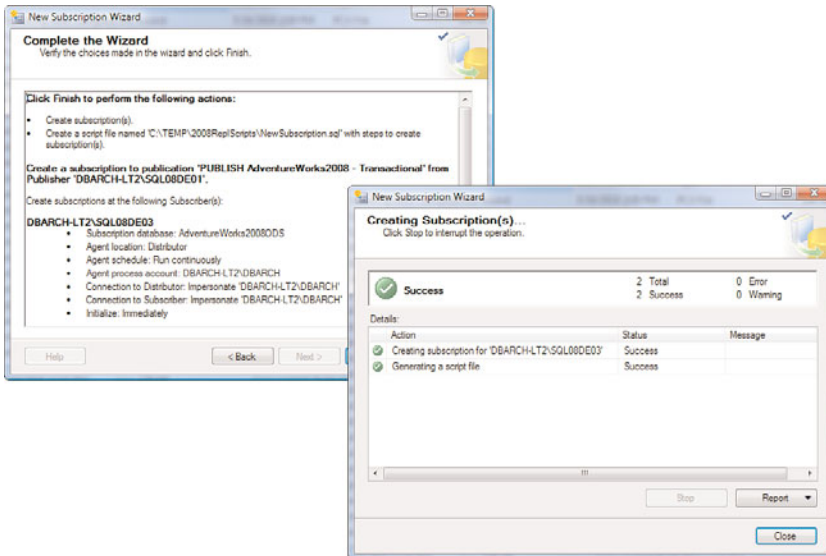

FIGURE 19.52 The New Subscription Wizard summary.

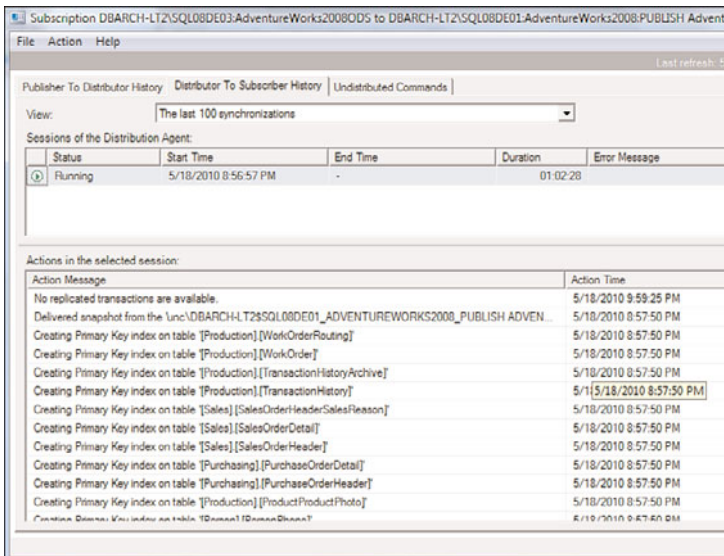

FIGURE 19.53 Delivering schemas and data to the subscriber.

The complete replication buildup is finished, and you should be fully functional for replicating transactions to the subscriber.

Figure 19.54 shows what the replication buildup looks like from the Replication Monitor as transactions flow through the replication topology. This screenshot shows the transaction counts and commands being delivered on the last leg in the journey (from the distributor to a subscriber). Figure 19.55 shows the full replication topology that was built (Publisher, Distributor and Subscriber).

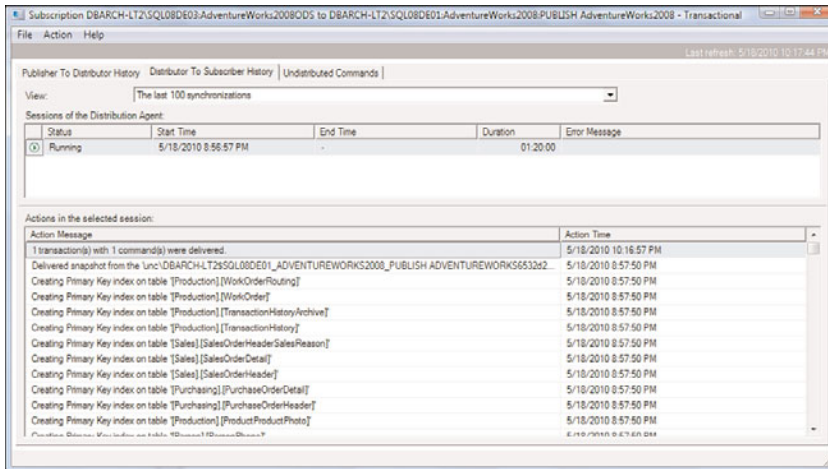

FIGURE 19.54 Transactions replicating to the subscriber (pushed).

Your replication topology is now completely functional and will replicate flawlessly for as long as you require.

Scripting Replication

Earlier, it was strongly suggested that you generate SQL scripts for all that you do because going through wizards every time you have to configure replication is a difficult way to run a production environment. In the example in the preceding section, you always chose to generate these scripts as you built up the replication configuration. This was only half the scripts needed, however. You must also generate the breakdown scripts (that is, those that drop and remove replication components) to remove each component of the replication topology in case you need to start from scratch or, as an example, rebuild a subscriber that is completely nonfunctional. As you can see in Figure 19.56, SQL Server Management Studio has a great feature that allows the complete generation of all aspects of replication topology (including disabling and removing replication).

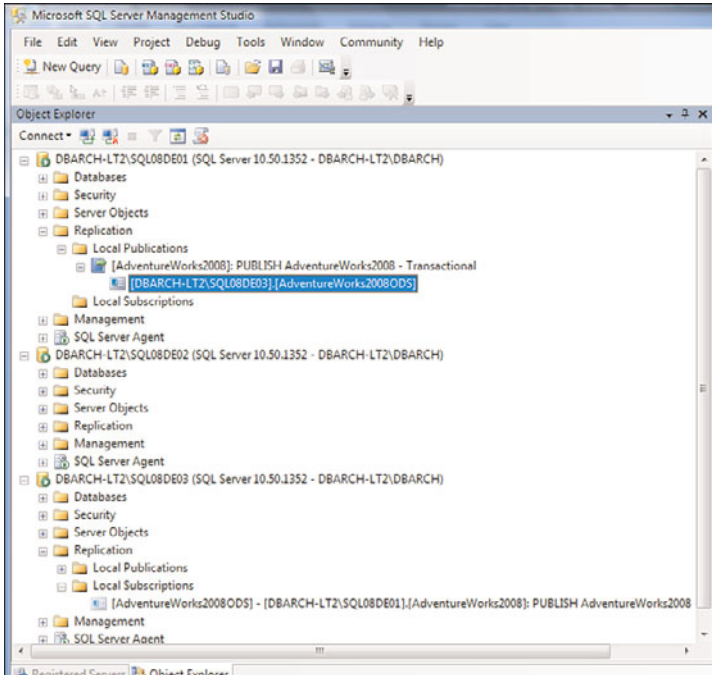

FIGURE 19.55 Full replication topology that was built (Publisher, Distributor, Subscriber).

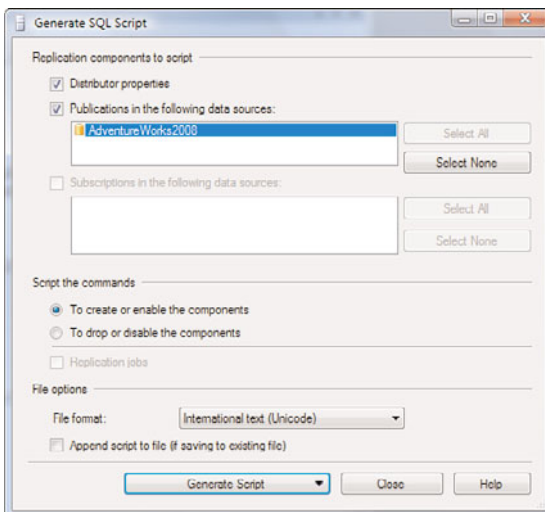

FIGURE 19.56 A script-generation feature for all replication topology components.

NOTE

Remember that working from scripts minimizes the errors you make while supporting your data replication environments (especially at 3:00 a.m.).

The following example shows the SQL scripts needed to generate the part of the data replication configuration you just built with the wizard:

```

-----
-- From distribution Server --
-----
/***** Scripting replication configuration. Script Date: 6/30/2009 10:49:03 AM
*****/
/***** Please Note: For security reasons, all password parameters were scripted
with either NULL or an empty string. *****/

/***** Begin: Script to be run at Distributor *****/

/***** Installing the server as a Distributor. Script Date: 6/30/2009 10:49:03 AM
*****/
use master
exec sp_adddistributor @distributor = N'DBARCH-LT2\SQL08DE02', @password = N''
GO

-- Adding the agent profiles
-- Updating the agent profile defaults
exec sp_MSupdate_agenttype_default @profile_id = 1
GO
exec sp_MSupdate_agenttype_default @profile_id = 2
GO
exec sp_MSupdate_agenttype_default @profile_id = 4
GO
exec sp_MSupdate_agenttype_default @profile_id = 6
GO
exec sp_MSupdate_agenttype_default @profile_id = 11
GO

-- Adding the distribution databases
use master
exec sp_adddistributiondb @database = N'distribution', @data_folder = N'C:\
Program Files\Microsoft SQL Server\MSSQL10.SQL08DE02\MSSQL\Data', @data_file =
N'distribution.MDF', @data_file_size = 6, @log_folder = N'C:\Program Files\
Microsoft SQL Server\MSSQL10.SQL08DE02\MSSQL\Data', @log_file =
N'distribution.LDF', @log_file_size = 3, @min_distretention = 0,
@max_distretention = 72, @history_retention = 48, @security_mode = 1
GO

-- Adding the distribution publishers
exec sp_adddistpublisher @publisher = N'DBARCH-LT2\SQL08DE01', @distribution_db =
N'distribution', @security_mode = 1, @working_directory = N'C:\Program
Files\Microsoft SQL Server\MSSQL10.SQL08DE02\MSSQL\Rep1Data', @trusted = N'false',

```

```
@thirdparty_flag = 0, @publisher_type = N'MSSQLSERVER'
GO
```

```
/****** End: Script to be run at Distributor *****/
use master
GO
```

The complete set of buildup and breakdown scripts for the example used here are available on this book's CD. They are labeled `CreatingXXX.sql` for the buildup scripts and `RemoveXXX.sql` for the breakdown scripts.

Monitoring Replication

After replication is up and running, it is important for you to monitor it and see how things are running. You can do this in several ways, including using SQL statements, SQL Server Management Studio, and Windows Performance Monitor. You are interested in the agent's successes and failures, the speed at which replication is done, and the synchronization state of tables involved in replication. Other issues to watch for are the sizes of the distribution database, growth of the subscriber databases, and available space on the distribution server's snapshot working directory.

Replication Monitoring SQL Statements

One way to look at the replication configuration and validate row counts, for example, is to use various replication stored procedures, including the following:

- ▶ **sp_helppublication**—Information on the publication server
- ▶ **sp_helparticle**—Article definition information
- ▶ **sp_helpdistributor**—Distributor information
- ▶ **sp_helpsubscriberinfo**—Subscriber server information
- ▶ **sp_helpsubscription**—Subscription information

These stored procedures are all extremely useful for verifying exactly how the replication configuration is really configured. If you execute these stored procedures (from the publication database), you get a great documentation of your complete replication topology that can be included in run books or other system documentation. Here's what you might do to see how the current replication configuration has been built out:

```
use AdventureWorks2008
go
exec sp_helppublication
exec sp_helparticle @publication='PUBLISH AdventureWorks2008 - Transactional'
exec sp_helpdistributor
exec sp_helpsubscriberinfo
exec sp_helpsubscription
go
```

It yields this result:

```

1 PUBLISH AdventureWorks2008 - Transactional      0      1      1      0
-----
1 Address          [Person].[Address]          Address
2 AddressType     [Person].[AddressType]     AddressType
3 AWBuildVersion  [dbo].[AWBuildVersion]     AWBuildVersion
4 BillOfMaterials [Production].[BillOfMaterials] BillOfMaterials
5 Contact         [Person].[Contact]         Contact
6 ContactCreditCard [Sales].[ContactCreditCard] ContactCreditCard
7 ContactType     [Person].[ContactType]     ContactType
...

```

In addition, `sp_replcounters` shows the activity of this replication session. You can see the volume of traffic and the throughput here:

```

exec sp_replcounters
go

```

It yields this result:

```

database repl_trans rate trans/sec latency (sec) etc.
AdventureWorks2008  0      1562.5    1.243

```

For actual row count validation, you can use `sp_publication_validation`, which goes through and checks the row counts of the publication and subscribers:

```

exec sp_publication_validation @publication
    = 'PUBLISH AdventureWorks2008 - Transactional'
go

```

It yields this result:

```

Generated expected rowcount value of 19614 for Address.
Generated expected rowcount value of 6 for AddressType.
Generated expected rowcount value of 1 for AWBuildVersion.
Generated expected rowcount value of 2679 for BillOfMaterials.
Generated expected rowcount value of 19972 for Contact.
Generated expected rowcount value of 19118 for ContactCreditCard.
Generated expected rowcount value of 20 for ContactType.
Generated expected rowcount value of 238 for CountryRegion.
Generated expected rowcount value of 109 for CountryRegionCurrency.
Generated expected rowcount value of 19118 for CreditCard.
Generated expected rowcount value of 8 for Culture.

```

Another way to monitor replication is to look at the actual data being replicated. To do this, you first run the `SELECT count (*) FROM tblname` statement against the table where data is being replicated. Then you verify directly whether the most current data available is in the database. If you make a change to the data in the published table, do the changes show up in the replicated tables? If not, you might need to investigate how replication was configured on the server.

If you are allowing updatable subscriptions, the replication queue comes into play. You need to learn all about the `queueread` command prompt utility. This utility configures and begins the queue reader agent, which reads messages stored in the SQL Server queue or a Microsoft message queue and applies those messages to the publisher.

To help you visualize how replication works, and to help you monitor replication, the following sample stored procedure, called `REPL_ROWS_GENERATOR`, takes one parameter (the number of rows [new customers in the Customer table] you want to have inserted at a time) and generates new rows in the Customer table that can reflect different data activity that will be published (this stored procedure has been included on the CDROM for this book. Pull it off the CDROM and create it quickly within the AdventureWorks2008 Database.):

```
Use AdventureWorks2008
Go
-----
-- generate 500 new customers for replication testing --
-----
exec REPL_ROWS_GENERATOR 500
go
```

This example shows how to execute this stored procedure to insert 500 new customers. If you don't supply any parameter, the default is 100 new customers. Try it out.

The following messages appear after you execute the `REPL_ROWS_GENERATOR` stored procedure:

```
INSERTING ROW: 1
INSERTING ROW: 2
INSERTING ROW: 3
INSERTING ROW: 4
INSERTING ROW: 5
INSERTING ROW: 6
INSERTING ROW: 7
INSERTING ROW: 8
INSERTING ROW: 9
INSERTING ROW: 10
...
INSERTING ROW: 500
```

Figure 19.57 shows this stored procedure, which is included on the CD for this book.

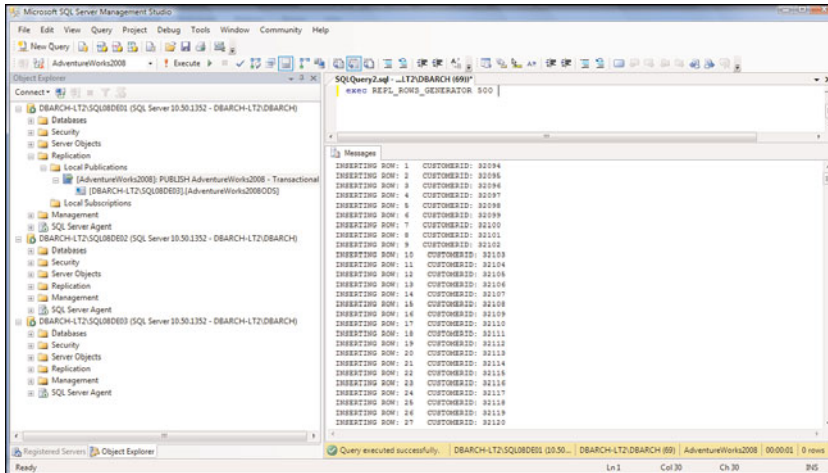

FIGURE 19.57 The executing **REPL_ROWS_GENERATOR** stored procedure for testing data replication.

Monitoring Replication within SQL Server Management Studio

As you can imagine, SQL Server Management Studio provides considerable information about the status of replication. Most of this information is available via Replication Monitor. In Replication Monitor, you can see the activity for publishers, distributors, and subscribers; you can see all agent details; and you can configure alerts.

Through Replication Monitor, you also can invoke validation subscriptions processing to see if replication is in sync. You just navigate to the publication whose subscription you want to validate, right-click, and choose Validate Subscription option. This allows you to verify that the subscriber has the same number of rows of replicated data as the publisher. You can validate all subscriptions or just a particular one. Validation options are extensive and include using fast row count methods, actual row count methods, and even checksum comparisons of row data. This is a huge feature for SQL Server 2008.

Figure 19.58 shows the results of running a complete subscription validation.

Another great feature to help monitor replication is tracer tokens. Essentially, you create a marker (called a token) that flows through the full replication topology (from publisher to distributor to subscriber). It does not affect data tables! This flow is monitored and measured, down to the millisecond, and is for a specific publisher-to-subscriber path.

Figure 19.59 shows the Tracer Tokens tab of the Replication Monitor and the Insert Tracer

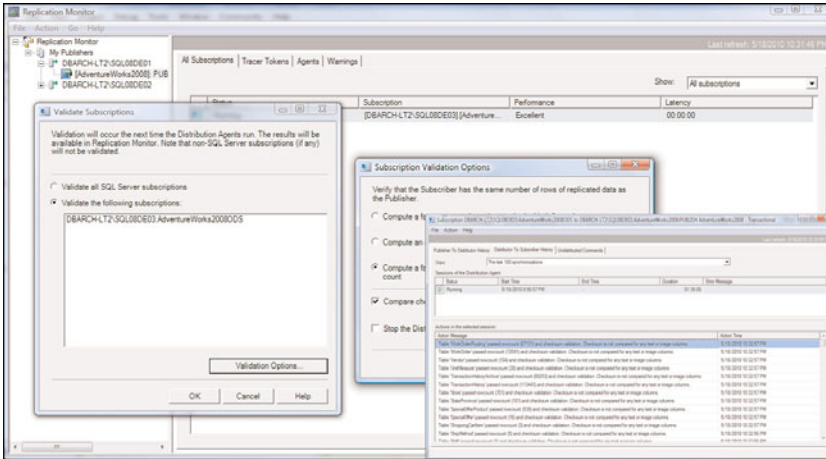

FIGURE 19.58 Validation of subscriptions via Replication Monitor.

button that you can click to fire off the token through the topology. You can click this button to quickly see where bottlenecks exist (for example, from publisher to distributor, from distributor to subscriber) and the latency of the data flow along the way. In this example, it took the tracer token 2 seconds in total to traverse from the publisher to the distributor and to the subscriber.

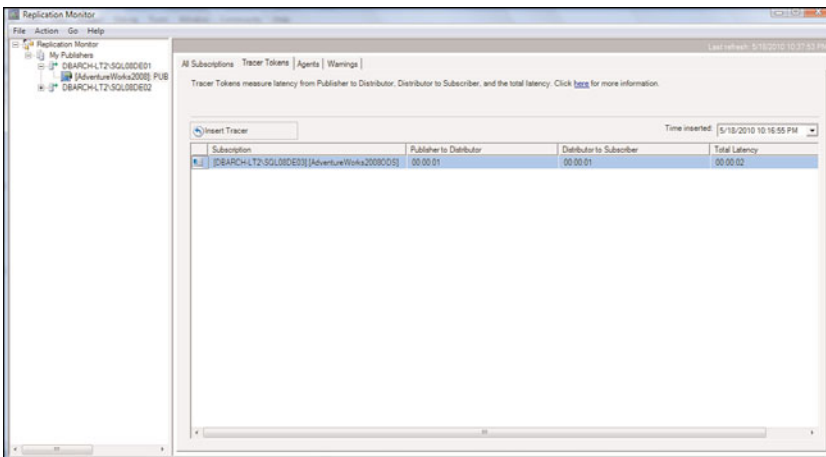

FIGURE 19.59 Tracer tokens for monitoring data replication throughput.

Troubleshooting Replication Failures

Configuring replication and monitoring for successful replication is relatively easy. The fun begins when failures start arising. Replication Monitor pays for itself quickly. Red flags begin appearing to indicate agent failures. Depending on how you have the alerts defined, you probably also get numerous emails or pages.

The following are the most common issues you find with data replication:

- ▶ Data row count inconsistencies, as discussed in the preceding section
- ▶ Subscriber/publisher schema change failures
- ▶ Connection failures
- ▶ Agent failures

For the conventional replication situations, if the problem is with the validation of subscriptions processing, it is usually best to resynchronize the subscription by dropping it and resubscribing or by reinitializing the subscription.

Another common issue is that the SQL Server Agent service doesn't start. Manually attempting to restart this service usually shakes things loose. Sometimes an object on the subscriber becomes messed up. The solution is usually to create that object again and reload its data via BCP or IS. Then you can resynchronize the subscription. In such a case, the subscription included this object originally, but it has become invalid in some way. With a heterogeneous subscriber, you often see connection errors due to invalid login IDs used in the ODBC connection. The quick fix is usually to just redefine the ODBC data source connection information.

A much more complex failure can arise when the replication queue is stopped due to some type of SQL language failure in the command being replicated. This situation is extremely serious because it stops all replication from continuing, and the distribution database starts growing rapidly. Replication keeps trying to execute, but it fails each time. This situation is essentially a permanent roadblock. The solution is to locate the exact transaction in the distribution database and delete it physically from the transaction queue. This action is highly unusual, but it is necessary when the circumstance presents itself. First, by looking at the error detail information in the distribution agent history, you can isolate the SQL statement on which it is choking. Then you have to find it in the distribution database. You start by executing the `sp_browsereplcmds` stored procedure from the distribution database. This gives you all the replication transactions (that is, each `xact_seqno`) along with the associated SQL command. You have to pump this to a text file for searching. You then search this data for the matching SQL command. When you locate it, you look for its associated transaction number (`xact_seqno`). You use this `xact_seqno` value to delete it from the `Msrep1_commands` table in the distribution database. This frees up the roadblock. You see this type of issue only about once every six months, if at all (it is hoped).

New and Improved Peer-to-Peer Replication

For data distribution requirements that must have updates in multiple nodes, peer-to-peer replication is ideal. You must worry about conflicts, but typically they are rare and very easily handled by a simple conflict handler. Peer-to-peer replication is transactional replication based, and can have any number of peers. A separate wizard is used to set up peer-to-peer replication because of its unique characteristics. Remember, there are essentially no subscribers, just publishers. All peers are handled by one or more distributors and are assigned a unique peer originator ID value to help in transactional consistency and conflict resolution. If you have been doing replication since the SQL Server 6.5 days, the peer-to-peer configuration topology viewer is much like that old user interface. Figure 19.60 shows the special invocation of peer-to-peer creation from SQL Server Management Studio.

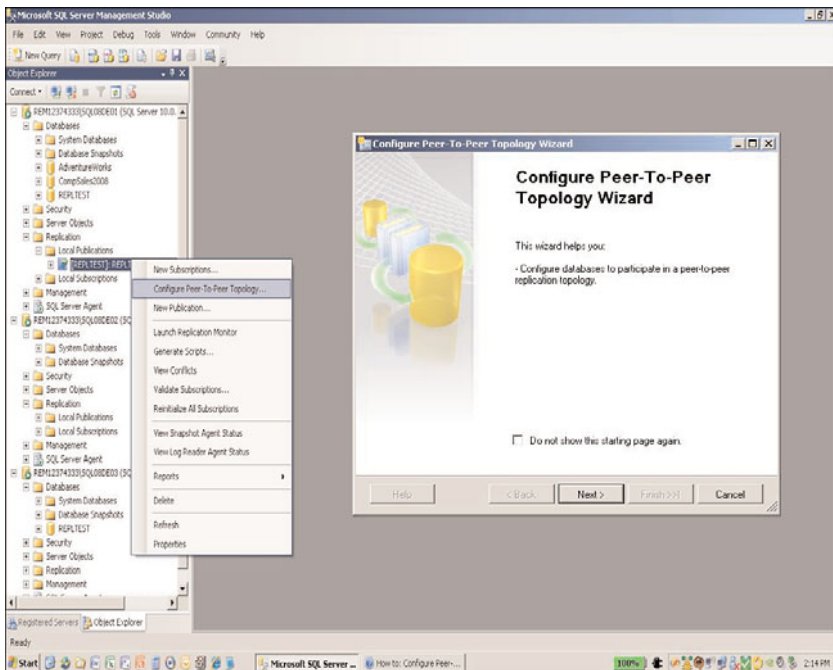

FIGURE 19.60 Peer-to-peer wizard launch.

You basically create publications that become shared in the peer-to-peer topology. You add “nodes” on an equal hierarchical level that participate in the publication equally. You can add any number of peers (nodes), and new in SQL Server 2008, this can be done without interrupting the existing replication topology. Figure 19.61 shows the setup of a publication for a database named REPLTEST_PEER2PEER and the addition of two nodes to the topology.

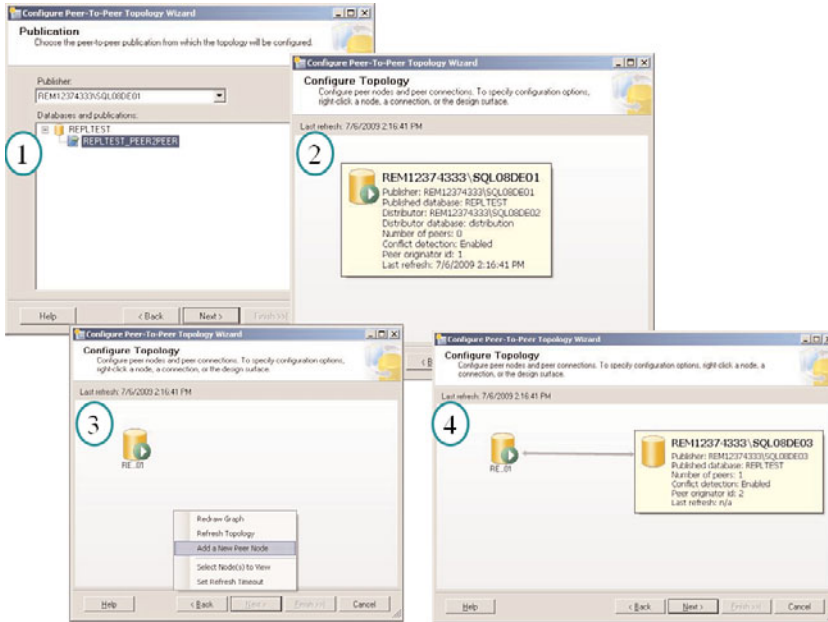

FIGURE 19.61 Setup of the publication and two nodes in a peer-to-peer topology (1 thru 4).

Peers are typically initialized manually for consistency purposes. Figure 19.62 shows the Configure Peer-to-Peer Topology Wizard summary and the successful creation of the full (two-node) topology. Note that each node is assigned a unique originator ID, and conflict detection has been enabled. Notice also that it really doesn't matter which node is listed first in the wizard topology because they are equal (no hierarchy exists) and the arrow is bidirectional.

The Performance Monitor

You can use Windows Performance Monitor to monitor the health of your replication scenario. When you install SQL Server, you get several new objects and counters in Performance Monitor:

- ▶ **SQLServer:Replication Agents**—This object contains counters used to monitor the status of all replication agents, including the total number running.
- ▶ **SQLServer:Replication Dist**—This object contains counters used to monitor the status of the distribution agents, including the latency and number of transactions transferred per second.
- ▶ **SQLServer:Replication Logreader**—This object contains counters used to monitor the status of the log reader agent, including the latency and number of transactions transferred per second.

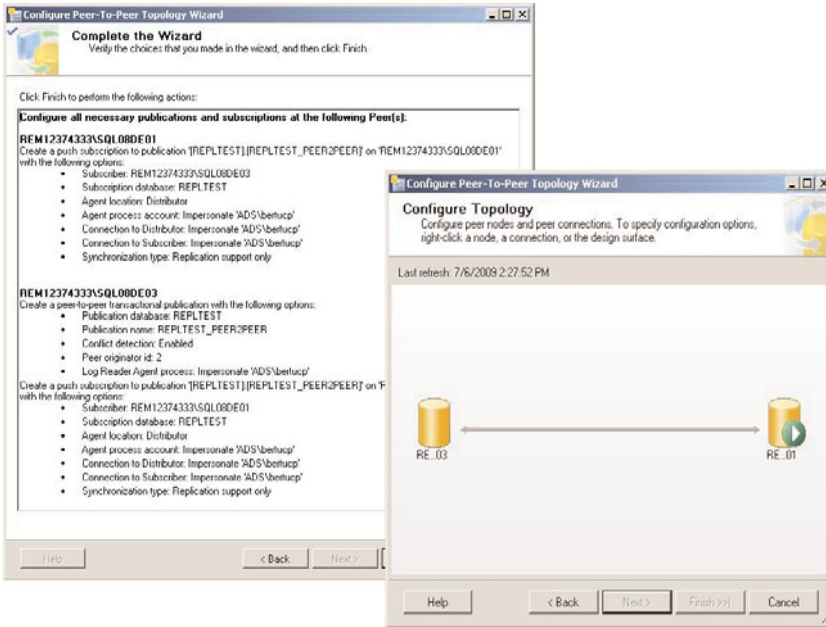

FIGURE 19.62 Configure Peer-to-Peer Topology Wizard summary and complete topology.

- ▶ **SQLServer:Replication Merge**—This object contains counters used to monitor the status of the merge agents, including the number of transactions and number of conflicts per second.
- ▶ **SQLServer:Replication Snapshot**—This object contains counters used to monitor the status of the snapshot agents, including the number of transactions per second.

As you can see in Figure 19.63, we chose to monitor the typical things critical for replication: the LogReader counters, the distribution server counters, some default processor times, and disk queue lengths to keep an eye on load at the publisher. Figure 19.63 shows some spikes during log reader activity as big transactions hit the publisher. However, they drop off quickly, easily handling the large transaction volumes.

Replication in Heterogeneous Environments

SQL Server 2008 allows for transactional and snapshot replication of data into and out of environments other than SQL Server. This is termed *heterogeneous* replication. The easiest way to set up this replication is to use ODBC or OLE DB and create a push subscription to the subscriber. This is much easier to make work than you might imagine. SQL Server can publish to the following database types:

- ▶ Microsoft Access
- ▶ Oracle
- ▶ Sybase

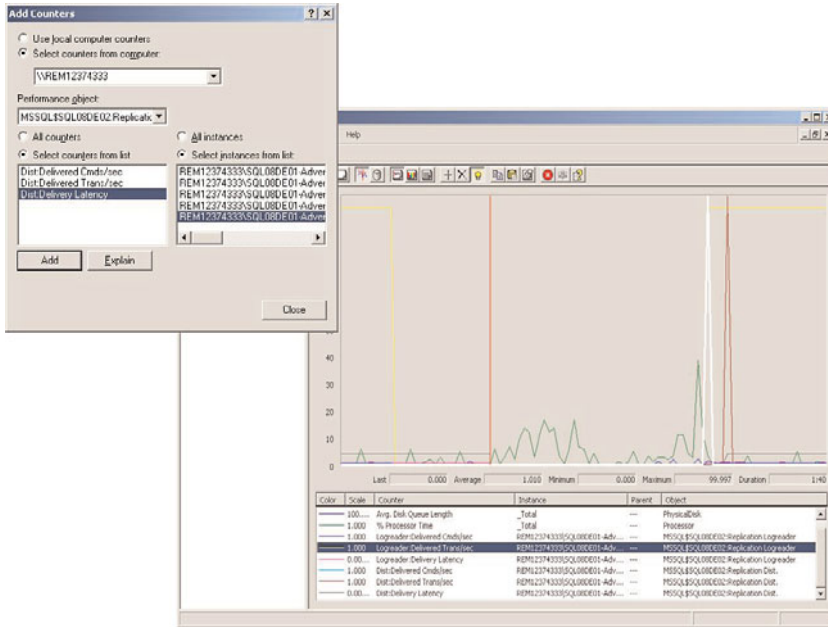

FIGURE 19.63 Performance Monitor counters for replication monitoring.

- ▶ IBM DB2/AS400
- ▶ IBM DB2/MVS

SQL Server can replicate data to any other type of database, provided that the following are true:

- ▶ The driver must be ODBC Level 1 compliant.
- ▶ The driver must be 32-bit, thread safe, and designed for the processor architecture on which the distribution process runs.
- ▶ The driver must support transactions.
- ▶ The driver and underlying database must support Data Definition Language (DDL).
- ▶ The underlying database cannot be read-only.

Backup and Recovery in a Replication Configuration

A replication-oriented backup strategy will reap major benefits for you after you have implemented a data replication configuration. You must realize that the scope of data and what you must back up together have changed. In addition, you must be aware of the recovery time frame and plan your backup/recovery strategy accordingly. You might not have multiple hours available to you to recover an entire replication topology. You now have databases that are conceptually joined, and you might need to back them up together in one synchronized backup. Figure 19.64 shows overall backup strategies for the most common recovery needs.

Recovery Need	Backup Strategy
100% data, All sites, Small Recovery Window	Coordinated DB backups at all sites involved in the replication configuration (publisher, distributor and all subscribers). Somewhat complex to do.
100% data, All sites, Medium Recovery Window	Backup Publication DB and Distribution DB together. Replication can be recovered from this point very easily without reconfiguring anything. Just have to re-initialize the subscribers. This is the most common approach being used.
100% data, All sites Big Recovery Window	Backup of Publication DB only. Can then reconfigure replication via scrips and reinitialize distribution, and all subscribers fairly easily.

FIGURE 19.64 Common backup strategies for different recovery needs.

When backing up environments, you need to back up the following at each site:

- ▶ Publisher (published database, msdb, and master)
- ▶ Distributor (distribution database, msdb, and master)
- ▶ Subscribers (subscriber database, optionally msdb, and master when pull subscriptions are being done)

You should always make copies of your replication scripts and keep them handy. At a minimum, you need to keep copies at the publisher and distributor and one more location, such as at one of your subscribers. You will use them for recovery someday.

You shouldn't forget to back up master and msdb when any new replication object is created, updated, or deleted.

If you have allowed updating of subscribers using queued updates, you need to expand your backup capability to include these queues.

In general, you will find that even when you walk up and pull the plug on your distribution server, publication server, or any subscribers, automatic recovery works well to get you back online and replicating quickly, without human intervention.

Some Thoughts on Performance

From a performance point of view, the replication configuration defaults err on the side of optimal throughput. That's the good news. The bad news is that everybody is different in some way, so you have to consider a bit of tuning of your replication configuration. In general, you can get your replication configuration working well by doing the following:

- ▶ Keeping the amount of data to be replicated at any one point small by running agents continuously, instead of at long, scheduled intervals.

- ▶ Setting a minimum amount of memory allocated to SQL Server by using the Min Server Memory option to guarantee ample memory across the board.
- ▶ Using good disk drive physical separation rules, such as keeping the transaction log on a separate disk drive from the data portion. Your transaction log is much more heavily used when you opt for transactional replication.
- ▶ Putting your snapshot working directory on a separate disk drive to minimize disk drive arm contention. You should use a separate snapshot folder for each publication.
- ▶ Publishing only what you need. By selectively publishing only the minimum amount of data required, you implement a much more efficient replication configuration, which is faster overall.
- ▶ Trying to run snapshots in nonpeak times so your network and production environments aren't bogged down.
- ▶ Minimizing transformation of data involved with replication.

Log Shipping

If you have a small need to create a read-only (ad hoc query/reporting) database environment that can tolerate a high degree of data latency, you might be a candidate for using log shipping. Log shipping is still a feature for SQL Server 2008, but it will be deprecated by the next release. In other words, it might be easy to use and easy to manage, but it is being phased out as a feature of SQL Server. For this reason, we do not describe it in this book (it is described in detail in *SQL Server 2000 Unleashed*, though). For those who have current log shipping configurations, it is time to move to database mirroring. This transition will be easy because the two capabilities are so much alike. (Actually, many aspects of database mirroring came from log shipping.)

Data Replication and Database Mirroring for Fault Tolerance and High Availability

SQL Server 2008 allows you to use combinations of options to achieve higher availability levels. A prime example is combining data replication with database mirroring to provide maximum availability of data, scalability to users, and fault tolerance via failover at potentially each node in the replication topology. You can start with the publisher and distributor, making them both database mirror failover configurations. Building up a combination of both options together is the best of both worlds: the super low latency of database mirroring for fault tolerance and the high availability (and scalability) of data through replication. (For more information, see Chapter 20, "Database Mirroring.")

Summary

Replication is a powerful feature of SQL Server that can be used in many business situations. Companies can use replication for anything from roll-up reporting to relieving the main server from ad hoc queries and reporting. It is critical to let your company's requirements drive the type of replication technique to use. Determining the replication option and configuration to use is difficult, but actually setting it up is reasonably easy. Microsoft has come a long way in this regard. Peer-to-peer replication seems to have the most promise of delivering master-master symmetric replication in a production environment. Microsoft's overall architectural approach and implementation is the model for the industry. You should not be afraid to use this facility. It is more than production-worthy, and the flexibility it offers and the overall performance are just short of incredible, incredible, incredible (replication humor for you).

In Chapter 20 we delve into the capability to make an image of a database (a mirror) for failover purposes using the database mirroring mechanism available within SQL Server 2008. This is a landmark addition for SQL Server.

This page intentionally left blank

CHAPTER 20

Database Mirroring

Database mirroring is such a huge technology jump in capabilities that even the smallest company can now provide near-real-time database failover without the fancy, expensive hardware required with more complex configurations, such as with SQL Server Clustering (that is built on Microsoft Cluster Services [MSCS]). MSCS requires shared resources, separate network connections for internal heartbeat communication, and so on. In addition, multiple layers of software are involved (MSCS plus SQL Server). With database mirroring, you can set up a near-real-time database failover environment using all conventional, low-cost machines, without any complex hardware compatibility requirements, and database mirroring can fail over in as little as 3 seconds!

Database mirroring effectively allows anyone to immediately step up to nearly 99.9% (at least three nines) availability at the database layer at a very low cost, and it is easily configured and managed.

What's New in Database Mirroring

Performance, performance, and more performance! This is the key improvement for database mirroring in SQL Server 2008. This performance improvement was brought about by Microsoft's efforts to isolate and resolve the bottleneck in database mirroring that existed with SQL Server 2005. That bottleneck centered around the bulky transmission of full-size log records from one SQL Server to another.

Improvements in SQL Server 2008 are centered around the data compression used on the log records sent from one server to the other. Later in this chapter we show you some

IN THIS CHAPTER

- ▶ Using Replication and Database Mirroring Together
- ▶ Using Database Snapshots from a Mirror for Reporting

results of a benchmark involving SQL Server 2005 and SQL Server 2008 that show the major impact of this enhancement. In addition, as records are being written to the mirror, automatic page repair can occur if SQL Server finds any page that is not intact, adding more reliability and stability to the overall SQL Server platform. A few more interesting performance counters and new dynamic management views that provide visibility into the health of your mirroring implementation round out the new features.

Microsoft SQL Server 2008 is shifting very strongly to a goal of providing a Database Engine foundation that can be highly available 7 days a week, 365 days a year. With database mirroring, Microsoft is providing the masses with the opportunity to achieve that dream much more quickly. Database mirroring was first introduced in SQL Server 2005. It was earlier known as Real-time Log Shipping (RTLS) and then had another name for a while, and it finally ended up being called *database mirroring*—which is what it really is.

The key breakthrough that allowed Microsoft to offer database mirroring was something called “copy-on-write” technology. We describe it in more detail in a bit. Suffice it to say that with copy-on-write technology, a transaction can be distributed (that is, written) to another completely separate SQL Server database immediately, and that other database can, in turn, be used as a failover (that is, it can be used to fail over to in less than 3 seconds).

NOTE

The examples in this chapter are based on the SQL Server 2005 version of the AdventureWorks database rather than the newer AdventureWorks2008 or AdventureWorks2008R2 sample databases used for many of the examples in the other chapters in this book. The reason for this is because Database Mirroring cannot be implemented on a database that is also configured for FILESTREAM storage. The 2008 and 2008R2 versions of the AdventureWorks database make use of FILESTREAM storage.

Fortunately, the 2005 version of the AdventureWorks database can be installed using the same installer that installs the AdventureWorks2008 or AdventureWorks2008R2 database. If you didn't install AdventureWorks when you installed either of these sample databases, simply relaunch the installer and choose to install the AdventureWorks OLTP database.

For more information on downloading and installing the AdventureWorks sample databases, see the Introduction chapter.

What Is Database Mirroring?

When you mirror a database, you are essentially asking for a complete copy of a database to be created and maintained, with as much up-to-the-second completeness as possible; you are asking for a mirror image. Database mirroring is a database-level feature. This means that there is no support for filtering, subsetting, or any form of partitioning. You

mirror a complete database or nothing at all. This limitation actually keeps database mirroring simple and clean to implement. It also certainly provides some drawbacks, such as burning up twice the amount of disk storage, but what you get in return is well worth the cost in storage.

Database mirroring works through the transaction log of the principal database (of the database that is to be mirrored). You can mirror only a database that uses the full database recovery model. Otherwise, it would not be possible to forward transaction log entries to another server. Through the use of copy-on-write technology, a change to data in a primary server's database (as reflected in active transaction log entries) is first "copied" to the target server, and then it is "written" (that is, applied or restored) to the target database server (that is, to the mirror server) transaction log. That is why it's called *copy-on-write*.

Database mirroring is very different from data replication. With replication, database changes are at the logical level (insert, update, delete statements; stored procedure executions; and so on), whereas database mirroring uses the actual physical log entries on both the primary database server side and the mirror database server side. Effectively, the physical "active" log records from the transaction log of the principal database are copied and written directly to the transaction log of the mirror database. These physical log record-level transactions can be applied extremely quickly. As these physical log records are being applied to the mirror database, even the data cache reflects the forward application of the log records. This makes the entire database and data cache ready for the principal to take over extremely quickly. And, now with SQL Server 2008, the log records are compressed on the principal side before transmission, which allows more records per transmission to be sent to the mirror server, thus speeding up the whole topology quite a bit.

Figure 20.1 shows a typical database mirroring configuration that has three components:

- ▶ **Principal database server**—This is the source of the mirroring. You can mirror one or more databases on a single SQL Server instance to another SQL Server instance. You cannot mirror a database on one SQL Server instance to itself (that is, the same SQL Server instance). Remember, you mirror a database, not a subset of the database or a single table. It's all or nothing.
- ▶ **Mirror database server**—The mirror server is the recipient of the mirroring from the principal database server. This mirrored database is kept in hot standby mode and cannot be used directly in any way. In fact, after you configure database mirroring, this database shows its status as being in continuous "restore" mode. The reason is that the physical transaction records are continuously applied to this mirror database. This database is essentially a hot standby database and is not available for direct database usage of any kind. The reason is that it is used in case the principal fails and must not be tainted in any way (it must be the exact mirror image of the principal). The one exception to this nonusage scenario is creating database snapshots from the mirror database (creating database snapshots with a database mirror is described in more detail later in this chapter and in Chapter 32 "Database Snapshots").

FIGURE 20.1 A basic database mirroring configuration with principal, mirror, and witness servers.

- Witness database server**—You use the witness database server, which is optional, when you want to be continually checking to see if any failures have occurred to the primary database server and to help make the decision to fail over to the mirror database server. Using a witness server is a sound way to configure database mirroring. If you do not identify a witness server, the principal and mirror are left on their own to decide whether to fail over. With the witness server, a quorum is formed (that is, two out of three servers), and it takes the quorum to make a failover decision. A typical scenario is that the principal server fails for some reason, the witness sees this failure, the mirror also sees the failure, and together they agree that the principal is lost and that the mirror must take over the principal role. If the witness still sees that the principal is alive and well, but the communication between the mirror and principal has been broken, the witness does not agree to fail over to the mirror (even though the mirror thinks it must do this because it lost connection to the principal). Witness servers are usually put on separate physical servers.

Copy-on-Write Technology

The copy-on-write technology is at the core of the database mirroring capability. Look back at Figure 20.1, and notice what happens in a High Safety with Automatic Failover mode (synchronous mode):

1. A transaction from a client connection to the principal server (A) is written to the AdventureWorks database (D).
2. When the transaction is written to the principal server's transaction log, it is immediately copied (B) and written to the mirror server (D).
3. When this physical log record is written to the mirror server, it sends back an acknowledgment (C) to the principal of its write success.

This is the copy-on-write technology. The end result is that the mirror server is in exactly the same state as the principal server (if the physical log record has been successfully written on the mirror side). If failure occurs now, the mirror server can pick up all processing from the clients extremely quickly and without data loss.

NOTE

Database mirroring cannot be used for any of SQL Server's internal databases—tempdb, masterdb, msdb, or modeldb. Database mirroring is fully supported in SQL Server Standard Edition, Developer Edition, and Enterprise Edition, but it is *not* supported in SQL Server Workgroup Edition or Express Edition. However, machines running these server editions could be used as witness servers.

When to Use Database Mirroring

As mentioned earlier in this chapter, database mirroring elevates the availability level of a SQL Server-based application to a very high level without any special hardware and extra administration staff skills. However, when you should use database mirroring varies depending on your true needs.

Basically, if you need to increase the availability of the database layer, have automatic data protection (that is, redundant storage of data), or decrease the downtime that would normally be required to do upgrades, you should use database mirroring. An ever more popular scenario for database mirroring is when you need to offload reporting that is easily satisfied with periodic database snapshots. This usage provides great relief from heavily burdened transactional servers also used for reporting. Finally, if you need data distribution, high availability, and high data resiliency, using data replication with database mirroring is also a good idea. We discuss these latter two ideas later in this chapter.

Roles of the Database Mirroring Configuration

As you have seen, a typical database mirroring configuration has a principal server, mirror server, and witness server. Each of these servers plays a role at some point. The principal and mirror switch roles, so it is important to understand what these roles are and when a server is playing a particular role.

Playing Roles and Switching Roles

A *role* corresponds to what a server is doing at a particular point in time. There are three possible roles:

- ▶ **Witness role**—If a server is playing a witness role, it is essentially standing alongside both partners of a database mirror configuration and is used to settle all arguments. It is getting together with any one of the other servers and forming a quorum to come up with decisions. The decision that it will participate in is whether to fail over. That is it. As mentioned before, the witness server can be any edition of a SQL Server (even SQL Server Express, the free version).
- ▶ **Principal role**—If a server is playing a principal role, it is the server that the application will be connected to and that is generating the transactions. One of the partners in the database mirror must start out as the principal. After a failure, the mirror server takes over the principal role, and the roles reverse.
- ▶ **Mirror role**—If a server is playing a mirror role, it is the server that is having transactions written to it. It is in a constant recovery state (that is, the database state needed to be able to accept physical log records). One of the partners in the database mirroring configuration must start out in the mirror role. Then, if a failure occurs, the mirror server changes to the principal role.

Database Mirroring Operating Modes

With database mirroring, you have the option of deploying in one of three modes: high safety *with* automatic failover mode (high availability with a witness server), high safety *without* automatic failover mode (high protection without a witness server), and high-performance mode. Each mode has different failure and protection characteristics and uses the database mirroring configurations slightly differently. As you might expect, the high-performance mode offers the least amount of protection; you must sacrifice levels of protection for performance.

Database mirroring runs with either asynchronous or synchronous operations:

- ▶ **Synchronous operations**—With synchronous operations, a committed transaction is committed (that is, written) on both partners of the database mirroring pair. This obviously adds some latency cost to a complete transaction because it is across two servers. High-safety modes use synchronous operations.
- ▶ **Asynchronous operations**—With asynchronous operations, transactions commit without waiting for the mirror server to write the log to disk. This can speed up performance significantly. High-performance mode uses asynchronous operations.

Whether the operations are asynchronous or synchronous depends on the transaction safety setting. You control this setting through the `SAFETY` option when configuring with Transact-SQL (T-SQL) commands. The default for `SAFETY` is `FULL` (which provides

synchronous operations). You set it to OFF for asynchronous operations. If you are using the mirroring wizard, this option is set for you automatically.

Of the three modes, only the high safety with automatic failover mode (high-availability mode) requires the witness server. The others can operate fine without this third server in their configuration. Remember that the witness server is looking at both the principal and mirror server and will be utilized (in a quorum) for automatic failover.

Role switching is the act of transferring the principal role to the mirror server. It is the mirror server that acts as the failover partner for the principal server. When a failure occurs, the principal role is switched to the mirror server, and its database is brought online as the principal database.

Failover variations are

- ▶ **Automatic failover**—Automatic failover is enabled with a three-server configuration involving a principal, mirror, and witness server. Synchronous operations are required, and the mirror database must already be synchronized (that is, in sync with the transactions as they are being written to the principal). Role switching is done automatically. This is for high-availability mode.
- ▶ **Manual failover**—Manual failover is needed when there is no witness server and you are using synchronous operations. The principal and mirror are connected to each other, and the mirror database is synchronized. Role switching is done manually. This is for high safety without automatic failover mode (high-protection mode). You are making the decision to start using the mirror server as the principal (no data loss).
- ▶ **Forced service**—In the case of a mirror server being available but possibly not synchronized, the mirror server can be forced to take over when the principal server has failed. This possibly means data loss because the transactions were not synchronized. This is for either high safety without automatic failover mode (high-protection mode) or high-performance mode.

Setting Up and Configuring Database Mirroring

Microsoft uses a few other concepts and technologies in database mirroring. You have already learned about the copy-on-write technology. Microsoft also uses *endpoints*, which are assigned to each server in a database mirroring configuration. In addition, establishing connections to each server is much more tightly controlled and requires service accounts or integrated (domain-level) authentication. Within SQL Server, grants must also be given to the accounts that will be executing database mirroring.

You can completely set up database mirroring by using T-SQL scripts, or you can use the Database Mirroring Wizard within SQL Server Management Studio (SSMS). We always

advise that you use something that is repeatable, such as SQL scripts, and you can easily generate SQL scripts by using the new wizard. It's not fun to have to re-create or manage a database mirroring configuration in the middle of the night. Having this whole process in a script reduces almost all errors.

Getting Ready to Mirror a Database

Before you start setting up and configuring a database mirroring environment, it is always best to run through a simple checklist of basic requirements:

1. Verify that all server instances are at the same service pack level. In addition, the SQL Server edition you have must support database mirroring.
2. Verify that you have as much or more disk space available on the mirror server as on the principal server. You also need the same room for growth on both.
3. Verify that you have connectivity to each server from the others. You can most easily do this by trying to register each SQL Server instance in SSMS. If you can register the server, the server can be used for database mirroring. Do this for the principal, mirror, and witness servers.
4. Verify that the principal server database that is to be mirrored is using the full database recovery model. Right-click on the database you intend to mirror, choose Tasks, and then Mirroring. This brings you to the database mirroring properties dialog where you can configure mirroring. If you try to start configuring database mirroring and the database recovery model is not full for the principal database, you get a nasty message to that effect (see Figure 20.2). Because database mirroring is transaction log based, it makes sense to be using the full database recovery model: all transactions are written to the transaction log and are not truncated, as with other database recovery models.

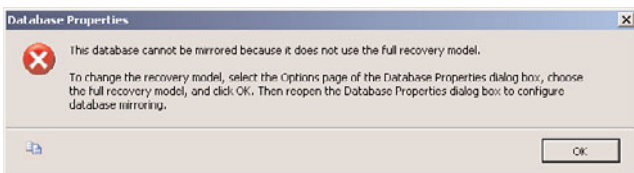

FIGURE 20.2 Trying to mirror a database that is not using the full database recovery model.

Before you go any further, you must establish the endpoints for each of the servers that will be a part of the database mirroring configuration. You can use the Configure Security option of the wizard to do this, but getting into the practice of using SQL scripts is really the best approach. Using SQL scripts is very easy, as you will soon see.

Endpoints utilize TCP/IP addressing and listening ports for all communication between the servers. Within a server, the endpoint is given a specific name (that is, an endpoint name) for easy reference and to establish the partner roles that this server (endpoint) will possibly play. In addition, a connection GRANT is needed for access to be allowed from each server to the other, and a service account should be used for this. This service account is usually a particular login that is known to the domain and is to be used for all connections in the database mirroring topology. Figure 20.3 shows the mirroring database properties of the AdventureWorks database on a SQL Server instance named SQL08DE01. As you can see, no server network addresses are set up for database mirroring of any kind, and the mirroring status says “This Database Has Not Been Configured for Mirroring.”

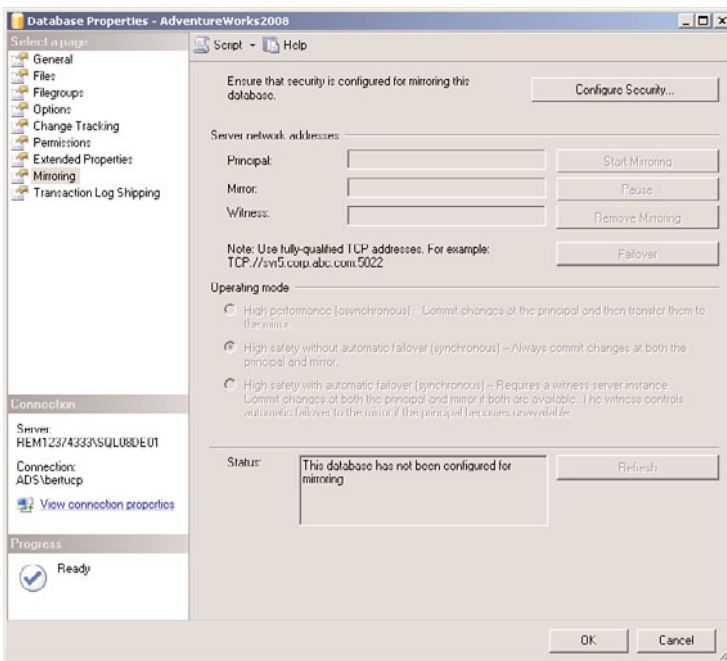

FIGURE 20.3 The Database Properties Mirroring page: mirroring network addressing and mirroring status.

Next, we look at how to set up high safety with automatic failover mode (high-availability mode) database mirroring with principal, mirror, and witness servers. For this, you can mirror the old reliable AdventureWorks database that Microsoft provides with SQL Server 2008.

Figure 20.4 illustrates the database mirroring configuration to set up.

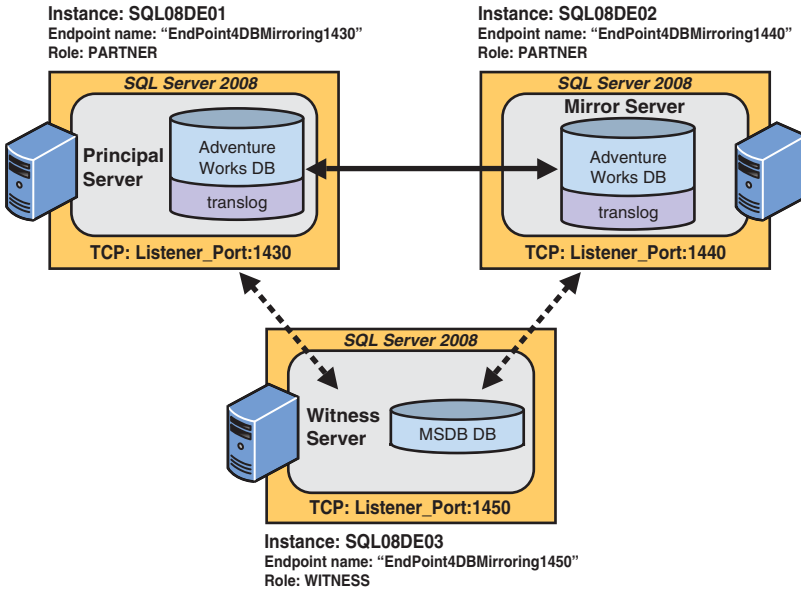

FIGURE 20.4 A high-availability database mirroring configuration with the **AdventureWorks** database.

The initial principal server is the SQL Server instance named `SQL08DE01`, the initial mirror server is the SQL Server instance named `SQL08DE02`, and the witness server is the SQL Server instance named `SQL08DE03`.

You need to establish a local endpoint named `EndPoint4DBMirroring9xxx` on each of these SQL Server instances and identify the TCP listening port that will be used for all database mirroring communication. We also like to embed the port number as part of the endpoint name, such as `EndPoint4DBMirroring1430` for the endpoint that will be listening on port 1430. In our configuration, the principal server will be listening on Port 1430, the mirror server on Port 1440, and the witness server on Port 1450. These port numbers must be unique within a single server machine, and the machine name and port combination must be unique within the network. An example of the fully qualified network address name of this server and the listening port is `TCP://REM1237433.ads.autodesk.com:1430`, where `REM1237433.ads.autodesk.com` is the machine name within the domain, and `1430` is the listening port created with the endpoint. In addition, each server's initial role needs to be specified. The `SQL08DE01` instance can play any partner role (that is, a mirror and/or principal), the `SQL08DE02` instance can play any partner role as well, and the `SQL08DE03` instance should play the witness role only.

We have included three SQL script templates with this book (in the Chapter 20 code directory on the CD) that have working examples of creating the endpoints, granting connection permissions to a login for the endpoints, verifying that the endpoints were created,

altering the endpoints, backing up and restoring databases, and backing up and restoring transaction logs.

The first ones to look at are `2008 Create EndPoint Partner1.SQL`, `2008 Create EndPoint Partner2.SQL`, and `2008 Create EndPoint Witness.SQL`. You can leverage these templates to start the setup process if you are not using the Configure Security Wizard.

Now that we've verified all aspects of our planned mirroring topology, let's configure full database mirroring!

Creating the Endpoints

Each server instance in the database mirroring configuration must have an endpoint defined so that the other servers can communicate with it. This is sort of like a private phone line to your friends. Let's use the scripts provided as opposed to using the Configure Security Wizard. The first endpoint script is in the file `2008 Create EndPoint Partner1.SQL`.

From SSMS, you need to open a new query connection to your principal database by selecting File, New and in the New Query dialog, selecting Query with Current Connection. Open the SQL file for the first endpoint.

The following CREATE ENDPOINT T-SQL creates the endpoint named `EndPoint4DBMirroring1430`, with the `listener_port` value of 1430, and the database mirroring role `Partner`:

```
-- create endpoint for principal server --
CREATE ENDPOINT [EndPoint4DBMirroring1430]
    STATE=STARTED
    AS TCP (LISTENER_PORT = 1430, LISTENER_IP = ALL)
    FOR DATA_MIRRORING (ROLE = PARTNER, AUTHENTICATION = WINDOWS NEGOTIATE
, ENCRYPTION = REQUIRED ALGORITHM RC4)
```

After this T-SQL runs, you should quickly run the following SELECT statements to verify that the endpoint has been correctly created:

```
select name,type_desc,port,ip_address from sys.tcp_endpoints;
```

```
SELECT db.name, m.mirroring_role_desc
FROM sys.database_mirroring m
JOIN sys.databases db
ON db.database_id = m.database_id
WHERE db.name = N'AdventureWorks';
```

```
select name,role_desc,state_desc from sys.database_mirroring_endpoints;
```

Figure 20.5 shows the desired result set from these queries.

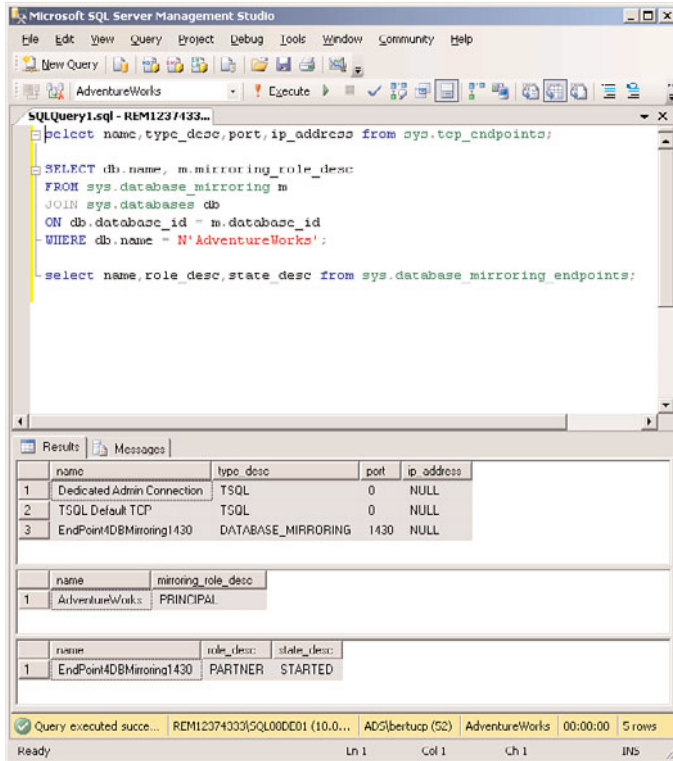

FIGURE 20.5 Verifying that an endpoint is created for database mirroring.

If you also look at the database properties for the AdventureWorks database on the principal server (SQL08DE01, in this example), you see the server network address for the principal server automatically appear now when you look at the Database Properties Mirroring page (see Figure 20.6).

Starting with the sample SQL scripts *2008 Create EndPoint Partner2.SQL* and *2008 Create EndPoint Witness.SQL*, you need to repeat the endpoint creation process for the mirror server (using a `listener_port` value of 1440) and the witness server (using a `listener_port` value of 1450) by opening a query connection to each one of these servers and running the following `CREATE ENDPOINT` commands:

```
-- create endpoint for mirror server --
CREATE ENDPOINT [EndPoint4DBMirroring1440]
    STATE=STARTED
    AS TCP (LISTENER_PORT = 1440, LISTENER_IP = ALL)
    FOR DATA_MIRRORING (ROLE = PARTNER, AUTHENTICATION = WINDOWS NEGOTIATE
, ENCRYPTION = REQUIRED ALGORITHM RC4)
```

For the witness server (notice that the role is now Witness), you run the following:

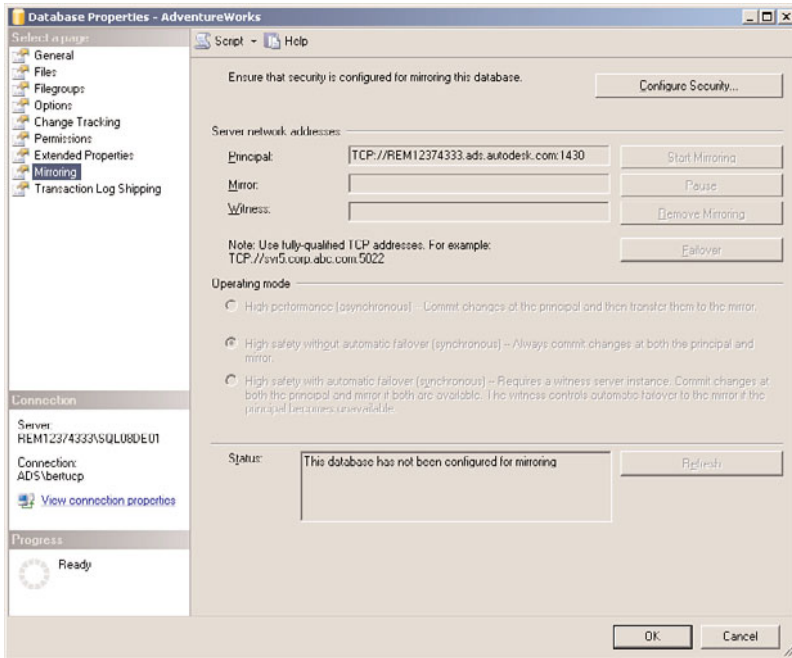

FIGURE 20.6 The Mirroring page of the **AdventureWorks** database on the principal server.

```
-- create endpoint for witness server --
CREATE ENDPOINT [EndPoint4DBMirroring1450]
    STATE=STARTED
    AS TCP (LISTENER_PORT = 1450, LISTENER_IP = ALL)
    FOR DATA_MIRRORING (ROLE = WITNESS, AUTHENTICATION = WINDOWS_NEGOTIATE
, ENCRYPTION = REQUIRED_ALGORITHM_RC4)
```

Granting Permissions

It is possible to have an `AUTHORIZATION [login]` statement in the `CREATE ENDPOINT` command that establishes the permissions for a login account to the endpoint being defined. However, separating this out into a `GRANT` greatly stresses the point of allowing this connection permission. From each SQL query connection, you run a `GRANT` to allow a specific login account to connect on the `ENDPOINT` for database mirroring. If you don't have a specific login account to use, default it to `[NT AUTHORITY\SYSTEM]`.

First, from the principal server instance (SQL08DE01), you run the following `GRANT` (substituting `[DBARCHLT\Paul Bertucci]` with your specific login account to be used by database mirroring):

```
GRANT CONNECT ON ENDPOINT::EndPoint4DBMirroring1430 TO [DBARCHLT\Paul Bertucci];
```

Then, from the mirror server instance (SQL08DE02), you run the following `GRANT`:

```
GRANT CONNECT ON ENDPOINT:: EndPoint4DBMirroring1440 TO [DBARCHLT\Paul Bertucci];
```

Then, from the witness server instance (SQL08DE03), you run the following GRANT:

```
GRANT CONNECT ON ENDPOINT:: EndPoint4DBMirroring1450 TO [DBARCHLT\Paul Bertucci];
```

Creating the Database on the Mirror Server

When the endpoints are configured and roles are established, you can create the database on the mirror server and get it to the point of being able to mirror. You must first make a backup copy of the principal database (AdventureWorks, in this example). This backup will be used to create the database on the mirror server. You can use SSMS tasks or use SQL scripts to do this. The SQL scripts (DBBackupAW2008.sql), which are easily repeatable, are used here.

On the principal server, you make a complete backup as follows:

```
BACKUP DATABASE [AdventureWorks]
    TO DISK = N'C:\Program Files\Microsoft SQL
Server\MSSQL.2\MSSQL\Backup\AdventureWorks4Mirror.bak'
    WITH FORMAT
GO
```

Next, you copy this backup file to a place where the mirror server can reach it on the network. When that is complete, you can issue the following database RESTORE command to create the AdventureWorks database on the mirror server (using the WITH NORECOVERY option):

```
-- use this restore database(with NoRecovery option)
to create the mirrored version of this DB --
RESTORE FILELISTONLY
    FROM DISK = 'C:\Program Files\Microsoft SQL
Server\MSSQL.2\MSSQL\Backup\AdventureWorks4Mirror.bak'
go
RESTORE DATABASE AdventureWorks
    FROM DISK = 'C:\Program Files\Microsoft SQL
        Server\MSSQL.2\MSSQL\Backup\AdventureWorks4Mirror.bak'
    WITH NORECOVERY,
        MOVE 'AdventureWorks_Data' TO 'C:\Program Files\Microsoft SQL
            Server\MSSQL.4\MSSQL\Data\AdventureWorks_Data.mdf',
        MOVE 'AdventureWorks_Log' TO 'C:\Program Files\Microsoft SQL
            Server\MSSQL.4\MSSQL\Data\AdventureWorks_Log.ldf'
GO
```

Because you don't necessarily have the same directory structure on the mirror server, you use the MOVE option as part of this restore to place the database files in the location you desire.

The restore process should yield something that looks like the following result set when restoring the AdventureWorks database that is shipped with SQL Server 2008:

```
-- Processed 21200 pages for database 'AdventureWorks',
      file 'AdventureWorks_Data' on file 1.
-- Processed 2 pages for database 'AdventureWorks',
      file 'AdventureWorks_Log' on file 1.
-- RESTORE DATABASE successfully processed 21202 pages
      in 14.677 seconds (11.833 MB/sec).
```

Basically, this result set says you are not ready to get into the mirroring business yet. You must now apply at least one transaction log dump to the mirror database. This brings the mirror database to a point of synchronization with the principal and leaves the mirror database in the Restoring state. At this database recovery point, you can run through the mirroring wizard and start mirroring for high availability.

From the principal server, you dump (that is, back up) a transaction log as follows:

```
BACKUP LOG [AdventureWorks] TO
DISK = N'C:\Program Files\Microsoft SQL
Server\MSSQL.2\MSSQL\Backup\AdventureWorksLog.bak'
Go
Processed 8 pages for database 'AdventureWorks', file 'AdventureWorks_Log' on file 2.
```

Then you move this backup to a place where it can be reached by the mirror server. When that is done, you restore the log to the mirror database. From the mirror server, you restore the transaction log as follows. Note the following `WITH FILE = statement`; the file number must match the value in the backup log results (see the `on file 2` reference in the previous code):

```
RESTORE LOG [AdventureWorks]
FROM DISK = N'C:\Program Files\Microsoft SQL
Server\MSSQL.4\MSSQL\Backup\AdventureWorksLog.bak'
WITH FILE = 2, NORECOVERY
GO
```

The restore log process should yield something that looks like the following result set:

```
RESTORE LOG successfully processed 8 pages
      in 0.034 seconds (9.396 MB/sec).
```

NOTE

You might need to update the `FILE = x` entry in the `RESTORE LOG` command to correspond to the “on file” value given during the log backup.

You are now ready to mirror the database in high-availability mode.

Identifying the Other Endpoints for Database Mirroring

To get each node in the topology to see each other, you have to identify the endpoints and listener port values to the databases involved in the database mirroring configuration (the principal and mirror). This also activates database mirroring. This process requires altering the database by using either the `SET PARTNER` or `SET WITNESS` statements within the `ALTER DATABASE` command. The Database Mirroring Wizard can also do this step for you, but doing it manually is easy.

We identify the unique endpoint listening port values for each endpoint that are unique within the server. They are port values 1430, 1440, and 1450 in our example.

Remember, you will be doing this *after* you create the AdventureWorks database on the mirror server side. After creating that database, you can run the following `ALTER DATABASE` command on the mirror server to identify the principal for the mirror to partner with:

```
-- From the Mirror Server Database: identify the principal server endpoint --
ALTER DATABASE AdventureWorks
    SET PARTNER = 'TCP://REM1237433.ads.autodesk.com:1430'
GO
```

Now, you are ready for the final step. From the principal server, you identify the mirror and witness. After you complete these step, the database mirroring topology tries to synchronize itself and begin database mirroring. The following statements identify the mirror server endpoint and witness server endpoint to the principal server's database:

```
-- From the Principal Server Database: identify the mirror server endpoint --
ALTER DATABASE AdventureWorks
    SET PARTNER = 'TCP://REM1237433.ads.autodesk.com:1440'
GO
-- From the Principal Server Database: identify the witness server endpoint --
ALTER DATABASE AdventureWorks
    SET WITNESS = 'TCP://REM1237433.ads.autodesk.com:1450'
GO
```

You do not have to alter any database from the witness server.

When this process completes successfully, you are mirroring! Yes, in fact, with this configuration, you are in automatic failover mode.

If you have issues or just want to start over, you can drop an endpoint or alter an endpoint quite easily. To drop an existing endpoint, you use the `DROP ENDPOINT` command. In this example, the following command would drop the endpoint you just created:

```
-- To DROP an existing endpoint --
DROP ENDPOINT EndPoint4DBMirroring1430;
```

Altering an endpoint (for example, to change the `listener_port` value) is just as easy as dropping one. The following example shows how to alter the currently defined endpoint to a new `listener_port` value of 1435 because of a conflict at the network level. (However,

because we use the port in the endpoint name, it might have been best to just drop and create a new endpoint to fit the naming convention. Either way, you can easily manipulate these endpoints to fit your networking needs.)

```
-- To ALTER an existing endpoint --
ALTER ENDPOINT EndPoint4DBMirroring1430
STATE = STARTED
AS TCP( LISTENER_PORT = 1435 )
FOR DATABASE_MIRRORING (ROLE = PARTNER)
```

Configuring Database Mirroring by Using the Wizard

After you have the endpoints created, the roles established, the connections to the endpoints granted, and the mirror database restored on the mirror server, you could easily run through the final short steps in the Database Mirroring Wizard to enable and start mirroring. Figure 20.7 shows the Mirror option from the AdventureWorks database (reached by right-clicking the database name) from what will be the principal server. Because this database is not enabled for mirroring yet, you must run through the Configure Security option on the top portion of the Mirroring page (refer to Figure 20.6). At this point, you can probably see only the network server address of the principal server. Don't worry; the rest (mirror and witness network server addresses) will be established and identified during the Configure Database Mirroring Security Wizard steps.

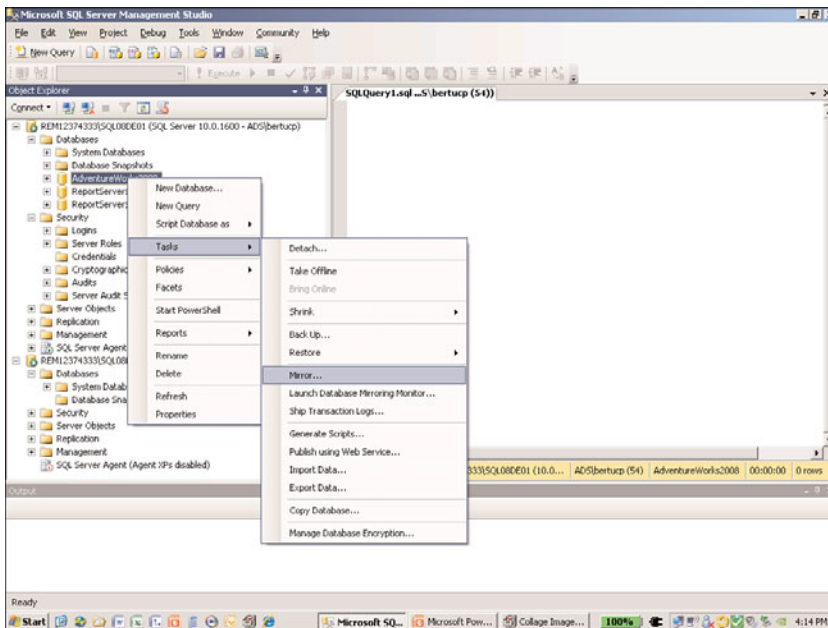

FIGURE 20.7 The Mirror option for the principal database server (AdventureWorks).

You need to click the Configure Security button on the Mirroring page. This immediately launches the Configure Database Mirroring Security Wizard for the database you have selected (AdventureWorks, in this example). Figure 20.8 shows this initial wizard splash page.

FIGURE 20.8 The Configure Database Mirroring Security Wizard for the **AdventureWorks** database.

You must configure all three server instances (principal, mirror, and witness servers) for the high-availability mode. The first option that must be indicated is whether you plan to include a witness server instance in your mirroring configuration. You are configuring a high-availability database mirroring configuration (synchronous mode with automatic failover), so you should select Yes on the wizard dialog shown in Figure 20.9; you do so because you want to create a full high-availability mode for automated failover.

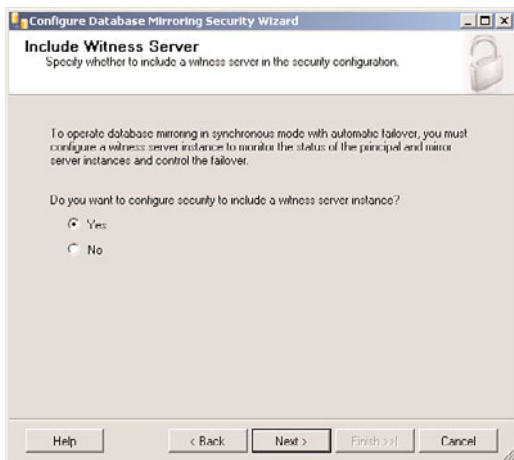

FIGURE 20.9 Including the witness server instance in the mirroring configuration.

The next page in the wizard prompts you to decide where to save the security configurations for database mirroring. You have no choice for the principal and mirror server instances; their security configuration information must be stored with them. You must also choose the default location for the witness server instance. The wizard then takes you through each server instance in the database mirroring configuration to establish all needed connection information to implement database mirroring. As you can see in Figure 20.10, this starts with the principal server instance. The wizard should find the endpoint and listener_port values you set up earlier (listener_port value 1430 and endpoint name EndPoint4DBMirroring1430, in this example).

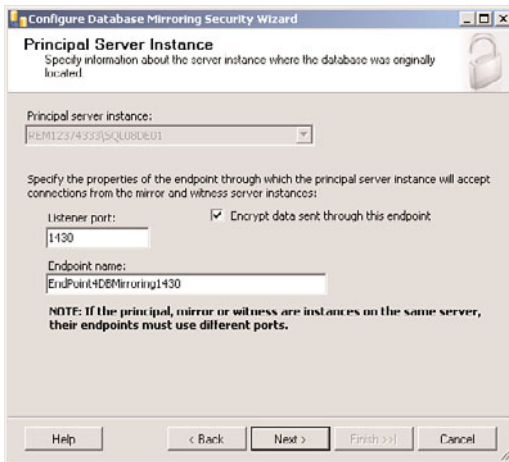

FIGURE 20.10 The Principal Server Instance screen of the Configure Database Mirroring Security Wizard.

Next comes the specification of the listener and endpoint entry for the mirror server instance (where the mirror copy of the database will be located). Initially, this page lists all server instances available on your network (that is, possible mirror server instances) and does not have a listener port or endpoint name specified yet. You need to identify which server you want to use as the mirror server instance (REM12374333\SQL08DE02, in this example) and click the Connect button to establish a valid (authorized) connection to the mirror server instance. Because you already set up the endpoint on this server (and granted connection permission, using a specific login ID), when you complete the connection dialog, the endpoint (EndPoint4DBMirroring1440, in this example) and listener_port value (1440, in this example) should be enabled, as shown in Figure 20.11.

Finally, you need to specify the witness server instance. Again, this dialog page lists all server instances available on the network (that is, possible witness server instances) and does not have a listener port or an endpoint name specified yet. You need to identify which server you want to use as the witness server instance (REM12374333\SQL08DE03, in this example) and click the Connect button to establish a valid (authorized) connection to the witness server instance. Because you already set up the endpoint on this server (and

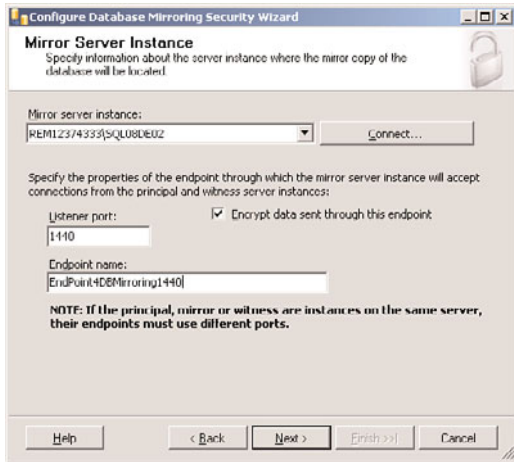

FIGURE 20.11 The Mirror Server Instance screen of the Configure Database Mirroring Security Wizard.

granted connection permission, using a specific login ID), when you complete the connection dialog, the endpoint (`EndPoint4DBMirroring1450`, in our example) and `listener_port` value (1450, in this example) should be enabled, as shown in Figure 20.12.

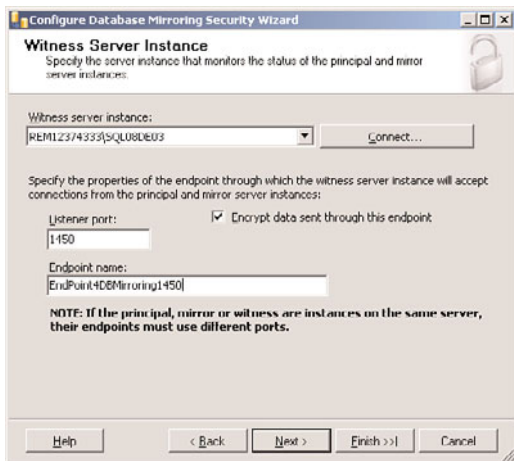

FIGURE 20.12 The Witness Server Instance screen of the Configure Database Mirroring Security Wizard.

The last step in the Configure Database Mirroring Security Wizard is to identify any service accounts that you want to use for the server instances in this database mirroring configu-

ration. You are already using a single domain login ID for this purpose and explicitly granted connect permissions on each endpoint. Therefore, nothing more needs to be done here. If the server instances use different accounts in the same or a trusted domain as their service accounts for SQL Server, you can enter these accounts here. It is best to do this via scripts (as you saw earlier, when you created the endpoints on each server instance).

As you can see in Figure 20.13, the Configure Database Mirroring Security Wizard now presents a summary list of all the actions on each server instance that it will perform. You click Finish to execute them.

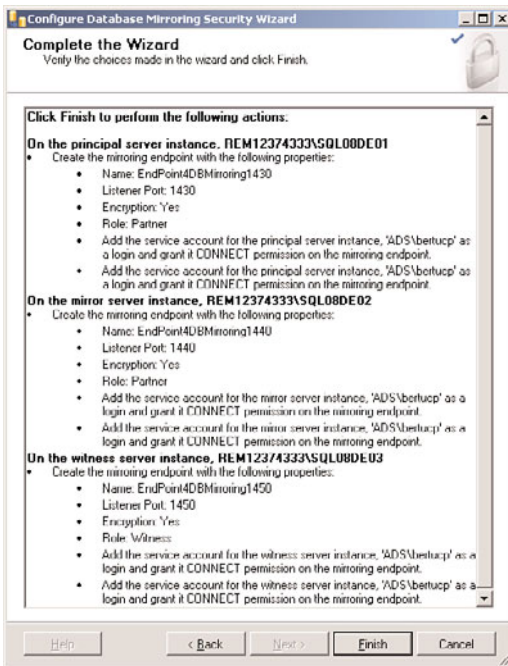

FIGURE 20.13 Summary of actions to be performed for the database mirroring configuration.

A report is generated, telling the total number of actions taken (three, in this case) and the status of each action. If any errors or warnings result, you can drill down into the Report button option in the bottom-right corner of this summary of actions page to determine what has occurred. If each status shows success, a Database Properties dialog, as shown in Figure 20.14, appears when you close this report page. This dialog gives you the option to start mirroring immediately or not start mirroring (because you will start mirroring at some other time). For this example, you want to start mirroring right away, so click the Start Mirroring button.

FIGURE 20.14 Specifying to start database mirroring for high safety with automatic failover.

Figure 20.15 shows the full Database Properties screen for the AdventureWorks database, all server network addresses, and the operating mode for mirroring.

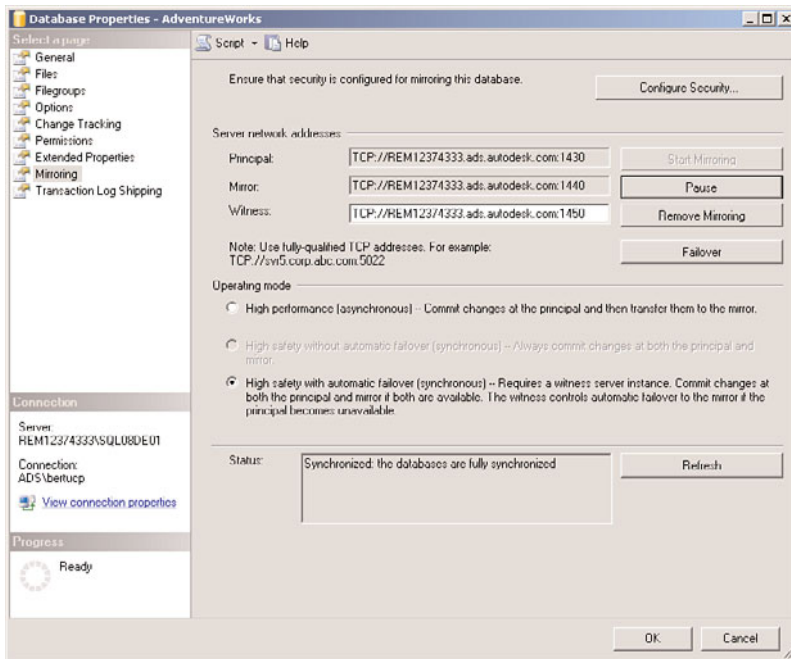

FIGURE 20.15 Fully configured properties and active mirroring for database mirroring.

If you look at the SQL Server log file (that is, the current log), you can see log entries indicating that database mirroring is active:

```
2/21/2009 22:33:33,spid21s,Unknown,Database mirroring is
active with database 'AdventureWorks' as the
principal copy. This is an informational message
only. No user action is required.
2/21/2009 22:33:09,spid17s,Unknown,Starting up database 'AdventureWorks'.
```

```
2/21/2009 22:33:07,Server,Unknown,SQL Server is now
ready for client connections. This is an
informational message; no user action is required.
2/21/2009 22:33:00,spid12s,Unknown,The Database
Mirroring protocol transport is now listening for connections.
2/21/2009 22:33:00,spid12s,Unknown,Server is
listening on [ 'any' <ipv4> 1430].
```

Congratulations. You are now mirroring a database!

Monitoring a Mirrored Database Environment

After active mirroring has started, you can monitor the complete mirrored topology in a few ways. You can start by registering the database being mirrored to a new facility within SSMS called Database Mirroring Monitor. Database Mirroring Monitor allows you to monitor roles of the mirroring partnership (that is, principal, mirror, and witness), see the history of transactions flowing to the mirror server, see the status and speed of this transaction flow, and set thresholds to alert you if failures or other issues occur. In addition, you can administer the logins/service accounts being used in the mirrored database topology.

Figure 20.16 shows how you launch the Database Mirroring Monitor from SSMS: you right-click the principal database being mirrored, choose Tasks, and then choose Launch Database Mirroring Monitor.

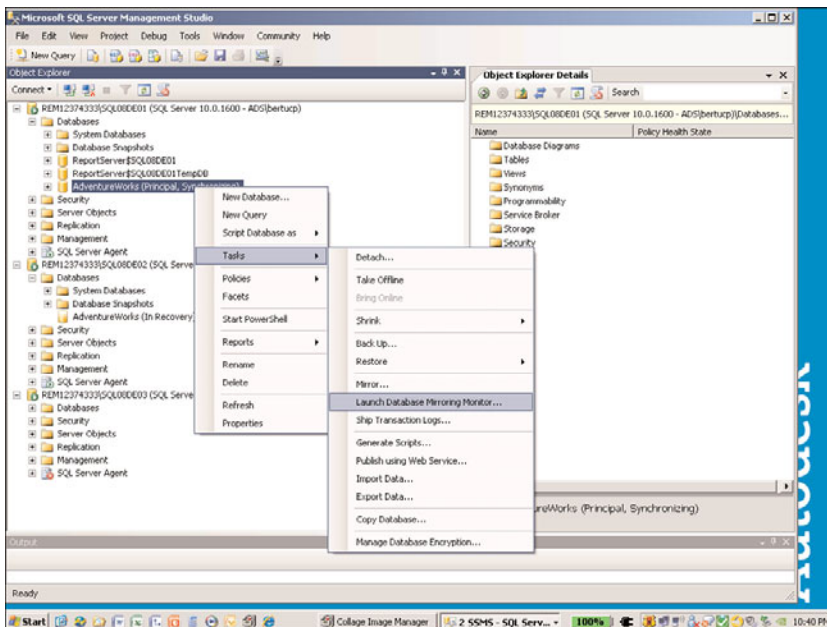

FIGURE 20.16 Launching Database Mirroring Monitor from SSMS.

You must register the database being mirrored. To do so, you select the principal or mirror server instance and set the Register check box for the database. Database Mirroring Monitor registers the database and both partner server instances, as shown in Figure 20.17.

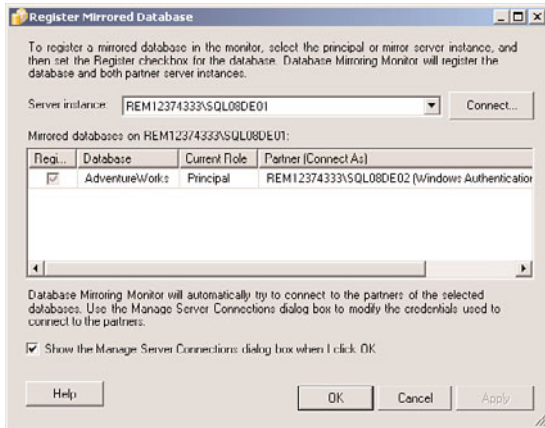

FIGURE 20.17 Registering the mirrored database within the Database Mirroring Monitor.

After the database is registered, all partners and the witness server instances show up in the Database Mirroring Monitor, as shown in Figure 20.18.

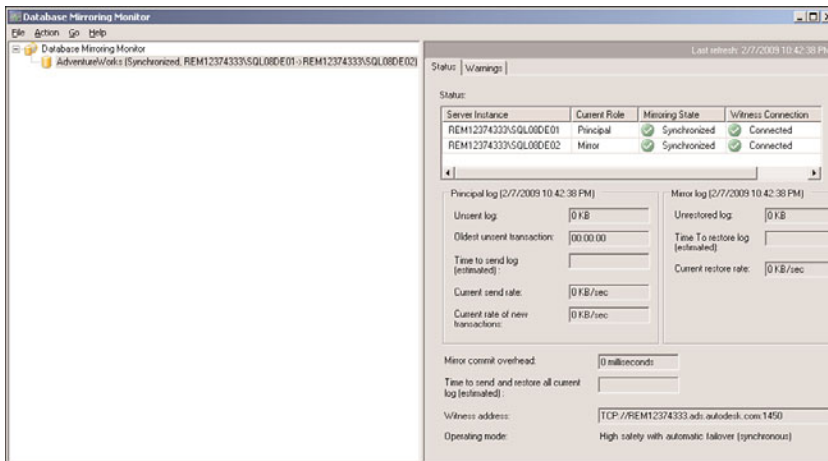

FIGURE 20.18 The registered database and status of each mirroring partner.

At a glance, you can see which server is playing what role (principal or mirror) and whether each partner has defined and is connecting to a witness server. In addition, you can see the unsent log (in size), the un-restored log (in size), when the oldest unsent transaction occurred, the amount of time it took to send the transaction to the mirror server instance, the send rate (KB/second), the current rate at which the transactions get restored

(KB/second), the mirror commit overhead (in milliseconds), the listener port of the witness server instance, and the operating mode of the mirroring (in this case, high safety with automatic failover—synchronous).

Figure 20.19 shows the detailed transaction history for a particular part of the mirroring flow (either the send out of the principal part or the restore to the mirror part). You can click the appropriate partner to see all transaction history details of the mirrored copy and restore process.

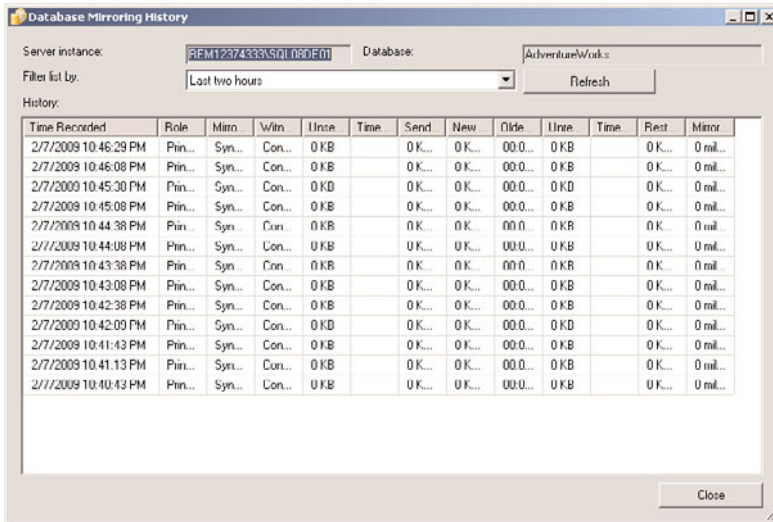

FIGURE 20.19 Transaction history of mirroring partners.

If you click the Warnings tab of the Database Mirroring Monitor, you can set various thresholds within the monitor to alert you when they have been reached (see Figure 20.20). Basically, you want to set thresholds that monitor the effectiveness of the mirroring operation.

If these key thresholds are ever exceeded, you want to be notified that something is very wrong and that failover may be in jeopardy. When a threshold is exceeded, an event is logged to the Application event log. You can configure an alert on this event by using SSMS or Microsoft Management Operations Manager (MOM). The threshold levels depend on your own failover tolerance. Our advice is to monitor the transaction and transfer rates for a peak period and then set the thresholds to be 100% higher than that. For example, if you see a peak mirror commit overhead value of 750 milliseconds, you should set the threshold to 1,500 milliseconds. This should be within the tolerance for commit overhead in your organization.

Figure 20.21 shows how easy it is to administer the service accounts/login IDs being used for database mirroring. You simply click an Edit button to change or set the login account you want to use for database mirroring at each instance in the mirroring topology.

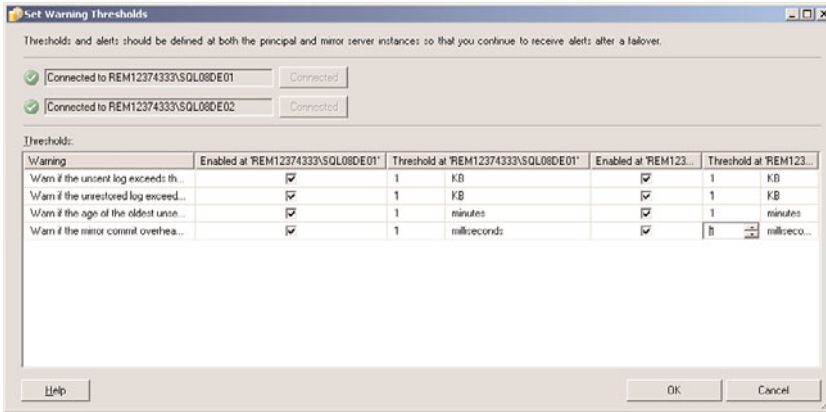

FIGURE 20.20 Setting thresholds to monitor mirroring effectiveness.

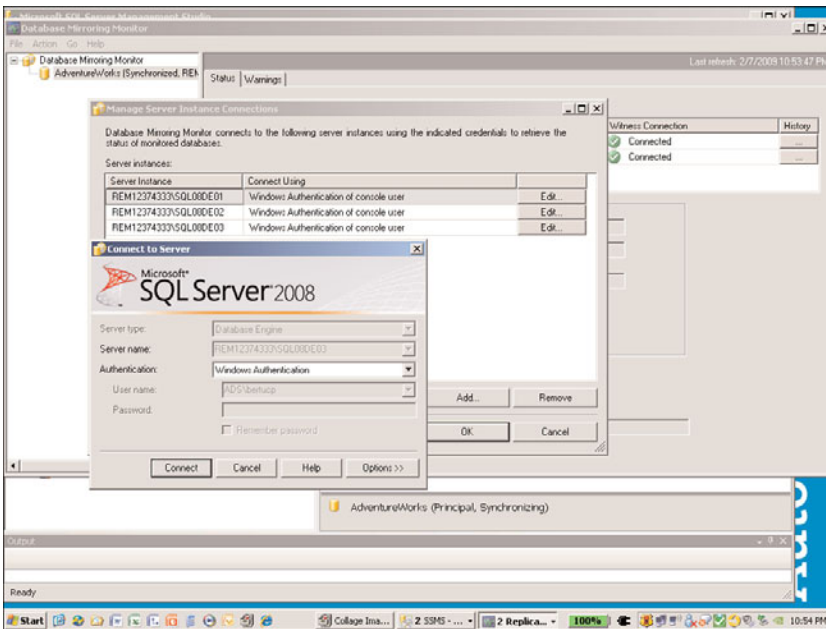

FIGURE 20.21 Setting service accounts/login IDs within the mirroring topology.

From the Database Properties Mirroring page, you can easily pause (and resume) database mirroring if you suspect that there are issues related to the mirroring operation. In addition, you can easily see what role each server instance is playing.

Removing Mirroring

Very likely, you will have to remove all traces of database mirroring from each server instance of a database mirroring configuration at some point. Doing so is actually pretty easy. Basically, you have to disable mirroring of the principal, drop the mirror server's database, and remove all endpoints from each server instance. You can simply start from the Database Properties page and the Mirroring option and do the whole thing. Alternatively, you can do this through SQL scripts. Let's first use the Mirroring options. Looking at the options on Figure 20.22, you simply choose to remove mirroring (from the principal server instance). This is just a bit too easy to do—almost dangerous!

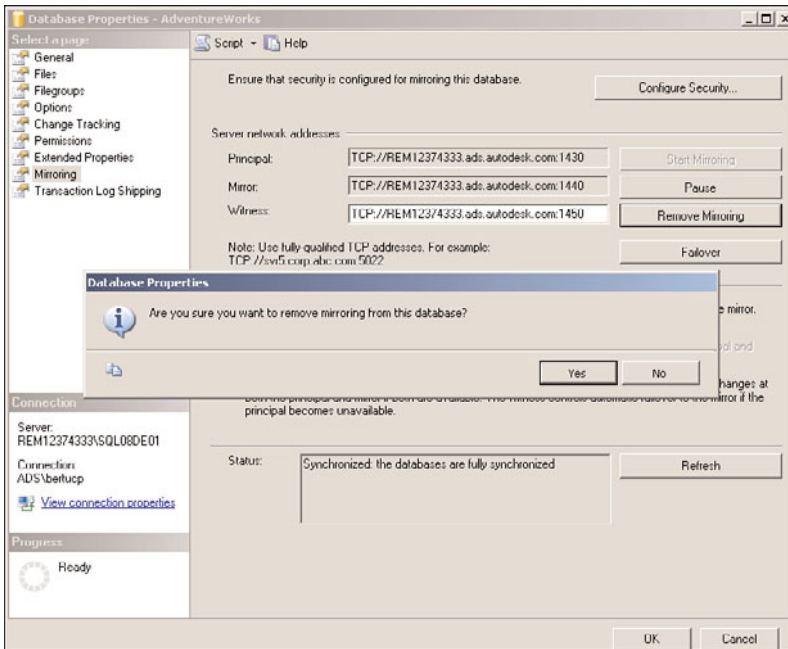

FIGURE 20.22 Removing database mirroring.

The mirroring process is immediately disabled. When mirroring is disabled, you can drop the database on the mirror server instance, remove the endpoints on each server instance (that is, principal, mirror, and witness instances), and be done—all through SSMS. This approach is straightforward.

If you're removing mirroring with SQL scripts, however, you need to break the mirroring from the principal, remove the principal's endpoint, drop the mirror database and remove the mirror's endpoint, and then drop the witness server's endpoint. At this point, all mirroring is removed. Follow along as we remove the database mirroring configuration we just set up.

The ALTER DATABASE and DROP ENDPOINT SQL commands break mirroring on the principal and remove the endpoint:

```
ALTER DATABASE AdventureWorks set partner off
go
DROP ENDPOINT EndPoint4DBMirroring1430
go
```

From the mirror server instance (not the principal!), you run the DROP DATABASE and DROP ENDPOINT SQL commands, as follows:

```
DROP DATABASE AdventureWorks
go
DROP ENDPOINT EndPoint4DBMirroring1440
go
```

From the witness server instance, you remove the endpoint as follows:

```
DROP ENDPOINT EndPoint4DBMirroring1450
go
```

To verify that you have removed these endpoints from each server instance, you simply run the following SELECT statements:

```
select name,type_desc,port,ip_address from sys.tcp_endpoints
select name,role_desc,state_desc from sys.database_mirroring_endpoints
```

All references to the endpoints and roles are removed.

You can also take a peek at the SQL Server log entries being made as you remove database mirroring:

```
02/05/2009 13:06:42,spid55,Unknown,The Database
    Mirroring protocol transport is disabled or not configured.
02/05/2009 13:06:40,spid55,Unknown,The Database Mirroring
    protocol transport has stopped listening for connections.
02/05/2009 12:52:55,spid19s,Unknown,Database mirroring
    connection error 4 'An error occurred while receiving
    data: '64(The specified network name is no longer
    available.)'.' for 'TCP:// REM1233..:1440'.
02/05/2009 12:52:55,spid19s,Unknown,Error: 1474
    <c/> Severity: 16<c/> State: 1.
02/05/2009 12:52:55,spid19s,Unknown,Database mirroring
    connection error 4 'An error occurred while
    receiving data: '64(The specified network name is
    no longer available.)'.' for 'TCP://REM1233..:1450'.
02/05/2009 12:52:55,spid19s,Unknown,Error: 1474
```

```
<c/> Severity: 16<c/> State: 1.
02/05/2009 12:51:14,spid21s,Unknown,Database mirroring
has been terminated for database 'AdventureWorks'.
```

These are all informational messages only. No user action is required. As you can see from these messages, you are now in a state of no database mirroring. You have to completely build up database mirroring again if you want to mirror the database again.

Testing Failover from the Principal to the Mirror

From the SSMS, you can easily fail over from the principal to the mirror server instance (and back again) by using the Failover button on the Database Properties Mirroring page, as shown in Figure 20.23.

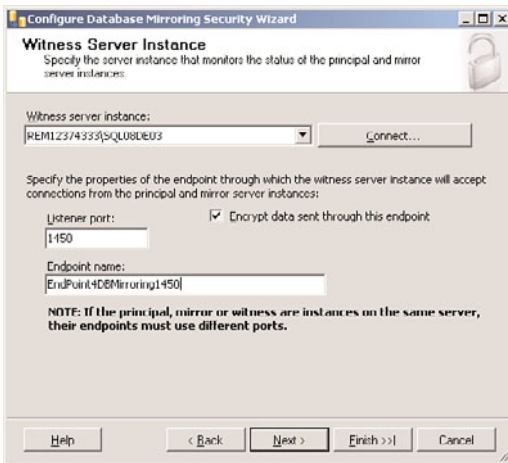

FIGURE 20.23 Testing failover of a mirrored database.

You must test this failover at some point to guarantee that it works. When you click the Failover button for this database mirroring configuration, you are prompted to continue with the failover by clicking Yes or No, as in the dialog shown in Figure 20.24.

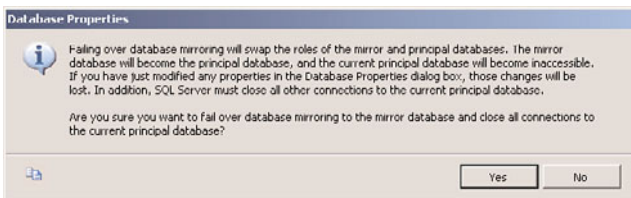

FIGURE 20.24 The failover message for database mirroring.

Remember that clicking Yes closes all connections to the principal server instance that are currently connected to this database. Later, we show you how to make your clients aware of both the principal and mirror server instances so that they can just pick up and run against either server instance, by design.

Now, if you look at the Database Properties Mirroring page (see Figure 20.25), you see that the principal and mirror listener port values have switched: the principal instance is now port value 1440, and the mirror instance is port value 1430. The server instances have completely switched their roles. You must now go to the server instance playing the principal role to fail over back to the original operating mode. If you try to open the current mirror server instance database, you get an error stating that you cannot access this database because it is in restore mode.

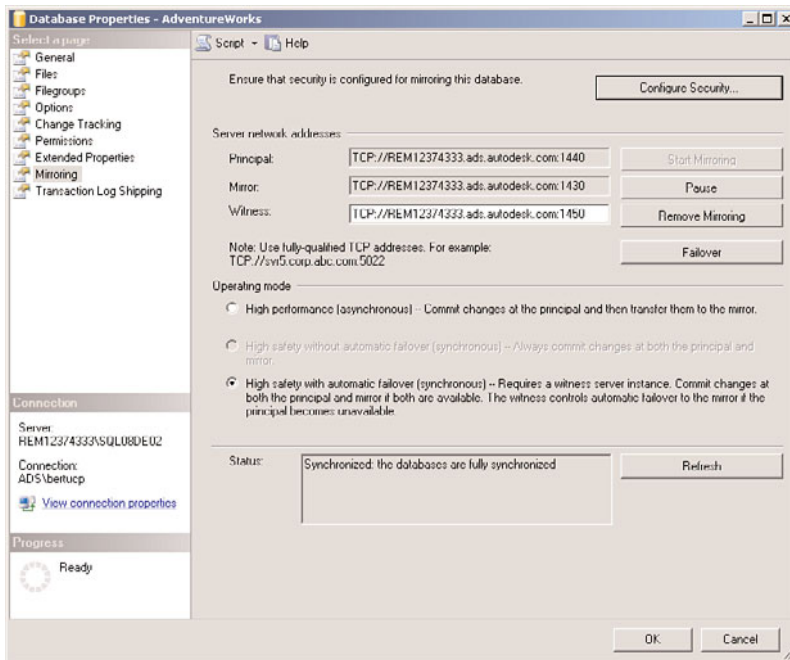

FIGURE 20.25 Server instances switch roles following a failover.

You can also manually run an `ALTER DATABASE` command to force failover to the mirrored server as follows:

```
ALTER DATABASE AdventureWorks set partner FAILOVER;
```

This command has the same effect as using SSMS or even shutting down the principal SQL Server instance service.

One last note with mirroring a database is that you cannot bring the principal offline as you would be able to do in an unmirrored configuration.

Client Setup and Configuration for Database Mirroring

Microsoft has enhanced the client connection capabilities to become mirroring aware. In other words, a client application is now able to connect to either partner in a mirrored configuration. The client would, of course, be connecting only to the server instance that is the current principal. With the help of an extension to the client connection configuration file, all .NET applications can easily add both partners to their connection string information, and when a principal fails, they can automatically establish a connection to the new principal (in a mirrored configuration). Figure 20.26 shows the added connection string information that you provide in the configuration file (app.config) for your application. This enhancement uses the `Failover Partner=` addition that identifies the proper failover server instance for this mirrored configuration.

FIGURE 20.26 A client connection string configuration identifying the failover partner.

As a bonus, we have provided a small .NET C# client application that you can easily use to test client connections in a database mirroring configuration. This C# solution file, `SQL Client DB Mirroring Test.zip`, is included in the Chapter 20 code samples on the CD supplied with this book. When you expand this file, it builds a complete .NET solution directory with all code needed for this test application. With Visual Studio, you just open the `WindowsApplication4.sln` file (solution file), and the entire application comes up in Visual Studio. Figure 20.27 shows this simple application in Visual Studio.

This simple test program displays data from the `Product` table in the `AdventureWorks` database (which you are mirroring), along with the exact date and time of the data retrieval, the name of the server instance the data came from, and the SQL process ID (SPID) of the current server instance. This way, you can easily see which physical server the data is coming from. If you are trying to use this program, all you have to do is update the `app.config` file connection string entry with your two partner server instance names (`REM12374333\SQL08DE01` and `REM12374333\SQL08DE02`, in this example):

```
ConnectionString=
"Server= REM12374333\SQL08DE01;
  Failover Partner= REM12374333\SQL08DE02;
  Database=AdventureWorks;..."
```

Then you execute the test application. This application automatically connects to the current principal database (`AdventureWorks` on the `REM12374333\SQL08DE01` server instance, in this example), as you can see in Figure 20.28.

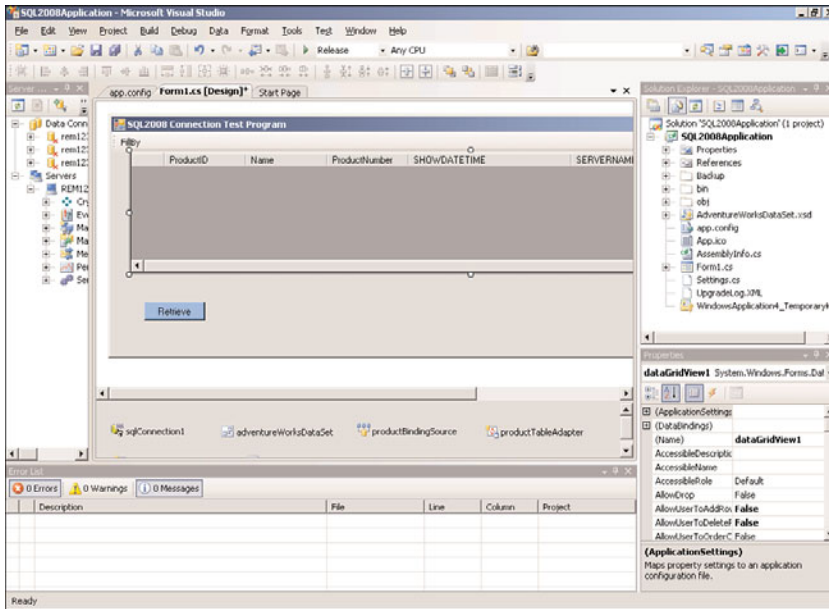

FIGURE 20.27 A SQL client test program for database mirroring in Visual Studio.

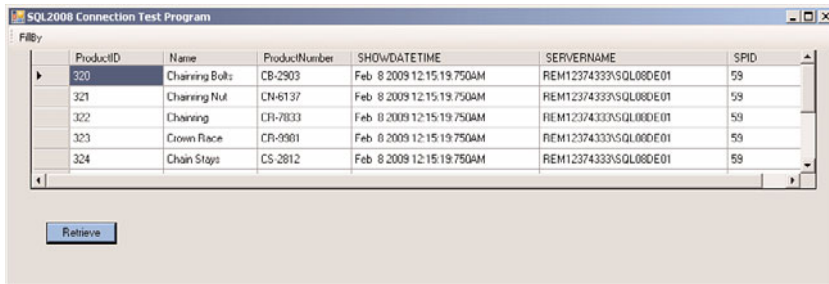

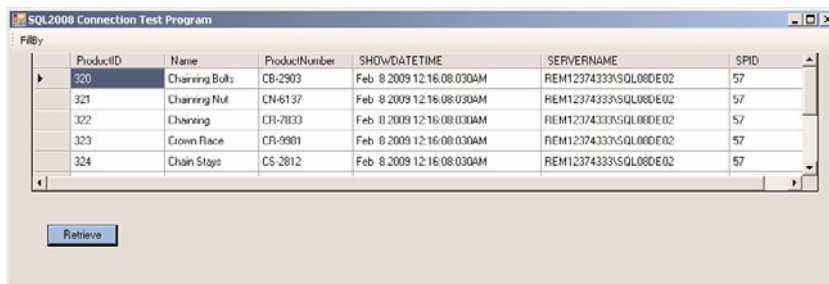

FIGURE 20.28 A SQL client test against the current principal server instance.

Next, you can fail over the principal to the mirror server, using the Database Properties Mirroring page's Failover button (refer to Figure 20.22). After you have failed this server over to its mirror (that is, switched roles), you simply click the Retrieve button at the bottom of the client test program to access the data in the AdventureWorks database again. Figure 20.29 shows this subsequent data retrieval. The test application shows the same data rows, along with the date and time of this data retrieval and the name of the server instance from which it got its data.

In this case, the data came from the other partner server instance (AdventureWorks on the REM12374333\SQL08DE02 server instance, in this example). The test application simply uses the added connection information to reestablish its connection to the failed-over server instance (that is, the mirror server), completely transparently to the application.

The screenshot shows a window titled "SQL2008 Connection Test Program". It contains a table with the following columns: ProductID, Name, ProductNumber, SHOWDATETIME, SERVERNAME, and SPID. The table has five rows of data. Below the table is a "Retrieve" button.

ProductID	Name	ProductNumber	SHOWDATETIME	SERVERNAME	SPID

FIGURE 20.29 A SQL client test against the current principal server instance (formerly the mirror server) after failover.

Migrate to Database Mirroring 2008 as Fast as You Can

During our ramp-up on SQL Server 2008, we decided to conduct a benchmark that pitted SQL Server 2005 database mirroring against the exact same configuration with SQL Server 2008 database mirroring. Microsoft had described some performance improvements and other added features that sounded like viable reasons to upgrade to SQL Server 2008. At the heart of our benchmark we would be seeing how much performance improvement was possible with the changes that Microsoft has made to compression of the transaction log records on the principal side, their transmission to the mirror, and the restore to the mirror. Using identical servers, we conducted a fully loaded test with heavy transaction rates—first on SQL Server 2005 and then the exact same database mirroring configuration and transaction load on SQL Server 2008 database mirroring. The results may astound you! First, we ran a transaction sequence of 100,000 iterations of complex update and insert processing against the SQL Server 2005 database mirroring configuration that we built up in this chapter. Figure 20.30 shows the overall load and elapsed time that execution took on SQL Server 2005.

As you can see from Figure 20.30, the load was heavy, and it took 6 hours and 5 minutes to complete the 100,000 transactions on the SQL Server 2005 database mirroring configuration. We then upgraded the exact same machines to SQL Server 2008 and ran the same transaction load. No other changes of any kind were made. Figure 20.31 shows the overall load and elapsed time of that identical transaction load (100,000 transactions) on SQL Server 2008.

As you can see, the exact same transaction load took 3 hours and 34 minutes to complete. This result is nearly 50% faster and is completely transparent from the database and transaction point of view. Truly remarkable. This translates into being roughly 50% faster in high availability and failover. We think this example provides more than enough justification to upgrade to SQL Server 2008 as fast as you can.

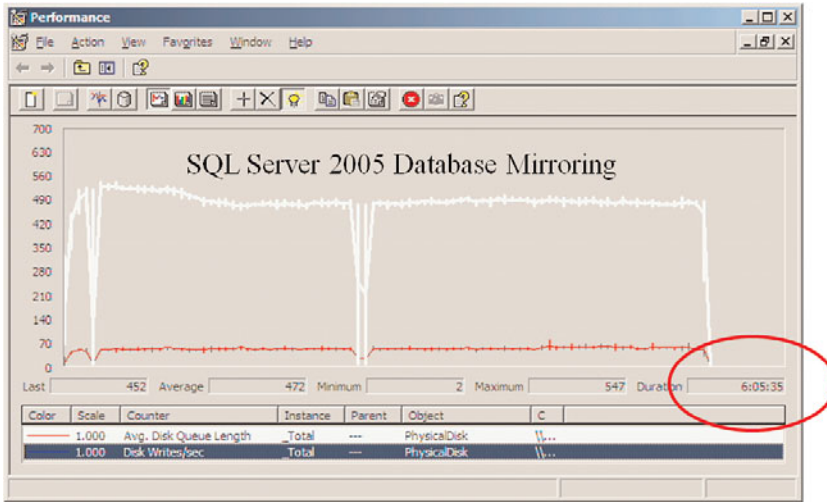

FIGURE 20.30 Transaction benchmark against SQL Server 2005 database mirroring.

FIGURE 20.31 Transaction benchmark against SQL Server 2008 database mirroring.

Summarizing, the benchmark results are as follows:

- ▶ Overall send rate 41% faster (2008 versus 2005)
- ▶ Overall restore rate 52% faster (2008 versus 2005)
- ▶ Overall availability topology inherits the restore rate yielding ~50% more availability.

We would like to thank the Peace Health database team of John Martin and Jason Riedberger for flawless benchmarking on both of these topologies.

Using Replication and Database Mirroring Together

SQL Server 2008 allows you to use combinations of options to achieve higher availability levels. A prime example would be to combine data replication with database mirroring to provide maximum availability of data, scalability to users, and fault tolerance via failover, potentially at each node in a replication topology. By starting with the publisher and perhaps the distributor, you make them both database mirror failover configurations. Figure 20.32 shows a possible data replication and database mirroring configuration (database mirroring of the publisher and database mirroring of the distributor). For further explanation of a transactional replication topology, see Chapter 19, “Replication.”

FIGURE 20.32 Rolling out database mirroring failover within data replication for scalability, availability, and fault tolerance.

Using database mirroring and replication together is essentially the best of both worlds: you get the super-low latency of database mirroring for fault tolerance, and you get high

availability (and scalability) of data through replication. The downside of this type of combined capability is that it requires additional servers (for mirroring of the databases). The upside is the increased scalability and resilience of your applications.

Using Database Snapshots from a Mirror for Reporting

A powerful configuration to help offload reporting workload is to use database snapshots with database mirroring. A database snapshot is a highly efficient feature of SQL Server 2008 that allows for the generation and use of a read-only, stable view of a database at a moment in time (hence, it's called a snapshot). The database snapshot is also created without the overhead of creating a complete copy of the database or having completely redundant storage. A database snapshot is simply a reference point of the pages used in the database (that is defined in the system catalog). When pages are updated, a new page chain is started that contains the data pages changed since the database snapshot was taken, as illustrated in Figure 20.33.

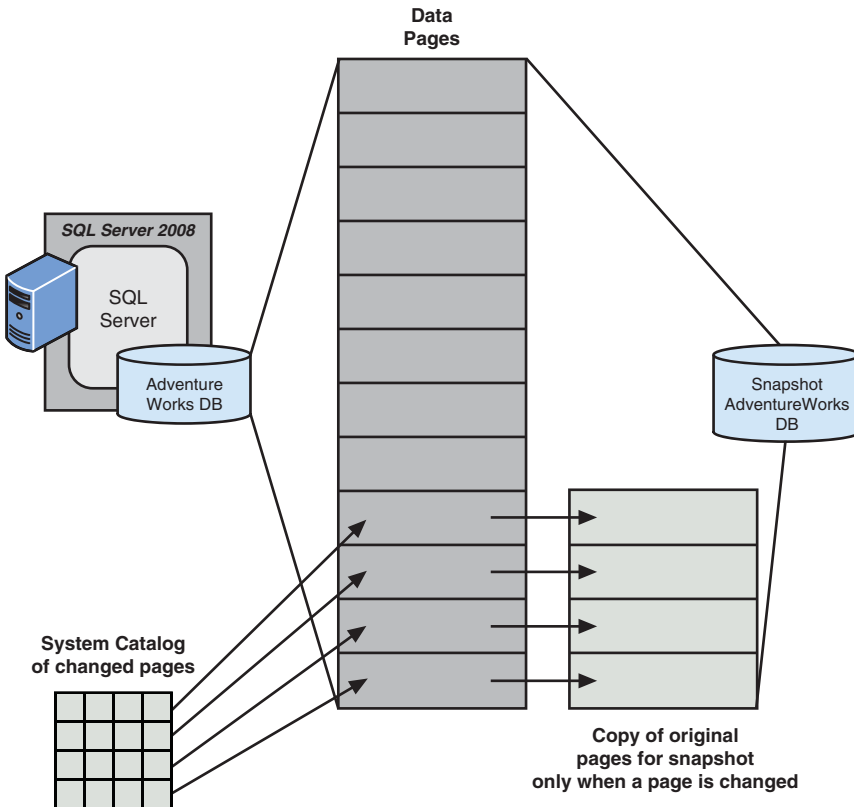

FIGURE 20.33 Database snapshots and the original database share pages and are managed within the system catalog of SQL Server 2008.

As the original database diverges from a snapshot, the snapshot gets its own copy of original pages when they are modified. The copy-on-write technology used for database mirroring also enables a database snapshot. When a database snapshot is created on a database (a mirror database, in this case), all writes check the system catalog of changed pages first; if the snapshot is not there, the original page is copied (using copy-on-write) and is put in a place for reference by the database snapshot (because the snapshot must be kept intact). In this way, a database snapshot and the original database share the data pages that have not changed.

Unlike a mirror database, a database snapshot can be accessed by a reporting client in read-only mode, as shown in Figure 20.34. As long as the mirror server is communicating to the principal, reporting clients can access the snapshot database.

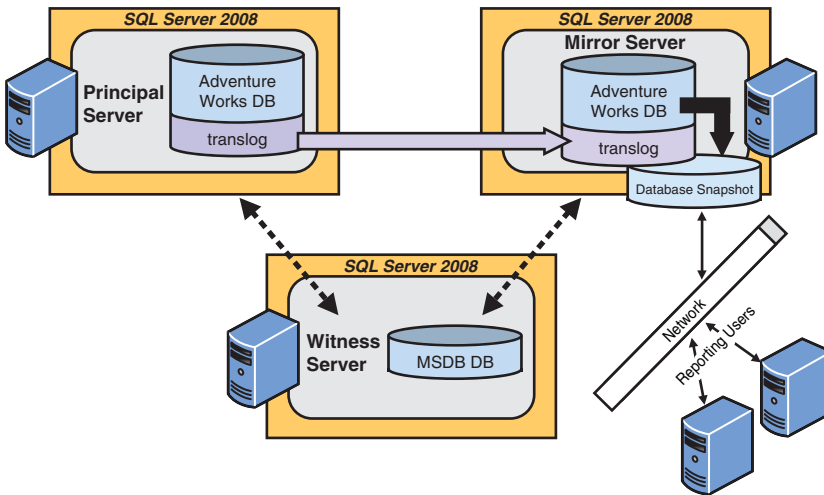

FIGURE 20.34 A database snapshot defined from a mirror server for reporting use.

If the principal fails over to the mirror server, the connections to the snapshot database are disconnected during the database restart process (which makes the mirror server the new principal server). It is possible to reconnect the reporting clients to the database snapshot after a failover is completed, but you must remember that now both the transactional clients and reporting clients are connected to a single SQL Server instance. This may not be acceptable from a performance point of view. Also, it is always a good idea to keep the number of snapshots to a minimum when creating them against a database mirror.

Chapter 32, “Database Snapshots,” covers how to create database snapshots.

Summary

Database mirroring is one of the most significant SQL Server features to come along in a long time. This feature has provided a way for users to get to a minimum level of high availability for their databases and applications without having to use complex hardware and software configurations (as are needed with MSCS and SQL Server Clustering configurations).

To mirror a database, you essentially ask for a complete copy of a database to be created and maintained up to the last committed transaction. The ease and simplicity of creating and monitoring database mirroring will quickly make it a configuration that many people use. Adding variations to this configuration, such as enhancing data replication or offloading reporting users, adds even more availability, resilience, and scalability possible than ever existed before. And, as you have seen, it is very easy to have your applications take advantage of database mirroring transparently. In addition, Microsoft has now improved on its overall performance and stability, coupled with three more years' worth of production implementations by companies around the globe. Moving to SQL Server 2008 database mirroring is now more than a rock solid path.

Chapter 21, "SQL Server Clustering," delves into the complexities and significant benefits of building high-availability solutions by using SQL Server Clustering.

CHAPTER 21

SQL Server Clustering

Enterprise computing requires that the entire set of technologies you use to develop, deploy, and manage mission-critical business applications be highly reliable, scalable, and resilient. These technologies include the network, entire technology stack, operating systems on the servers, applications you deploy, database management systems, and everything in between.

An enterprise must now be able to provide a complete solution in regards to the following:

- ▶ **Scalability**—As organizations grow, so does the need for more computing power. The systems in place must enable an organization to leverage existing hardware and to quickly and easily add computing power as needs demand.
- ▶ **Availability**—As organizations rely more on information, it is critical that the information be available at all times and under all circumstances. Downtime is not acceptable. Moving to five-nines reliability (which means 99.999% uptime) is a must, not a dream.
- ▶ **Interoperability**—As organizations grow and evolve, so do their information systems. It is impractical to think that an organization will not have many heterogeneous sources of information. It is becoming increasingly important for applications to get to all the information, regardless of its location.
- ▶ **Reliability**—An organization is only as good as its data and information. It is critical that the systems providing that information be bulletproof.

IN THIS CHAPTER

- ▶ What's New in SQL Server Clustering
- ▶ How Microsoft SQL Server Clustering Works
- ▶ Installing SQL Server Clustering

It is assumed that you will provide a certain level of foundational capabilities in regard to network, hardware, and operating system resilience. The good news is that you can achieve many of your enterprise's demands easily and inexpensively by using Microsoft Cluster Services (MSCS), Network Load Balancing (NLB), and SQL Server Clustering (or combinations of them).

What's New in SQL Server Clustering

Much of what's new for MSCS and SQL Server Clustering has to do with the expanded number of nodes that can be managed together and several ease-of-use enhancements in MSCS, including the following:

- ▶ **Setup changes for SQL Server failover clustering**—One option forces you to run the Setup program on each node of the failover cluster. To add a node to an existing SQL Server failover cluster, you must run SQL Server Setup on the node that is to be added to the SQL Server failover cluster instance. Another option creates an enterprise push to nodes from the active node.
- ▶ **Cluster nodes residing on different subnets**—With Windows 2008, cluster nodes can now reside on different network subnets across network routers. You no longer have to stretch virtual local area networks to connect geographically separated cluster nodes. This opens the door to clustered disaster recovery options.
- ▶ **Instances per cluster**—SQL Server 2008 Enterprise Edition supports up to 25 SQL Server instances per cluster (up to 50 for a nonclustered server).
- ▶ **More cluster-aware applications**—Many of the MS SQL Server 2008 products are cluster aware, such as Analysis Services, Full Text Search, Integration Services, Reporting Services, FILESTREAM, and others, making these applications more highly available and resilient.
- ▶ **Isolation of the quorum disk in MSCS**—A shared disk partition that is *not* on the same physical drive/LUN as the quorum drive must be available in an attempt to reduce failure dependencies.
- ▶ **Number of nodes in a cluster**—With Windows 2003 Enterprise Edition (or Datacenter), you can now create up to 8 nodes in a single cluster, and with Windows 2008 Enterprise Edition (or Datacenter), you can create up to 16 nodes.

These new features and enhancements combine to make setting up SQL Server Clustering an easy high-availability proposition. They take much of the implementation risk out of the equation and make this type of installation available to a broader installation base.

How Microsoft SQL Server Clustering Works

Put simply, SQL Server 2008 allows failover and failback to or from another node in a cluster. This is an immensely powerful tool for achieving higher availability virtually transparently. There are two approaches to implementing SQL Server Clustering: active/passive or active/active modes.

In an active/passive configuration, an instance of SQL Server actively services database requests from one of the nodes in a SQL Server cluster (that is, the active node). Another node is idle until, for whatever reason, a failover occurs (to the passive node). With a failover situation, the secondary node (the passive node) takes over all SQL Server resources (for example, databases and the Microsoft Distributed Transaction Coordinator [MSDTC]) without the end user ever knowing that a failover has occurred. The end user might experience a brief transactional interruption because SQL Server Failover Clustering cannot take over in-flight transactions. However, the end user still just looks at a single (virtual) SQL Server and truly doesn't care which node is fulfilling requests.

Figure 21.1 shows a typical two-node SQL Server Clustering configuration using active/passive mode, in which Node 2 is idle (that is, passive).

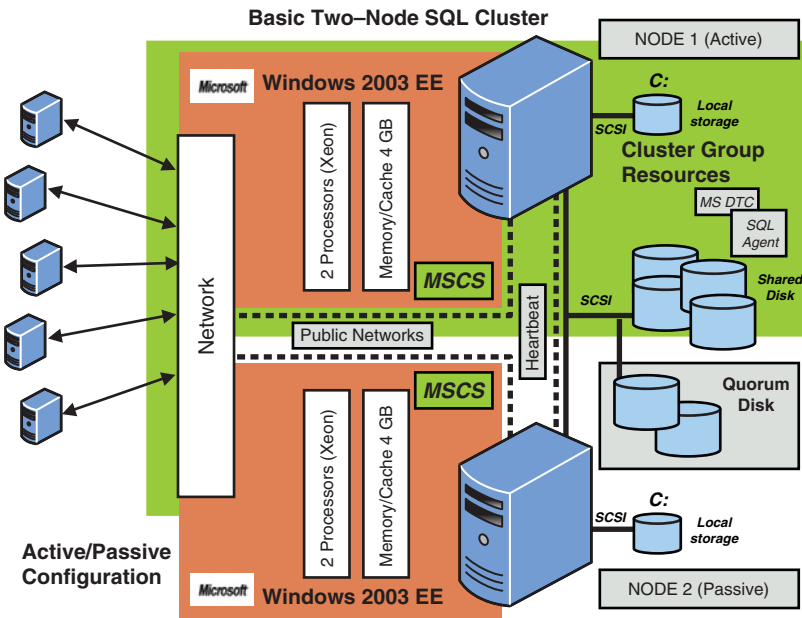

FIGURE 21.1 A typical two-node active/passive SQL Server Clustering configuration.

In an active/active configuration, SQL Server runs multiple servers simultaneously with different databases. This gives organizations with more constrained hardware requirements a chance to use a clustering configuration that can fail over to or from any node, without having to set aside idle hardware.

As previously mentioned, SQL Server Clustering is actually created within (on top of) MSCS. MSCS, not SQL Server, is capable of detecting hardware or software failures and automatically shifting control of the managed resources to a healthy node. SQL Server 2008 implements failover clustering based on the clustering features of the Microsoft Clustering Service. In other words, SQL Server is a fully cluster-aware application and

becomes a set of resources managed by MSCS. The failover cluster shares a common set of cluster resources (or cluster groups), such as clustered (that is, shared) disk drives.

NOTE

You can install SQL Server on as many servers as you want; the number is limited only by the operating system license and SQL Server edition you have purchased. However, MSCS (for Windows 2008) can manage only up to 16 instances of Microsoft SQL Server Standard Edition at a time and up to 25 instances of Microsoft SQL Server Enterprise Edition at a time.

Understanding MSCS

A *server cluster* is a group of two or more physically separate servers running MSCS and working collectively as a single system. The server cluster, in turn, provides high availability, scalability, and manageability for resources and applications. In other words, a group of servers is physically connected via communication hardware (network), shares storage (via SCSI or Fibre Channel connectors), and uses MSCS software to tie them all together into managed resources.

Server clusters can preserve client access to applications and resources during failures and planned outages. If one of the servers in a cluster is unavailable due to failure or maintenance, resources and applications move to another available cluster node.

NOTE

You cannot do clustering with Windows 2000 Professional or older server versions. Clustering is available only on servers running Windows 2000 Advanced Server (which supports two-node clusters), Windows 2000 Datacenter Server (which supports up to four-node clusters), Windows 2003 Enterprise Edition and Datacenter Server, and Windows 2008 Enterprise Edition and Datacenter Server.

Clusters use an algorithm to detect a failure, and they use failover policies to determine how to handle the work from a failed server. These policies also specify how a server is to be restored to the cluster when it becomes available again.

Although clustering doesn't guarantee continuous operation, it does provide availability sufficient for most mission-critical applications and is the building block of numerous high-availability solutions. MSCS can monitor applications and resources, automatically recognizing and recovering from many failure conditions. This capability provides great flexibility in managing the workload within a cluster, and it improves the overall availability of the system. Technologies that are "cluster aware"—such as SQL Server, Microsoft Message Queuing (MSMQ), Microsoft Distributed Transaction Coordinator (MSDTC), and file shares—have already been programmed to work within (under the control of) MSCS.

TIP

In previous versions of MSCS, the COMCLUST.EXE utility had to be run on each node to cluster the MSDTC. It is now possible to configure MSDTC as a resource type, assign it to a resource group, and then have it automatically configured on all cluster nodes.

MSCS is relatively sensitive to the hardware and network equipment you put in place. For this reason, it is imperative that you verify your own hardware's compatibility *before* you go any further in deploying MSCS (check the hardware compatibility list at <http://msdn.microsoft.com/en-us/library/ms189910.aspx>). In addition, SQL Server failover cluster instances are not supported where the cluster nodes are also domain controllers.

Let's look a little closer at a two-node active/passive cluster configuration. As you can see in Figure 21.2, the *heartbeat* (named ClusterInternal in this figure) is a private network set up between the nodes of the cluster that checks whether a server is up and running ("is alive"). This occurs at regular intervals, known as *time slices*. If the heartbeat is not functioning, a failover is initiated, and another node in the cluster takes over for the failed node. In addition to the heartbeat private network, at least one public network (named ClusterPublic in this figure) must be enabled so that external connections can be made to the cluster. Each physical server (node) uses separate network adapters for each type of communication (public and internal heartbeat).

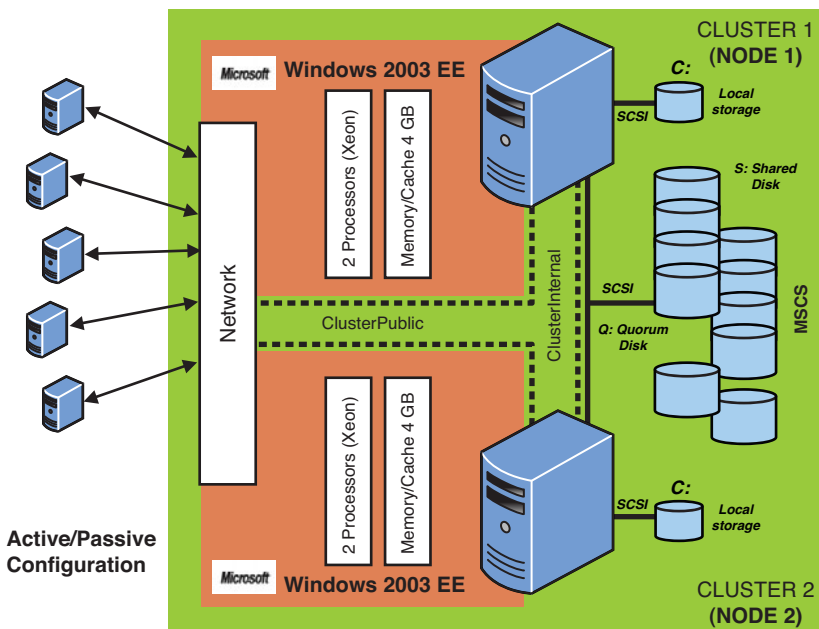

FIGURE 21.2 A two-node active/passive MSCS cluster configuration.

The *shared disk* array is a collection of physical disks (SCSI RAID or Fibre Channel–connected disks) that the cluster accesses and controls as resources. MSCS supports *shared nothing* disk arrays, in which only one node can own a given resource at any given moment. All other nodes are denied access until they own the resource. This protects the data from being overwritten when two computers have access to the same drives concurrently.

The *quorum drive* is a logical drive designated on the shared disk array for MSCS. This continuously updated drive contains information about the state of the cluster. If this drive becomes corrupt or damaged, the cluster installation also becomes corrupt or damaged.

NOTE

In general (and as part of a high-availability disk configuration), the quorum drive should be isolated to a drive all by itself and be mirrored to guarantee that it is available to the cluster at all times. Without it, the cluster doesn't come up at all, and you cannot access your SQL databases.

The MSCS architecture requires there to be a single quorum resource in the cluster that is used as the tie-breaker to avoid split-brain scenarios. A *split-brain scenario* happens when all the network communication links between two or more cluster nodes fail. In these cases, the cluster may be split into two or more partitions that cannot communicate with each other. MSCS guarantees that even in these cases, a resource is brought online on only one node. If the different partitions of the cluster each brought a given resource online, this would violate what a cluster guarantees and potentially cause data corruption. When the cluster is partitioned, the quorum resource is used as an arbiter. The partition that owns the quorum resource is allowed to continue. The other partitions of the cluster are said to have “lost quorum,” and MSCS and any resources hosted on nodes that are not part of the partition that has quorum are terminated.

The quorum resource is a storage-class resource and, in addition to being the arbiter in a split-brain scenario, is used to store the definitive version of the cluster configuration. To ensure that the cluster always has an up-to-date copy of the latest configuration information, you should deploy the quorum resource on a highly available disk configuration (using mirroring, triple-mirroring, or RAID 10, at the very least).

Starting with Windows 2003, a more durable approach of managing the quorum disks with clustering was created, called *majority node set*. It all but eliminates the single-point-of-failure weakness in the traditional quorum disk configuration that existed with Windows 2000 servers. However, even this approach isn't always the best option for many clustered scenarios.

The notion of quorum as a single shared disk resource means that the storage subsystem has to interact with the cluster infrastructure to provide the illusion of a single storage device with very strict semantics. Although the quorum disk itself can be made highly available via RAID or mirroring, the controller port may be a single point of failure. In addition, if an application inadvertently corrupts the quorum disk or an operator takes down the quorum disk, the cluster becomes unavailable.

This situation can be resolved by using a majority node set option as a single quorum resource from an MSCS perspective. In this set, the cluster log and configuration information are stored on multiple disks across the cluster. A new majority node set resource ensures that the cluster configuration data stored on the majority node set is kept consistent across the different disks.

The disks that make up the majority node set could, in principle, be local disks physically attached to the nodes themselves or disks on a shared storage fabric (that is, a collection of centralized shared storage area network [SAN] devices connected over a switched-fabric or Fibre Channel–arbitrated loop SAN). In the majority node set implementation that is provided as part of MSCS in Windows Server 2003 and 2008, every node in the cluster uses a directory on its own local system disk to store the quorum data, as shown in Figure 21.3.

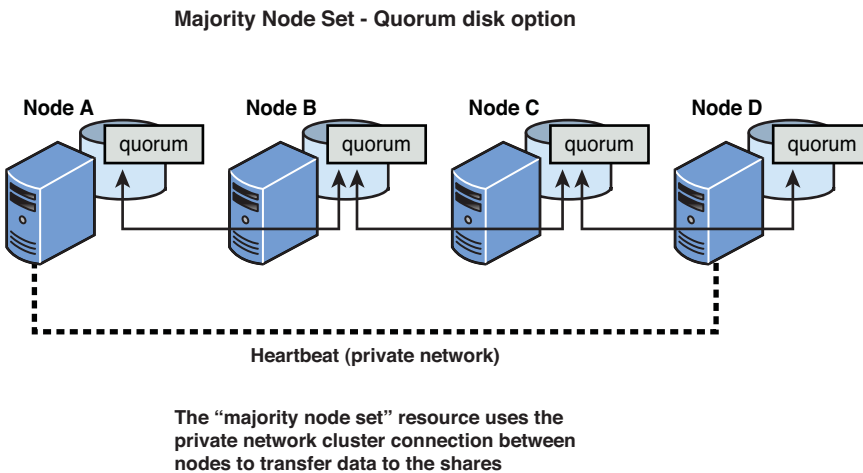

FIGURE 21.3 A majority node set.

If the configuration of the cluster changes, that change is reflected across the different disks. The change is considered to have been committed (that is, made persistent) only if that change is made to a majority of the nodes (that is, $\lceil \text{Number of nodes configured in the cluster} / 2 \rceil + 1$). In this way, a majority of the nodes have an up-to-date copy of the data. MSCS itself starts up only if a majority of the nodes currently configured as part of the cluster are up and running as part of MSCS.

If there are fewer nodes, the cluster is said *not* to have quorum, and therefore MSCS waits (trying to restart) until more nodes try to join. Only when a majority (or quorum) of nodes are available does MSCS start up and bring the resources online. This way, because the up-to-date configuration is written to a majority of the nodes, regardless of node failures, the cluster always guarantees that it starts up with the most up-to-date configuration.

With Windows 2008, a few more quorum drive configurations are possible that address various voting strategies and also support geographically separated cluster nodes.

In Windows Server 2008 failover clustering, you have four choices on how to implement the quorum:

- ▶ One option is to use Node majority; a vote is given to each node of the cluster, and the cluster continues to run as long as a majority of nodes are up and running.
- ▶ A second option is to use both the nodes and the standard quorum disk, a common option for two-node clusters. Each node gets a vote, and the quorum, now called a *witness disk*, also gets a vote. As long as two of the three are running, the cluster continues. The cluster can actually lose the witness disk and still run.
- ▶ A third option is to use the classic/legacy model and assign a vote to the witness disk only. This type of quorum equates to the well-known, tried-and-true model that has been used for years.
- ▶ A fourth option is, of course, to use the majority node set (MNS) model with a file share witness.

We describe only the standard majority node set approach here.

TIP

A quick check to see whether your hardware (server, controllers, and storage devices) is listed on Microsoft's Hardware Compatibility List will save you headaches later. See the hardware pre-installation checklist at <http://msdn.microsoft.com/en-us/library/ms189910.aspx>.

Extending MSCS with NLB

You can also use a critical technology called Network Load Balancing (NLB) to ensure that a server is always available to handle requests. NLB works by spreading incoming client requests among a number of servers linked together to support a particular application. A typical example is to use NLB to process incoming visitors to your website. As more visitors come to your site, you can incrementally increase capacity by adding servers. This type of expansion is often referred to as *software scaling*, or *scaling out*. Figure 21.4 illustrates this extended clustering architecture with NLB.

By using both MSCS and NLB clustering technologies together, you can create an *n*-tier infrastructure. For instance, you can create an *n*-tiered e-commerce application by deploying NLB across a front-end web server farm and use MSCS clustering on the back end for your line-of-business applications, such as clustering your SQL Server databases. This approach gives you the benefits of near-linear scalability without server- or application-based single points of failure. This, combined with industry-standard best practices for designing high-availability networking infrastructures, can ensure that your Windows-based, Internet-enabled business will be online all the time and can quickly scale to meet

MSCS with Network Load Balancing

FIGURE 21.4 An NLB configuration.

demand. Other tiers could be added to the topology, such as an application-center tier that uses component load balancing. This further extends the clustering and scalability reach for candidate applications that can benefit from this type of architecture.

How MSCS Sets the Stage for SQL Server Clustering

Figure 21.5 shows an Excel spreadsheet that documents all the needed Internet Protocol (IP) addresses, network names, domain definitions, and SQL Server references to set up a two-node SQL Server Clustering configuration (configured in an active/passive mode). CLUSTER1 is the first node, CLUSTER2 is the second node, and the cluster group name is CLUSTER >GROUP (simple naming is used here to better illustrate the point). The public network name is ClusterPublic, and the internal heartbeat network name is ClusterInternal. This spreadsheet has also been included in the download files on the CD for this book. It's a good idea to fill out this spreadsheet *before* you start installing and configuring your servers.

FIGURE 21.5 An Excel spreadsheet for a two-node active/passive SQL Cluster configuration.

The cluster controls the following resources:

- ▶ Physical disks (Q: is for the quorum disk, S: is for the shared disks, and so on.)
- ▶ The cluster IP address
- ▶ The cluster name (network name)
- ▶ The Distributed Transaction Coordinator (MSDTC)
- ▶ The SQL Server virtual IP address
- ▶ The SQL Server virtual name (network name)
- ▶ SQL Server
- ▶ SQL Server Agent
- ▶ The SQL Server Full-Text Search service instance (if installed)

After you successfully install, configure, and test your cluster (MSCS), you are ready to add the SQL Server components as resources to be managed by MSCS. This is where the magic

happens. Figure 21.6 shows how the Cluster Administrator should look after you install/configure MSCS. It doesn't have SQL Server 2008 installed yet.

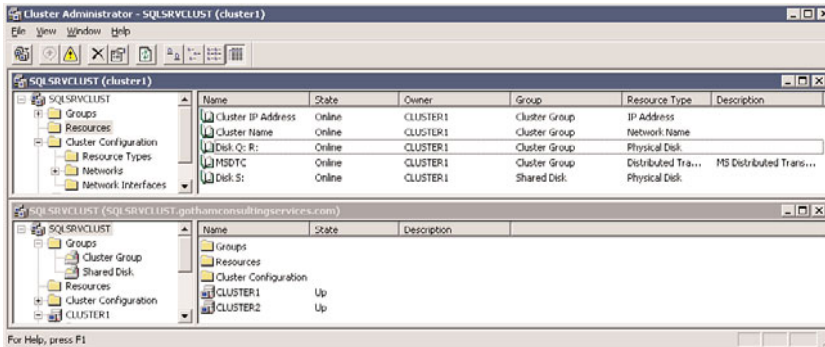

FIGURE 21.6 Windows 2003 Cluster Administrator, showing managed resources prior to installing SQL Server.

Installing SQL Server Clustering

When you install SQL Server in a clustered server configuration, you create it as a virtual SQL Server. A virtual SQL Server is not tied to a specific physical server; it is associated with a virtualized SQL Server name that is assigned a separate IP address (not the IP address or name of the physical servers on which it runs). Handling matters this way allows for your applications to be completely abstracted away from the physical server level.

Failover clustering has a new workflow for all Setup scenarios in SQL Server 2008. The two options for installation are

- ▶ **Integrated installation**—This option creates and configures a single-node SQL Server failover cluster instance. Additional nodes are added by using the Add Node functionality in Setup. For example, for Integrated installation, you run Setup to create a single-node failover cluster. Then you run Setup again for each node you want to add to the cluster.
- ▶ **Advanced/Enterprise installation**—This option consists of two steps; the prepare step prepares all nodes of the failover cluster to be operational. Nodes are defined and prepared during this initial step. After you prepare the nodes, the Complete step is run on the active node—the node that owns the shared disk—to complete the failover cluster instance and make it operational.

Figure 21.7 shows the same two-node cluster configuration as Figure 21.1, with all the SQL Server components identified. This virtual SQL Server is the only thing the end user will ever see. As you can also see in Figure 21.7, the virtual server name is `VSQSERVER2008`, and the SQL Server instance name defaults to `blank` (you can, of course, give your instance a name). Figure 21.7 also shows the other cluster group resources that will be part of the SQL Server Clustering configuration: MSDTC, SQL Agent, SQL Server Full-Text Search, and the shared disk where the databases will live.

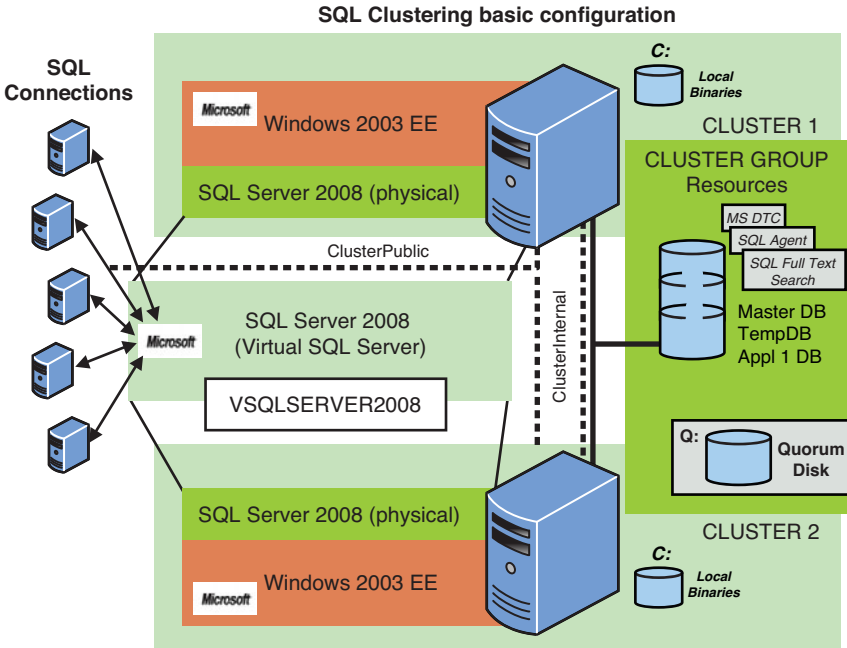

FIGURE 21.7 A basic SQL Server Clustering configuration.

SQL Server Agent will be installed as part of the SQL Server installation process, and it is associated with the SQL Server instance it is installed for. The same is true for SQL Server Full-Text Search; it is associated with the particular SQL Server instance that it is installed to work with. The SQL Server installation process completely installs all software on all nodes you designate.

Configuring SQL Server Database Disks

Before we go too much further, we need to talk about how you should lay out a SQL Server implementation on the shared disks managed by the cluster. The overall usage intent of a particular SQL Server instance dictates how you might choose to configure your shared disk and how it might be best configured for scalability and availability.

In general, RAID 0 is great for storage that doesn't need fault tolerance; RAID 1 or RAID 10 is great for storage that needs fault tolerance but doesn't have to sacrifice too much performance (as with most online transaction processing [OLTP] systems); and RAID 5 is great for storage that needs fault tolerance but whose data doesn't change that much (that is, low data volatility, as in many decision support systems [DSS]/read-only systems).

All this means that there is a time and place to use each of the different fault-tolerant disk configurations. Table 21.1 provides a good rule of thumb to follow for deciding which SQL Server database file types should be placed on which RAID level disk configuration. (This would be true regardless of whether or not the RAID disk array was a part of a SQL Server cluster.)

TABLE 21.1 SQL Server Clustering Disk Fault-Tolerance Recommendations

Device	Description	Fault Tolerance
Quorum drive	The quorum drive used with MSCS should be isolated to a drive by itself (often mirrored as well, for maximum availability).	RAID 1 or RAID 10
OLTP SQL Server database files	For OLTP systems, the database data/index files should be placed on a RAID 10 disk system.	RAID 10
DSS SQL Server database files	For DSSs that are primarily read-only, the database data/index files should be placed on a RAID 5 disk system.	RAID 5
tempdb	This is a highly volatile form of disk I/O (when not able to do all its work in the cache).	RAID 10
SQL Server transaction log files	The SQL Server transaction log files should be on their own mirrored volume for both performance and database protection. (For DSSs, this could be RAID 5 also.)	RAID 10 or RAID 1

TIP

A good practice is to balance database files across disk arrays (that is, controllers). In other words, if you have two (or more) separate shared disk arrays (both RAID 10) available within a cluster group's resources, you should put the data file of Database 1 on the first cluster group disk resource (for example, DiskRAID10-A) and its transaction log on the second cluster group disk resource (for example, DiskRAID10-B). Then you should put the data file of Database 2 on the second cluster group disk resource of DiskRAID10-B and its transaction log on the first cluster group disk resource of DiskRAID10-A. In this way, you can stagger these allocations and in general balance the overall RAID controller usage, minimizing any potential bottlenecks that might occur on one disk controller. In addition, FILESTREAM filegroups must be put on a shared disk, and FILESTREAM must be enabled on each node in the cluster that will host the FILESTREAM instance. You can also use geographically dispersed cluster nodes, but additional items such as network latency and shared disk support must be verified before you get started. Check the Geographic Cluster hardware Compatibility List (<http://msdn.microsoft.com/en-us/library/ms189910.aspx>). On Windows 2008, most hardware and iSCSI supported hardware can be used, without the need to use "certified hardware." When you are creating a cluster on Windows 2008, you can use the cluster validation tool to validate the Windows cluster; it also blocks SQL Server Setup when problems are detected with the Windows 2008 cluster.

Installing Network Interfaces

You might want to take a final glance at Cluster Administrator so that you can verify that both CLUSTER1 and CLUSTER2 nodes and their private and public network interfaces are completely specified and their state (status) is up. If you like, you should also double-check the IP addresses and network names against the Excel spreadsheet created for this cluster specification.

Installing MSCS

As you can see in Figure 21.8, the MSCS “service” is running and has been started by the ClusterAdmin login account for the GOTHAM domain.

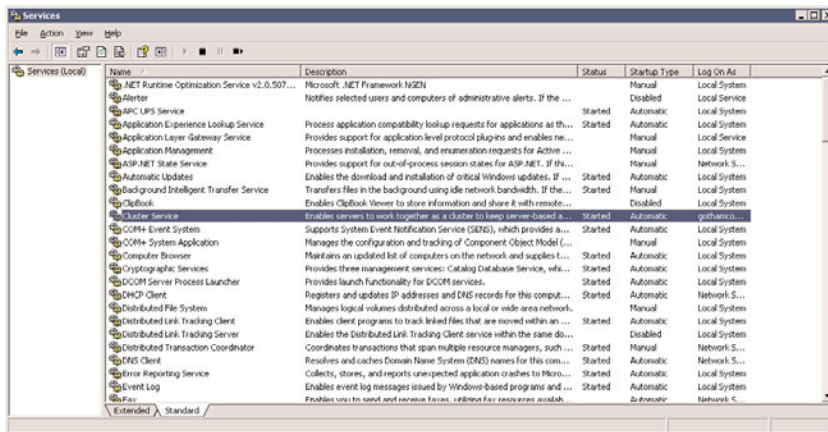

FIGURE 21.8 You need to make sure MSCS is running and started by the cluster account for the domain.

NOTE

If MSCS is not started and won't start, you cannot install SQL Server Clustering. You have to remove and then reinstall MSCS from scratch. You should browse the Event Viewer to familiarize yourself with the types of warnings and errors that can appear with MSCS.

Installing SQL Server

For SQL Clustering, you must install a new SQL Server instance within a minimum two-node cluster. You should not move a SQL Server instance from a nonclustered configuration to a clustered configuration. If you already have SQL Server installed in a nonclustered environment, you need to make all the necessary backups (or detach databases) first, and then you need to uninstall the nonclustered SQL Server instance. Some

upgrade paths and migration paths are possible from prior versions of SQL Server and Windows server. You are also limited to a maximum of 25 instances of SQL Server per failover cluster. There is no uninstall SQL Server failover cluster option; you must run Setup from the node that is to be removed. You must specify the same product key on all the nodes that you are preparing for the same failover cluster. You also should make sure you use the same SQL Server instance ID for all the nodes that are prepared for the failover cluster.

With all MSCS resources running and in the online state, you run the SQL Server Setup program from the node that is online (for example, CLUSTER1). You are asked to install all software components required prior to installing SQL Server (.NET Framework 3.0 or 3.5, Microsoft SQL Native Client, and the Microsoft SQL Server 2008 Setup support files).

SQL Server integrated failover cluster installation consists of the following steps:

1. Create and configure a single-node SQL Server failover cluster instance. When you configure the node successfully, you have a fully functional failover cluster instance. At this point, it does not have high availability because there is only one node in the failover cluster.
2. On each node to be added to the SQL Server failover cluster, run Setup with Add Node functionality to add that node.

Alternatively, you can use the following SQL Server Advanced/Enterprise failover cluster installation:

1. On each node that will be an owner of the new SQL Server failover cluster, follow the Prepare Failover Cluster setup steps listed in the Prepare section. After you run the Prepare Failover Cluster on one node, Setup creates the `Configuration.ini` file, which lists all the settings you specified. On the additional nodes to be prepared, instead of following these steps, you can supply the `Configuration.ini` file from first node as an input to the Setup command line. This step prepares the nodes ready to be clustered, but there is no operational instance of SQL Server at the end of this step.
2. After the nodes are prepared for clustering, run Setup on one of the prepared nodes, preferably on the node that owns the shared disk that has the Complete Failover Cluster functionality. This step configures and finishes the failover cluster instance. After completing this step, you have an operational SQL Server failover cluster instance, and all the nodes prepared previously for that instance are the possible owners of the newly created SQL Server failover cluster.

After you take these steps, the standard Welcome to SQL Server Installation Center Wizard begins. It starts with a System Configuration check of the node in the cluster (CLUSTER1). Figure 21.9 shows the SQL Server Installation Center launch dialog and the results of a successful system check for CLUSTER1.

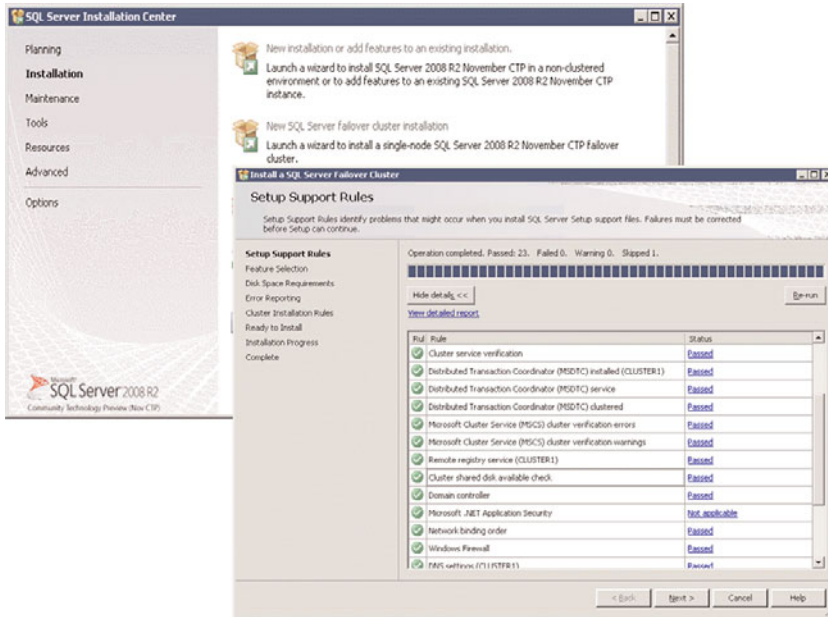

FIGURE 21.9 A Microsoft SQL Server Setup Support Rules check.

NOTE

SQL Server Clustering is available with SQL Server 2008 Standard Edition, Enterprise Edition, and Developer Edition. However, Standard Edition supports only a two-node cluster. If you want to configure a cluster with more than two nodes, you need to upgrade to SQL Server 2008 Enterprise Edition.

If this check fails (warnings are acceptable), you must resolve them before you continue. If the check is successful, you are then prompted for the checklist of features you want to install. Figure 21.10 shows the Feature Selection to install dialog.

You then see the Instance Configuration dialog, as shown in Figure 21.11, where you specify the network name for the new SQL Server failover cluster (the Virtual Server name, `VSQSERVER2008` in this example) and then either can use the default SQL Server instance name (no name) or specify a unique SQL Server instance name (we chose to use the default instance name of `MSSQLSERVER`).

This virtual SQL Server name is the name the client applications will see (and to which they will connect). When an application attempts to connect to an instance of SQL Server 2008 that is running on a failover cluster, the application must specify both the virtual server name and instance name (if an instance name was used), such as `VSQSERVER2008\VSQSRV1` (virtual server name\SQL Server instance name) or `VSQSERVER2008` (just the virtual server name without the default SQL Server instance

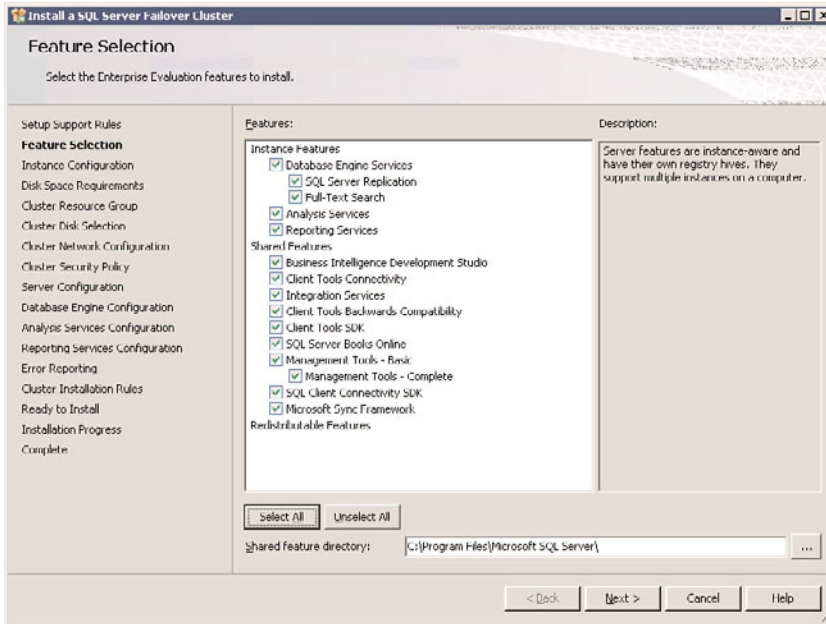

FIGURE 21.10 The SQL Server Setup Feature Selection dialog for a SQL Server Failover Cluster.

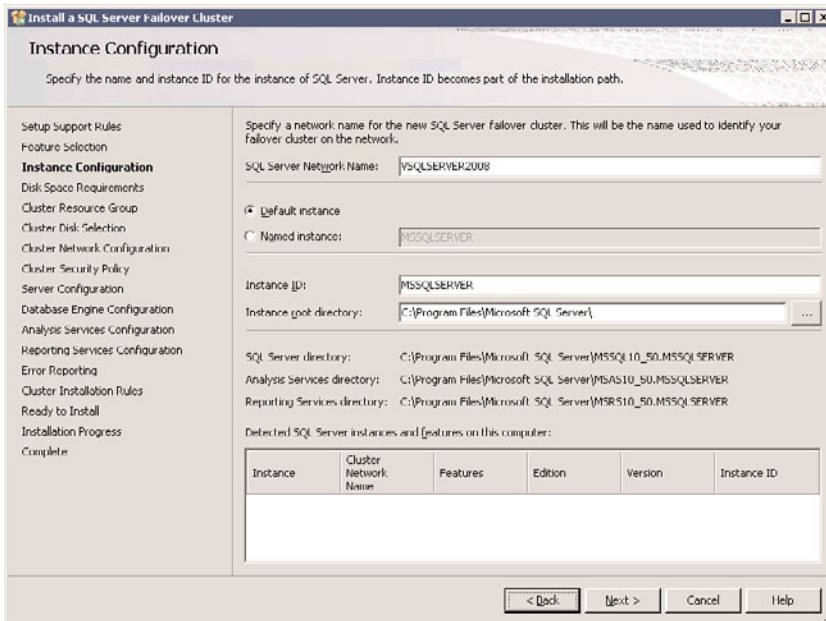

FIGURE 21.11 Specifying the virtual server name (VSQSERVER2008) and default instance.

name). The virtual server name must be unique on the network. You also specify the local directory locations (root) for the installation.

NOTE

A good naming convention to follow is to preface all virtual SQL Server names and virtual SQL Server instance names with a V. This way, you can easily identify which SQL Server machines on your network are clustered. For example, you could use `VSQSERVER2008` as a virtual SQL Server name and `VSQSRV1` as an instance name.

Next comes the disk space requirements dialog, followed by the Cluster Resource Group specification. This is where the SQL Server resources are placed within MSCS. Here, you use the existing resource cluster group (named `Cluster Group`). Immediately following the resource group assignment comes the identification of which clustered disks are to be used via the Cluster Disk Selection dialog, shown in Figure 21.12. It contains an `S:` drive (which you want SQL Server to use) and `Q:` and `R:` drive being used for the quorum files (do not select this drive!). You simply select the available drive(s) where you want to put your SQL database files (the `S:` drive in this example). As you can also see, the only “qualified” disk is the `S:` drive. If the quorum resource is in the cluster group you have selected, a warning message is issued, informing you of this fact. A general rule of thumb is to isolate the quorum resource to a separate cluster group.

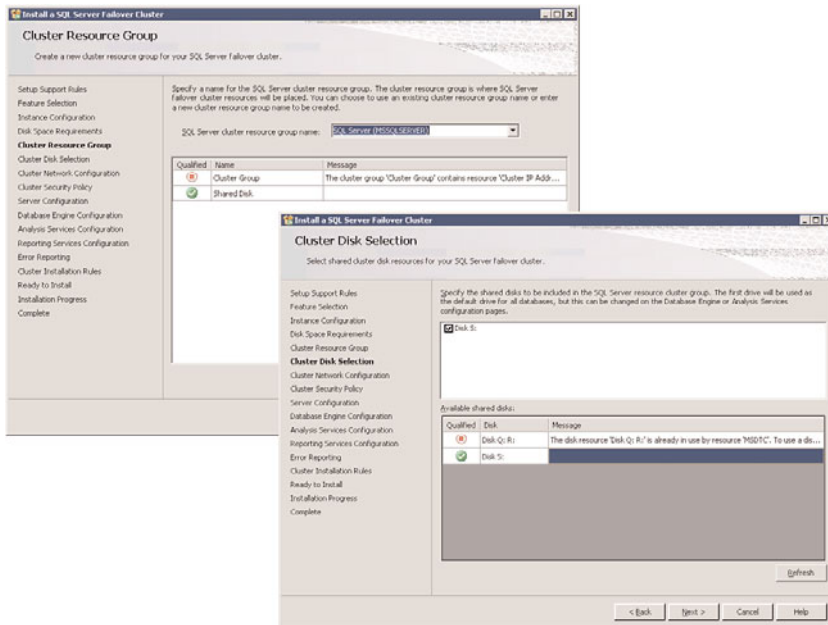

FIGURE 21.12 Cluster resource group specification and Cluster Disk Selection.

The next thing you need to do for this new virtual server specification is to identify an IP address and which network it should use. As you can see in the Cluster Network Configuration dialog, shown in Figure 21.13, you simply type in the IP address (for example, 192.168.3.110) that is to be the IP address for this virtual SQL Server for the available networks known to this cluster configuration (in this example, it is for the ClusterPublic network). If the IP address being specified is already in use, an error occurs.

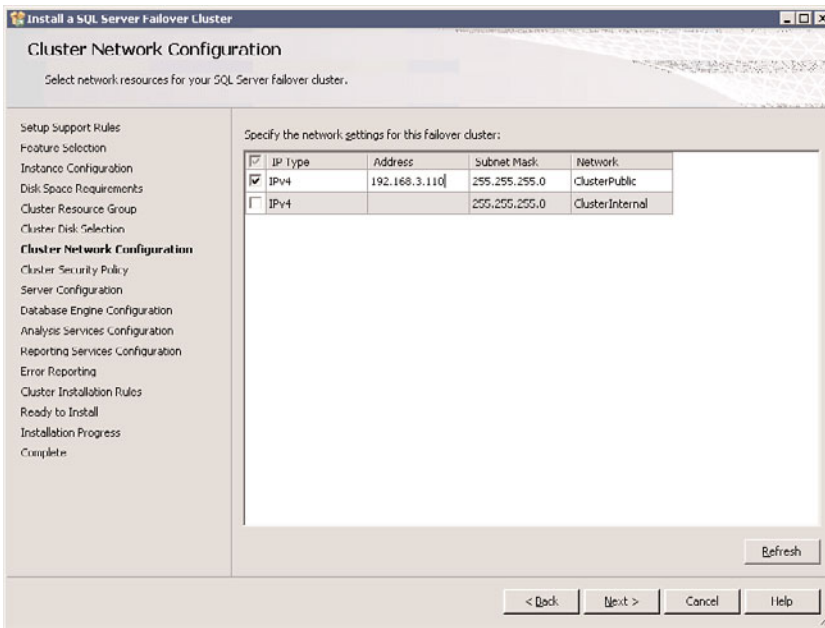

FIGURE 21.13 Specifying the virtual SQL Server IP address and which network to use.

NOTE

Keep in mind that you are using a separate IP address for the virtual SQL Server that is completely different from the cluster IP addresses. In a nonclustered installation of SQL Server, the server can be referenced using the machine's IP address. In a clustered configuration, you do not use the IP addresses of the servers themselves; instead, you use this separately assigned IP address for the "virtual" SQL Server.

Figure 21.14 shows the next step in identifying the Cluster Security Policy for each SQL Server component (Database Engine, SQL Server Agent, and Analysis Services). Here, you use the domain Admin group. Figure 21.14 also shows the Server Configuration "service accounts" to use for all the services within this SQL Server install. You use a ClusterAdmin account set up for this purpose. Remember, this account must have administrator rights within the domain and on each server (that is, it must be a member of the Administrators local group on any node in the cluster). This is followed by the Database Engine Configuration dialog, where you set what type of authentication mode to use, the data

directories for the root and subfolders, and the FILESTREAM options. Needless to say, the Data root directory is on the S: drive.

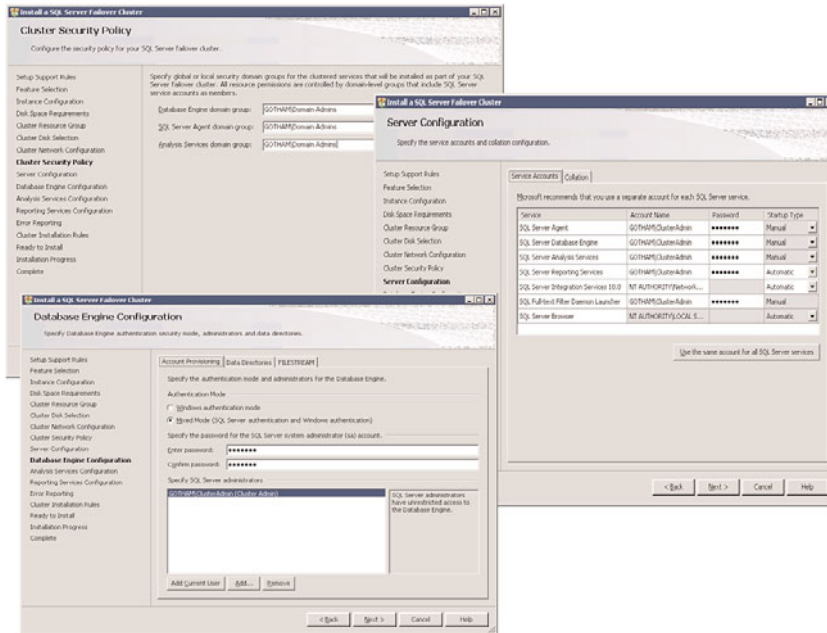

FIGURE 21.14 Specifying Cluster Security Policy, Server Config and Database Engine Config.

You then are prompted through the Analysis Services Configuration and Reporting Services Configuration dialogs. Your Analysis Services Data directories are within a subfolder of S:\OLAP\.

At this point, you have worked your way down to the Cluster Installation Rules check to determine if everything specified to this point is correct. Figure 21.15 shows this rules check “passing” status, a summary of what is about to be done, and the location of the configuration file (and path) that can be used later if you are doing command-line installs of new nodes in the cluster. A box appears around this configuration file path location at the bottom right of the Ready to Install dialog to show you where it is being created (if needed).

The next step is to click on the Install button.

The setup process installs SQL Server binaries locally on each node in the cluster (that is, in C:\Program Files\Microsoft SQL Server). The database files for the master, model, tempdb, and msdb databases are placed on the S: drive in this example. This is the shared disk location that must be available to all nodes in the SQL Server cluster.

When the process is complete, you can pop over into the Cluster Administrator and see all the resources just installed within the failover cluster. This is not highly available yet because you have completed only one node of the two-node failover cluster. But, as you

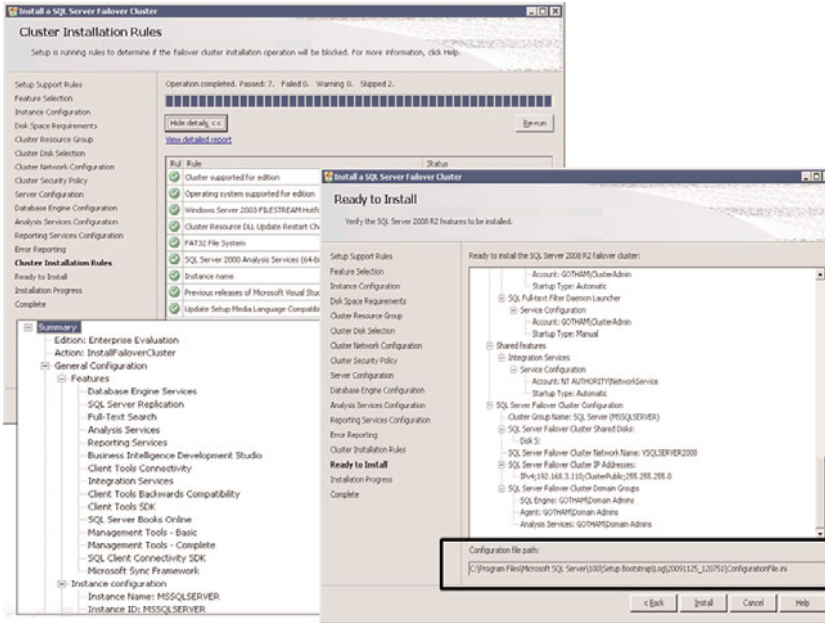

FIGURE 21.15 Cluster Installation Rules check and Ready to Install dialog.

As seen in Figure 21.16, the SQL Server components have been successfully installed and are usable within the cluster.

Adding the next node (and any more subsequent nodes) to the cluster will make this configuration highly available because you will have other nodes to fail over to. To install the second node, you must now start back over that the Setup process (using SQL Server Installation Center). But this time, you can choose the Add Node to a SQL Server Failover Cluster option, as shown in Figure 21.17. Just as before, the Setup Support Rules check occurs for the next cluster node (CLUSTER2, in this example). As you can also see, adding a node is much simpler (many fewer steps) than creating a completely new SQL Server failover cluster installation.

If all items have passed on the new node, you come to the Cluster Node Configuration dialog, as shown in Figure 21.18. Here, you can see that the name of this node (CLUSTER2) is being associated with (added to) the original cluster node (CLUSTER1). This is truly where the magic occurs. You are then prompted to specify the service accounts and collation configuration of this second node. Again, you should specify the domain account that was specified in the first cluster configuration setup (ClusterAdmin in this example).

Now you are ready to verify that the rules for adding this node are being followed. If any check doesn't pass, you must correct it before the node can be added. Figure 21.19 shows this Add Node Rules check along with the summary of all the features to be installed as part of the add node operation.

Again, click the Install button to install the SQL Server features and add this node to the cluster.

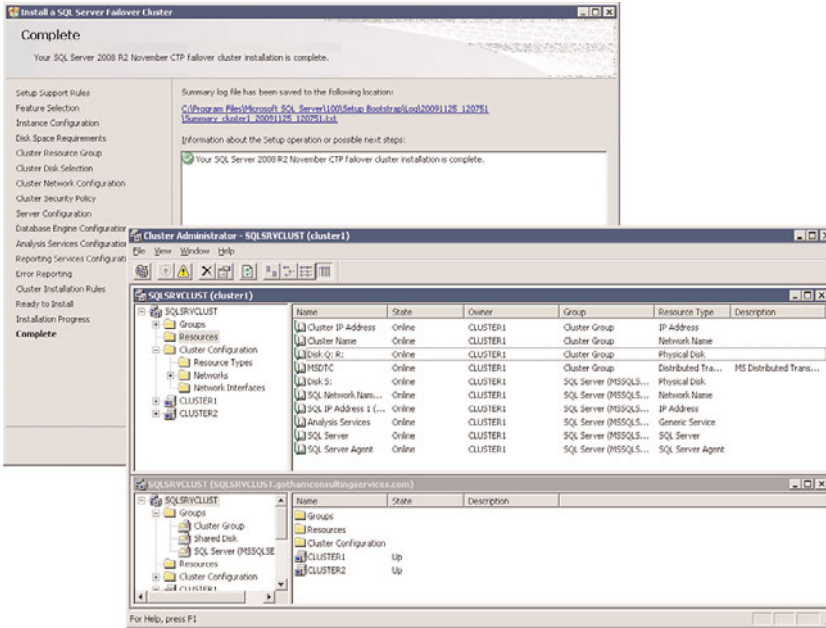

FIGURE 21.16 SQL Server Failover Cluster Node 1 install complete and within the Cluster Administrator.

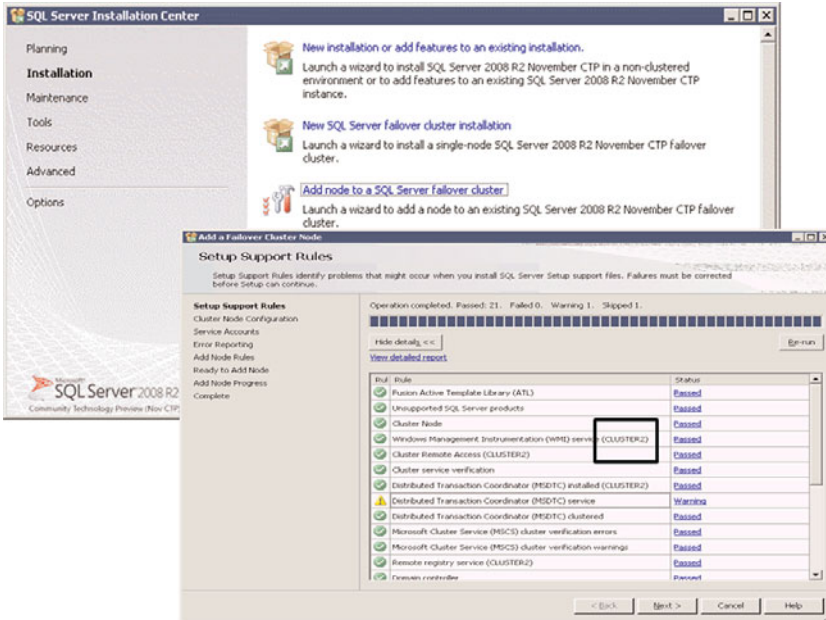

FIGURE 21.17 Adding a node to a SQL Server failover cluster and doing a Setup Support Rules check for the new cluster node.

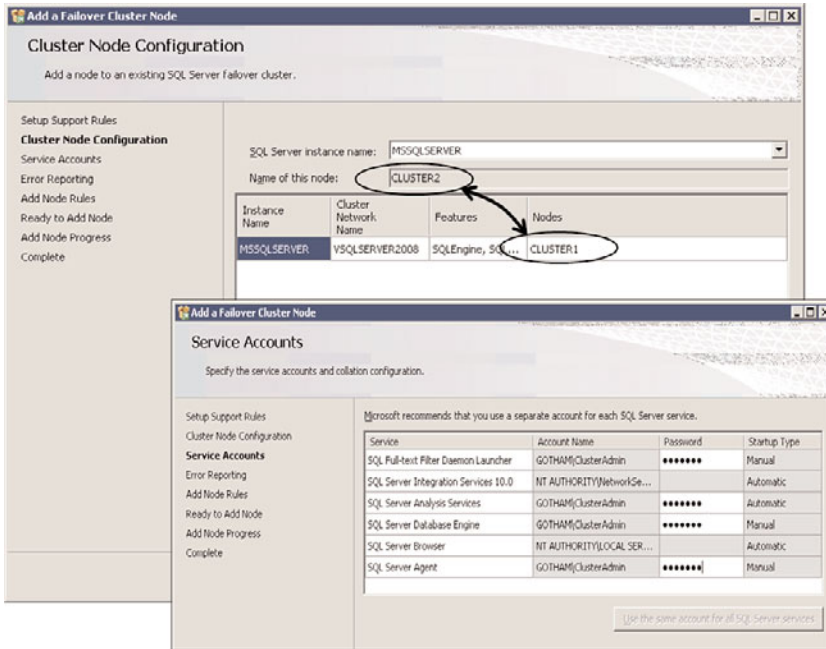

FIGURE 21.18 Specifying the cluster node configuration and the service accounts for the second node.

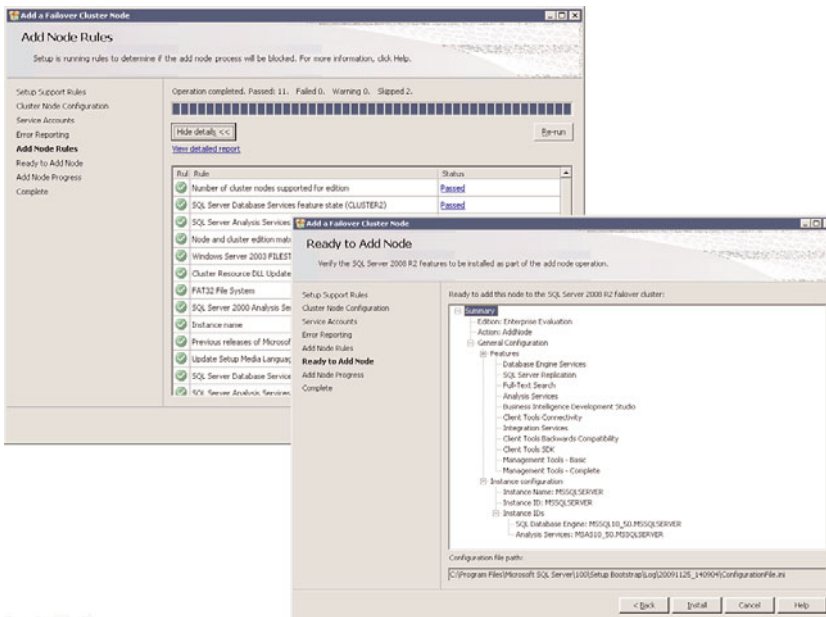

FIGURE 21.19 Cluster Installation Rules check and Ready to Install second node.

You must specify what type of authentication mode you want for SQL Server access: Windows Authentication (only) or mixed mode (Windows Authentication and SQL Server Authentication). For this example, you should choose the mixed mode option and provide a password for the sa SQL Server administration login.

Finally, you must specify the collation settings used for sorting order and compatibility with previous versions of SQL Server.

The SQL Setup program now has enough information to do the complete installation of the new node in the SQL Server cluster. Figure 21.20 shows the installation of the new SQL Server Failover Cluster node is complete. In particular, binaries are being installed locally, additional services are being created on the second node for SQL Server, and SQL resources are being associated to both cluster nodes.

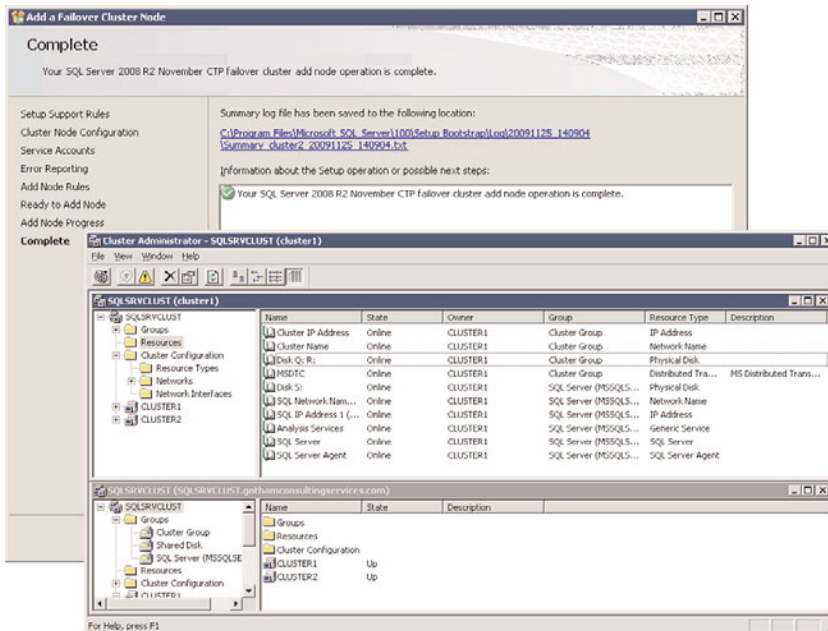

FIGURE 21.20 Second node installed (Complete) and the Cluster Administrator showing both nodes up.

As you can also see in Figure 21.20, Cluster Administrator shows the online resources within the cluster group and that both clusters are up and all resources are online (but controlled by CLUSTER1 now).

Following are the SQL Server resource entries:

- ▶ The SQL Server virtual IP address
- ▶ The SQL Server network name
- ▶ SQL Server (MSSQLSERVER)

- ▶ SQL Server Agent (for the instance)
- ▶ Analysis Services
- ▶ Disk S: (physical disks where the DBs reside)
- ▶ MSDTC

Each resource entry should say `Online` in the State column and be owned by the same node (`CLUSTER1` in this example).

In the Cluster Administrator, you can easily view the properties of each of the new SQL Server resources by right-clicking a resource and selecting Properties. Figure 21.21 shows the properties of the Networks and Network Interface IP Address resources.

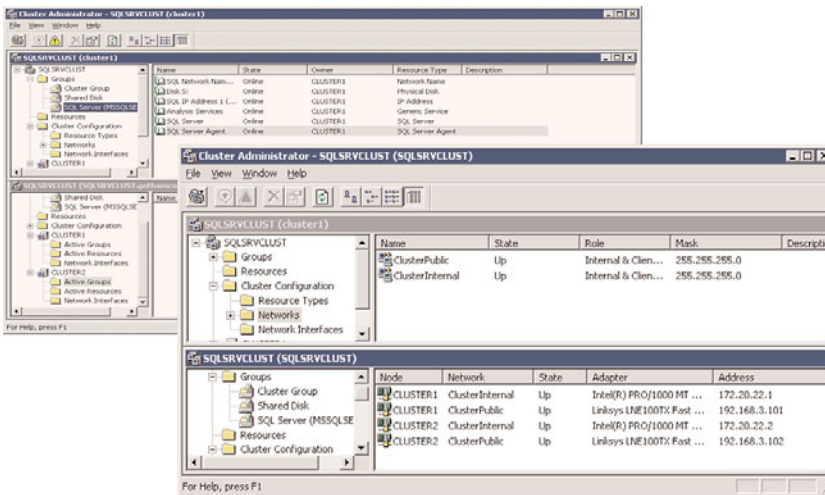

FIGURE 21.21 Properties of the Networks and Network Interfaces.

When you right-click a resource entry in the Cluster Administrator, you have an option to take the resource offline or to initiate a failure. You sometimes need to do this when you're trying to fix or test a SQL Server Clustering configuration. However, when you're initiating full SQL Server failover to another node (for example, from `CLUSTER1` to `CLUSTER2`), you typically use the Move Group cluster group technique because you want all the resources for the cluster group to fail over—not just one specific resource. Figure 21.22 shows that you simply right-click the Cluster Group item and select Move Group. All resources then fail over to `CLUSTER2`.

Failure of a Node

As you can see in Figure 21.23, one of the nodes in the SQL Server cluster (`CLUSTER1`) has failed, and MSCS is in the middle of failing over to the other node in the cluster (`CLUSTER2`). As you can also see, the `CLUSTER2` node item group has an hourglass on it, indicating that an MSCS operation is under way. The states of the resources on `CLUSTER2`

are mostly Online Pending. In other words, these resources are in the middle of failing over to this node. As they come up successfully, Online Pending turns to Online.

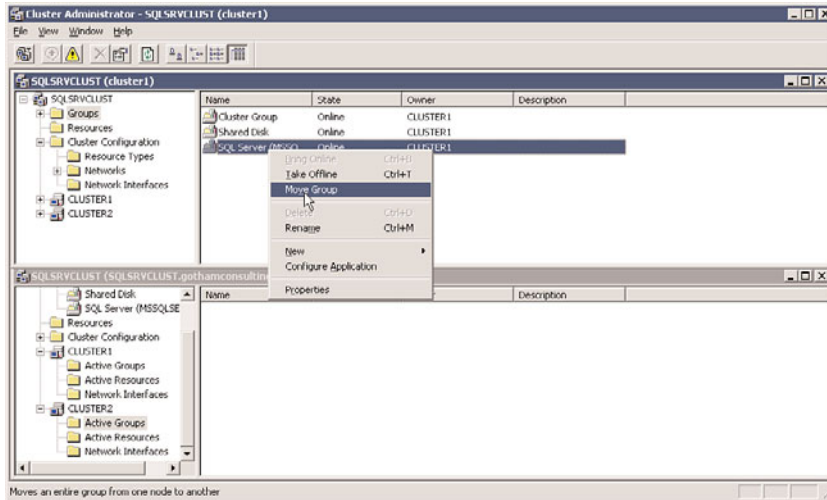

FIGURE 21.22 Using Move Group to fail over to another node in a cluster.

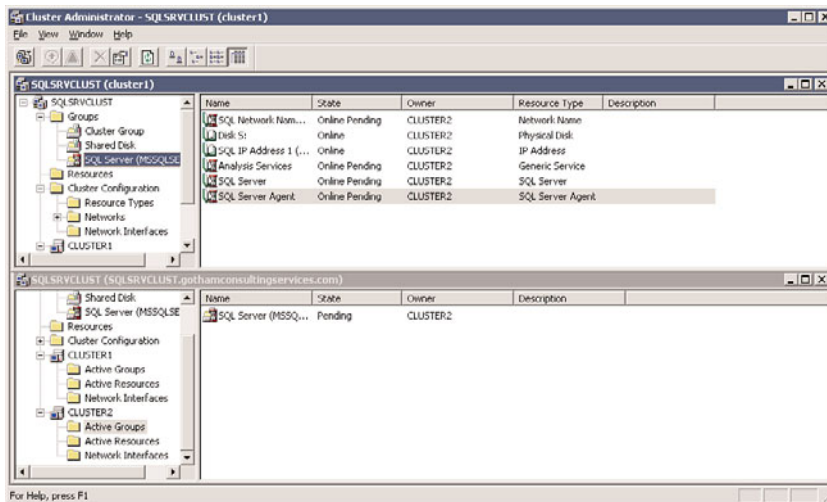

FIGURE 21.23 Failing over from **CLUSTER1** to **CLUSTER2**, Online Pending state.

In addition, the failure of a node (for any reason) is also written to the System event log. This example showed an intentional failure of the SQL Server instance via the Cluster Administrator. SQL Server Failover Clustering does the right thing by failing over to the

other node. This serves to verify that SQL Server Clustering is working properly. The next section illustrates what this effect has on a typical client application point of view, using a custom client test program called Connection Test Program.

Congratulations! You are now up and running, with your SQL Server Failover Cluster intact and should now be able to start achieving significantly higher availability for your end users. You can easily register this new virtual SQL Server (VSQSERVER2008) within SQL Server Management Studio (SSMS) and completely manage it as you would any other SQL Server instance.

The Connection Test Program for a SQL Server Cluster

To help in visualizing exactly what effect a SQL Server failure and subsequent failover may have on an end-user application, we have created a small test program using Visual Studio 2008. This small C# test program accesses the AdventureWorks2008 database available for SQL Server 2008 (see the Introduction chapter for information on how to download and install the AdventureWorks2008 sample database), and it was created in about 10 minutes. It displays a few columns of data, along with a couple system variables that show connection information, including the following:

- ▶ **ProductID, Name, and ProductNumber**—This is a simple three-column display of data from the Product table in the AdventureWorks2008 database.
- ▶ **SHOWDATETIME**—This shows the date and time (to the millisecond) of the data access being executed.
- ▶ **SERVERNAME**—This is the SQL Server name that the client is connected to.
- ▶ **SPID**—This is the SQL Server process ID (SPID) that reflects the connection ID to SQL Server itself by the client application.

This type of small program is useful because it always connects to the virtual SQL Server. This enables you to see what effect a failover would have with your client applications.

To populate this display grid, you execute the following SQL statement:

```
SELECT ProductID, Name, ProductNumber,
CONVERT (varchar(32), GETDATE(), 9) AS SHOWDATETIME,
@@SERVERNAME AS SERVERNAME,
@@SPID AS SPID
FROM Production.Product WHERE (ProductID LIKE '32%')
```

You use Visual Studio 2008 to set up a simple Windows form like the one shown in Figure 21.24. You build a simple button that will retrieve the data from the SQL Server database on the virtual server and also show the date, time, server name, and SPID information for each access invocation.

FIGURE 21.24 Visual Studio 2008 Windows form and data adapters needed for the test client C# program.

The Visual Studio 2008 project files for the Connection Test Program are available on the CD included with this book. The program, called `WindowsApplication4.sln` `SQLClientTest4` Visual Studio 2008 project, is zipped up in a file named `SQL Client SQL Clustering test program .zip`. If you want to install this program, you just unzip the `SQLClientTest.zip` file and locate the `WindowsApplication4.sln` solution file. You open this from your Visual Studio 2008 start page. Then you rebuild and deploy it after you have modified the connection string of the dataset adapter.

After deploying this simple test program, you simply execute it from anywhere on your network. As you can see in the `App.config` XML file for this application, shown here, the connection string references the `VSQLSERVER2008` virtual server name only:

```
<?xml version="1.0" encoding="utf-8" ?>
<configuration>
  <configSections>
  </configSections>
  <connectionStrings>
    <add name="WindowsApplication4.Properties.Settings.
AdventureWorksConnectionString"
connectionString="Data Source=VSQLSERVER2008;Initial
Catalog=AdventureWorks2008;
Integrated Security=True"
providerName="System.Data.SqlClient" />
  </connectionStrings>
</configuration>
```

Figure 21.25 shows the first execution of the Connection Test Program. If you click the Retrieve button, the program updates the data grid with a new data access to the virtual SQL Server machine, shows the name of the server that the client program is connecting to (SERVERNAME), shows the date and time information of the data access (in the SHOWDATETIME column), and displays the SQL SPID that it is using for the data access (in the SPID column). You are now executing a typical C# program against the virtual SQL Server. Note that the SPID value is 55; this represents the SQL connection to the virtual SQL Server machine servicing the data request.

FIGURE 21.25 Executing the Connection Test Program with current connection information.

Now let's look at how this high-availability approach works from the client application point of view. To simulate the failure of the active node, you simply turn off the machine (CLUSTER1 in this case). This is the best (and most severe) test case of all. Or, if you like, you can use the Cluster Administrator Move group approach shown earlier.

After you simulate this failure, you click the Retrieve button in the Connection Test Program again, and an unhandled exception occurs (see Figure 21.26). You can view the details of the error message, choose to quit the application, or choose to continue. You should click Continue for now.

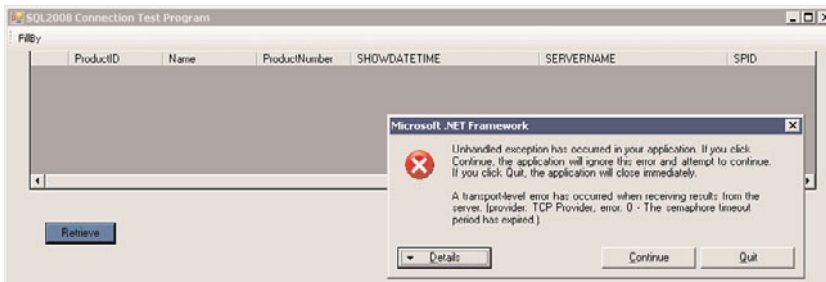

FIGURE 21.26 An unhandled exception has occurred; it is a transport-level error (that is, a TCP provider error).

What has happened is that the application can no longer connect to the failed SQL Server (because you turned off CLUSTER1), and it is still in the middle of failing over to CLUSTER2 in the two-node cluster.

A failover occurs in a short amount of time; the actual amount of time varies, depending on the power and speed of the servers implemented and the number of in-flight transactions that need to be rolled back or forward at the time of the failure. (A complete SQL failover often occurs in about 15 to 45 seconds. This is very minor and well within most service-level agreements and high-availability goals.) You then simply click the Retrieve button again in the Connection Test Program, and you are talking to SQL Server again, but now to CLUSTER2.

As you can see in Figure 21.27, the data connection has returned the customer data, SHOWDATETIME has been updated, and SERVERNAME still shows the same virtual SQL Server name that the application needs to connect to, but the SPID has changed from 55 to 52. This is due to the new connection of the Connection Test Program to the newly owned (failed-over) SQL Server machine. The Connection Test Program has simply connected to the newly started SQL Server instance on CLUSTER2. The unhandled exception (error) goes away, and the end user never knows a complete failover occurred; the user simply keeps processing as usual.

FIGURE 21.27 Executing the Connection Test Program again against the failed-over cluster node.

NOTE

You could program better error handling that would not show the “unhandled exception” error. You might want to display a simple error message, such as “database momentarily unavailable—please try again,” which would be much more user friendly.

Potential Problems to Watch Out for with SQL Server Clustering

Many potential problems can arise during setup and configuration of SQL Server Clustering. Following are some items you should watch out for:

- ▶ SQL Server service accounts and passwords should be kept the same on all nodes, or a node will not be able to restart a SQL Server service. You can use administrator or

a designated account (for example, `Cluster` or `ClusterAdmin`) that has administrator rights within the domain and on each server.

- ▶ Drive letters for the cluster disks must be the same on all nodes (servers). Otherwise, you might not be able to access a clustered disk.
- ▶ You might have to create an alternative method to connect to SQL Server if the network name is offline and you cannot connect using TCP/IP. You can use named pipes, specified as `\\.\pipe\$\SQL\sql\query`.
- ▶ It is likely that you will run into trouble getting MSCS to install due to hardware incompatibility. Be sure to check Microsoft's Hardware Compatibility List before you venture into this installation.

Summary

Building out your company's infrastructure with clustering technology at the heart is a huge step toward achieving five-nines reliability. If you do this, every application, system component, or database you deploy on this architecture has that added element of resilience. And, in many cases, the application or system component changes needed to take advantage of these clustering technologies are completely transparent. Utilizing a combination of NLB and MSCS allows you not only to fail over applications but to scale for increasing network capacity.

The two-node, active/passive node is one of the most common SQL Server Clustering configurations used. As you become more familiar with SQL Server Clustering and your high-availability requirements get closer to five-nines), you might need to put in place other, more advanced configurations, such as four-node SQL Server clusters and/or datacenter-class clusters (of up to eight-node SQL Server clusters and active/active variations). If you follow the basic guidelines of disk configurations and database allocations across these disk configurations, as described in this chapter, you can guarantee a certain level of stability, performance, and scalability. SQL Server Clustering is one of the best, most cost-effective solutions, and it is literally "out of the box" with SQL Server and the Windows family of servers.

Remember that SQL Server 2008 supports other concepts related to high availability, such as data replication, log shipping (soon to be deprecated), and database mirroring. You might use these solutions rather than SQL Server Clustering, depending on your requirements.

Clustering is a very complex subject. The information contained in this chapter is sufficient to start you in this area, but for a much more complete and thorough understanding of how to assess your high-availability needs, to evaluate what you should build for high availability, and to implement a high-availability platform that uses MSCS and SQL Server Clustering, you should find a copy of *Microsoft SQL Server High Availability* by Paul Bertucci (Sams Publishing). This book is loaded with full explanations, a formal approach to achieving five-nines reliability, and numerous live examples.

Chapter 22, "Administering Policy-Based Management," explains how to affectively administer servers using the Declarative Management Framework.

This page intentionally left blank

CHAPTER 22

Administering Policy-Based Management

Policy-Based Management is one of the new management features introduced in SQL Server 2008. Policy-Based Management enables an organization to define policies to manage one or more SQL Server instances, databases, or objects within the enterprise. In addition, policies can be evaluated against target systems to ensure that the standard configuration settings are not out of compliance. Policy-Based Management was developed in response to the following industry trends:

- ▶ Increasing amounts of data being stored
- ▶ Data center consolidation and virtualization
- ▶ Growing product capabilities
- ▶ Proliferation of SQL Server systems within the enterprise
- ▶ Need for a way to manage SQL Server settings from a holistic perspective
- ▶ Regulatory compliance demanding secure and standardized settings

Introduction to Policy-Based Management

A data explosion has been occurring over the past several years. In a 2006 study, International Data Corporation (IDC; <http://www.idc.com>) reported that 5 exabytes of digital media (5 billion gigabytes) were stored in 2003, and in 2006 this had ballooned to 161 exabytes. Not only is more data

IN THIS CHAPTER

- ▶ Introduction to Policy-Based Management
- ▶ Policy-Based Management Concepts
- ▶ Implementing Policy-Based Management
- ▶ Sample Templates and Real-World Examples
- ▶ Policy-Based Management Best Practices

being stored, but users are accessing more data than before. Part of this data growth is a result of the need for business intelligence (BI) systems to deliver actionable insights becoming more critical in the enterprise. Obtaining these insights requires large data volumes for trending and forecasting. As a result, data warehouses are becoming more critical in every enterprise.

This data explosion frequently results in a proliferation of SQL Servers.

Essentially, DBAs are being required to do more, frequently with less. In addition, the increasing complexities of the SQL Server product set are forcing DBAs to focus on efficient, scalable management and standardization. Due to the large numbers of SQL Servers involved, management by automation becomes critical as well to lessen the administrative burden. Monitoring also becomes more important to provide proactive support.

A well-managed SQL Server enterprise that follows best practices offers the following advantages:

- ▶ **Standardization**—Every SQL Server will have a common disk layout and settings, as well as consistent naming standards. As a result, DBAs moving from one SQL Server to another will not be surprised by different disk layouts or unusual settings that could account for a performance problem.
- ▶ **Best practices**—Microsoft internal studies have shown that 80% of the support calls to their Customer Service and Support (CSS) could have been avoided if the customer had been following best practices. Best practices not only offer performance advantages but also lead to fewer failure events caused by poorly configured SQL Servers, and security breaches due to SQL Servers that have not been hardened (security holes not locked down).
- ▶ **Ease of deployment**—A well-managed data center will have automated procedures for building SQL Servers (that is, unattended installations using configuration files) that require less time to build and minimal administrative interaction, resulting in fewer mistakes in a build and a reduction in administrative tasks.
- ▶ **Regulatory compliance**—By maintaining controlled and standardized settings, organizations can easily adhere to the demanding requirements of regulations such as Sarbanes-Oxley, the Health Insurance Portability and Accountability Act (HIPAA), and Payment Card Industry (PCI) standards.

The intent of Policy-Based Management is to provide a management framework that allows DBAs to automate management in their enterprise according to their own set of predefined standards. By implementing Policy-Based Management within a SQL Server infrastructure, organizations can reap the following benefits: total cost of ownership associated with managing SQL Server systems will be reduced, configuration changes to the SQL Server system can be monitored, unwanted system configuration changes can be prevented, and policies will ensure compliance.

The stated goals of Policy-Based Management fall into three categories:

- ▶ **Management by intent**—Allows DBAs to enforce standards and best practices from the start rather than in response to a performance problem or failure event

- ▶ **Intelligent monitoring**—Allows DBAs to detect changes that have been made to their SQL Server environments that deviate from the desired configuration
- ▶ **Virtualized management**—Provides a scalable framework that allows for management across the enterprise

Microsoft SQL Server 2008 and SQL Server 2008 R2 also ship with several predefined policies. These policies are not automatically imported into a default installation of SQL Server 2008. However, you can manually import them into SQL Server and use them as is or as a foundation for defining your own similar policies. These sample policies can be found in `C:\Program Files\Microsoft SQL Server\100\Tools\Policies\DatabaseEngine\1033`. Note that there are also policies for Reporting Services and Analysis Services, which can be found in the `ReportingServices` and `AnalysisServices` subdirectories of the `Policies` directory. Also note that Policy-Based Management can be used to manage SQL 2005 and 2000 servers.

NOTE

Microsoft has a blog focusing on Policy-Based Management (<http://blogs.msdn.com/sqlpbm/>) where it publishes scripts that can be used to enforce Microsoft best practices for SQL Server, as well as tips, tricks, and tutorials for using Policy-Based Management.

Policy-Based Management Concepts

Before we start learning about enforcing Policy-Based Management, there are a few key concepts DBAs must understand. These concepts include

- ▶ Facets
- ▶ Conditions
- ▶ Policies
- ▶ Categories
- ▶ Targets
- ▶ Execution mode
- ▶ Central Management Servers

Facets

A *facet* is a logical grouping of predefined SQL Server 2008 configuration settings. When a facet is coupled with a condition, a policy is formed and can be applied to one or more SQL Server instances and systems. Common facets include Surface Area Configuration, Server Audit, Database File, and Databases. Table 22.1 illustrates the complete list of predefined facets that can be selected, along with an indication of how each facet can be automated. Check On Schedule uses a SQL Server Agent job to evaluate a policy. Check On

Change uses event notification to evaluate based on when changes occur. Facets are included with SQL Server 2008 and cannot be modified.

TABLE 22.1 Facets for Policy-Based Management

Facet Name	Check on Change: Prevent	Check on Change: Log	Check on Schedule
Application Role	X	X	X

Xml Schema Collection			X

The complete list of facets can be viewed in SQL Server 2008 Management Studio by expanding the Management folder, the Policy-Based Management node, and then the Facets folder. Alternatively, to view facets applied to a specific database, you can right-click the database and select Facets.

NOTE

Currently, there are 74 facets available for use. Going forward, Microsoft will undoubtedly create more facets, which will be included with upcoming service packs.

Conditions

A *condition* is a Boolean expression that dictates an outcome or desired state of a specific management condition, also known as a facet. Condition settings are based on properties, comparative operators, and values such as `String`, `equal`, `not equal`, `LIKE`, `NOT LIKE`, `IN`, or `NOT IN`. For example, a check condition could verify that data and log files reside on separate drives, that the state of the database recovery model is set to Full Recovery, that database file sizes are not larger than a predefined value, and that database mail is disabled.

Policies

A *policy* is a standard for a single setting of an object. It ultimately acts as a verification mechanism of one or more conditions of the required state of SQL Server targets. Typical scenarios for creating policies include imposing Surface Area Configuration settings, enforcing naming conventions on database objects, enforcing database and transaction log placement, and controlling recovery models. As mentioned earlier, a tremendous number of policies can be created against SQL Server 2008 systems. Surface Area Configurations are a very common policy, especially because the SQL Server 2005 Surface Area Configuration tool has been deprecated in SQL Server 2008.

NOTE

A policy can contain only one condition and can be either enabled or disabled.

Categories

Microsoft recognized that although you may want to implement a set of rigid standards for your internal SQL Server development or deployments, your enterprise may have to host third-party software that does not follow your standards. Although your internally developed user databases will subscribe to your own policies, the third-party user applications will subscribe to their own categories. To provide flexibility, you can select which policies you want a table, database, or server to subscribe to and group them into groups called *categories*, and then have a database subscribe to a category and unsubscribe from a group of other policies if necessary. A policy can belong to only one policy category.

Targets

A *target* is one or more SQL Server instances, databases, or database objects that you want to apply your categories or policies to. Targets can be only SQL Server 2008 R2, 2008, 2005, or 2000 systems. All targets in a server instance form a target hierarchy. A target set is the set of targets that results from applying a set of target filters to the target hierarchy—for example, all the tables in a database contained in a specific schema.

Execution Modes

When you are implementing policies, there are three types of execution modes. The On Change mode has two variations:

- ▶ **On Demand**—The On Demand policy ensures that a target or targets are in compliance. This task is invoked manually by right-clicking on the policy in the Management folder, Policy Management folder, Policy folder, and selecting Evaluate. The policy is not enforced and is only verified against all targets that have been subscribed to that policy. You can evaluate a policy also by right-clicking on the database and selecting Policies and Evaluate.
- ▶ **On Schedule**—Policies can be evaluated on a schedule. For example, a policy can be scheduled to check all SQL Server 2008 systems once a day. If any anomalies arise, these out-of-compliance policies are logged to a file. This file should be reviewed on a periodic basis. In addition, whenever a policy fails, the complete tree in SQL Server Management Studio displays a downward-pointing arrow next to the policy, as shown in Figure 22.1.

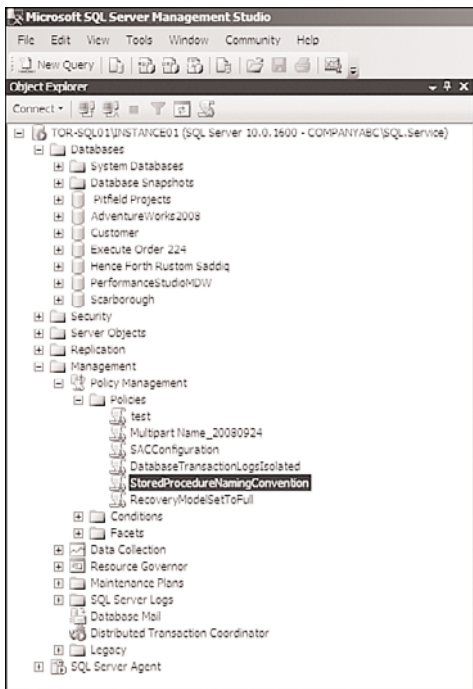

FIGURE 22.1 SQL Server management tree illustrating failed policies for table name.

- ▶ **On Change Prevent**—The On Change Prevent execution mode prevents changes to server, server object, database, or database objects that would make them out of

compliance. For example, if you select a policy that restricts table names to only those that begin with the prefix `tbl`, and you attempt to create a table called `MyTable`, you get the following error message, and your table is not be created:

```
Policy 'table name' has been violated by
'/Server/(local)/Database/iFTS/Table/dbo.mytable'.
This transaction will be rolled back.
Policy description: ''
Additional help: '' : ''.
Msg 3609, Level 16, State 1, Procedure sp_syspolicy_
dispatch_event, Line 50
The transaction ended in the trigger.
The batch has been aborted.
```

- **On Change Log Only**—If you select On Change Log Only, a policy condition that is evaluated as failed is logged in the SQL Server Error log. The change does not prevent out-of-compliance changes.

Central Management Servers

In large enterprises, organizations most likely have more than one SQL Server system they want to effectively manage from a Policy-Based Management perspective. Therefore, if DBAs want to implement policies to multiple servers, they have two options. The first option includes exporting the policy and then importing it into different SQL Server systems. After the policy is imported, it must be configured to be evaluated on demand, on schedule, or on change.

The second option includes creating one or more Central Management Servers in SQL Server 2008. Basically, by registering one or more SQL Servers with a Central Management Server, a DBA can deploy multiserver policies and administration from a central system.

For example, you could create two Central Management Servers, one called OLAP and another called OLTP, and then register servers into each Central Management Server, import the different policies into each Central Management Server, and then evaluate the policies on each different Central Management Server. So, on your OLTP Central Management Server, the servers OLTP1, OLTP2, OLTP3, which are registered in the OLTP Central Management Server, would have the OLTP policies evaluated on them.

Creating a Central Management Server

Follow these steps to register a Central Management Server:

1. In SQL Server Management Studio, open the View menu and click Registered Servers.
2. In Registered Servers, expand the Database Engine node, right-click Central Management Servers, and then select Register Central Management Server.

3. In the New Server Registration dialog, specify the name of the desired Central Management Server.
4. If necessary, specify additional connection properties on the Connection Properties tab or click Save.

Registering SQL Server Instances in a Central Management Server

The next task registers SQL Server instances to be associated with a Central Management Server. The following steps outline this task:

1. Right-click on the Central Management Server with which you want to associate your SQL Server instance.
2. Select New Server Registration.
3. In the New Server Registration dialog, specify the name of the SQL Server Instance and the proper connection information and click Save
4. Repeat steps 1-3 for all SQL Server instances that you want to register with this Central Management Server.

Figure 22.2 illustrates a Central Management Server with one Server Group and two SQL Server instances registered.

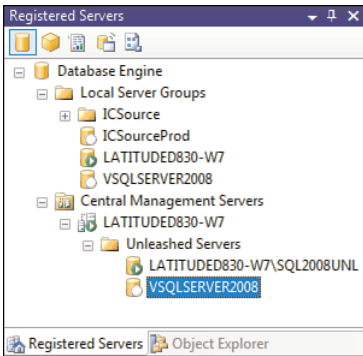

FIGURE 22.2 Central Management Server with Registered SQL Server instances.

Importing and Evaluating Polices to the Central Management Server

After the Central Management Server is established, the Server Group is created, and the desired SQL Server instances are registered, it is time to import and evaluate policies. You can import policies for multiple instances by right-clicking the Central Management Server or Server Group and selecting Import Policies. After the policies are imported, the next step is to evaluate the policies by right-clicking the Central Management Server or Server

Group and selecting Evaluate. The output indicates the status of policies associated with all the SQL Server instances associated with the Central Management Server or Server Group.

NOTE

Importing, exporting, and evaluating policies are covered throughout the rest of the chapter.

Implementing Policy-Based Management

Now that you understand the basic purpose and concepts behind Policy Based Management, let's look at how to administer Policy-Based Management, then how to apply it to a server, and then a group of servers.

There are essentially six steps to implementing and administering Policy-Based Management:

- ▶ Creating a condition based on a facet
- ▶ Creating a policy based on that condition
- ▶ Creating a category
- ▶ Creating a Central Management Server
- ▶ Subscribing to a category
- ▶ Exporting or importing a policy

Let's look at each of these steps in turn. The upcoming sections explain each step in its entirety.

Creating a Condition Based on a Facet

When you are creating conditions, the general principle includes three elements: selecting a property, an operator, and then a value. The following example walks through the steps to create a condition based on a facet which will enforce a naming standard on a table:

1. To create a condition, connect to a SQL Server 2008 instance on which you want to create a policy.
2. Launch SQL Server Management Studio (SSMS). In Object Explorer, expand the Management folder, expand the Policy Management folder, and then expand the Facets folder.
3. Within the Facets folder, browse to the desired facet on which you want to create the policy (in this case, the Table facet).

4. To invoke the Create New Condition window, right-click the facet and select New Condition.
5. In the Create New Condition dialog, type a name for the condition (for example, Table Name Convention) and ensure that the facet selected is correct.
6. In the Expression section, perform the following tasks:
 - a. Select the property on which you want to create your condition. For this example, use the @Name property.
 - b. In the Operator drop-down box, select the NOT LIKE operator.
 - c. In the value text box, enter 'tbl%'.
7. Repeat step 6 for any additional expressions. For this example, the following expressions were entered, as displayed in Figure 22.3.

AndOr	Field	Operator	Value
	@Name	NOT LIKE	'tbl%'
AND	Len(@Name)	<=	50
AND	@Name	NOT LIKE	'%s'

8. Click OK to finalize the creation of the condition. You may have to click on the Field text box again for the OK button to be enabled.

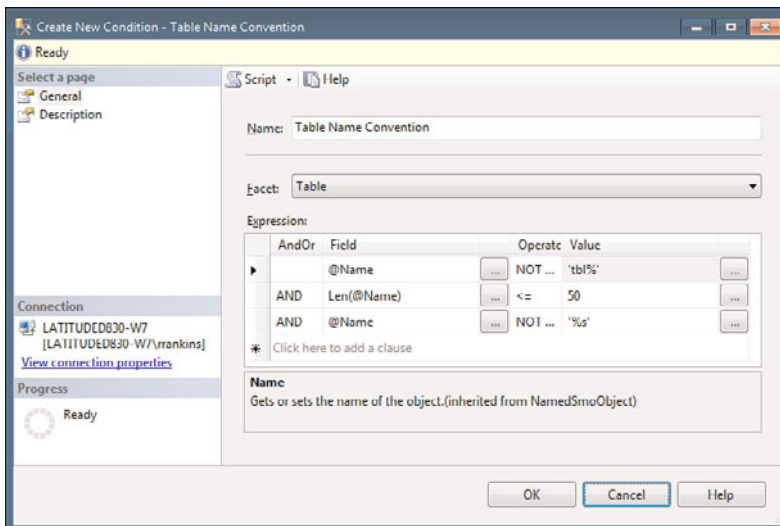

FIGURE 22.3 Creating a condition based on a facet.

NOTE

You can create conditions that query Windows Management Instrumentation (WMI) (using the `ExecuteWSQL` function) or SQL Server (using the `ExecuteSQL` function). For example, you can create conditions to check on available disk space or number of processors on the server. WMI allows you to issue SQL-like queries against management objects, which can return information on the physical machine hosting SQL Server and configuration and performance information, which is not accessible from within SQL Server itself.

Creating a Policy

After creating the condition or conditions, you need to create the policy. The *policy* is a standard that can be enforced on one or more SQL Server instances, systems, server objects, databases, or database objects. Follow these steps to create a policy with SQL Server Management Studio:

1. In Object Explorer, expand the Management folder, expand the Policy Management folder, and then click on Policies.
2. Right-click on the Policies folder and select New Policy.
3. On the General tab of the Create New Policy dialog, enter a name for the new policy, such as Check Table Naming Conventions.
4. In the Check Condition drop-down box, select a condition, such as the one created in the previous example, or select New to generate a new condition from scratch.
5. The Against Targets section indicates which objects the policy should be evaluated against. For example, you could create a new condition that applies to a specific database, all databases, a specific table, all tables, or to databases created after a specific date. In the Action Targets section, indicate which targets this condition should apply to.
6. Specify the Evaluation Mode by selecting one of the options in the drop-down menu. The options include On Demand, On Schedule, On Change Log Only, and On Change Prevent.

NOTE

If On Schedule is selected for the Evaluation Mode, specify a schedule from the predefined list or enter a new schedule.

- The final drop-down box is Server Restriction. You can restrict which servers you do not want the policy to be evaluated against or enforced on by creating a server condition. Create a server restriction or leave the default setting None. An example of the policy settings for checking table name conventions is displayed in Figure 22.4.

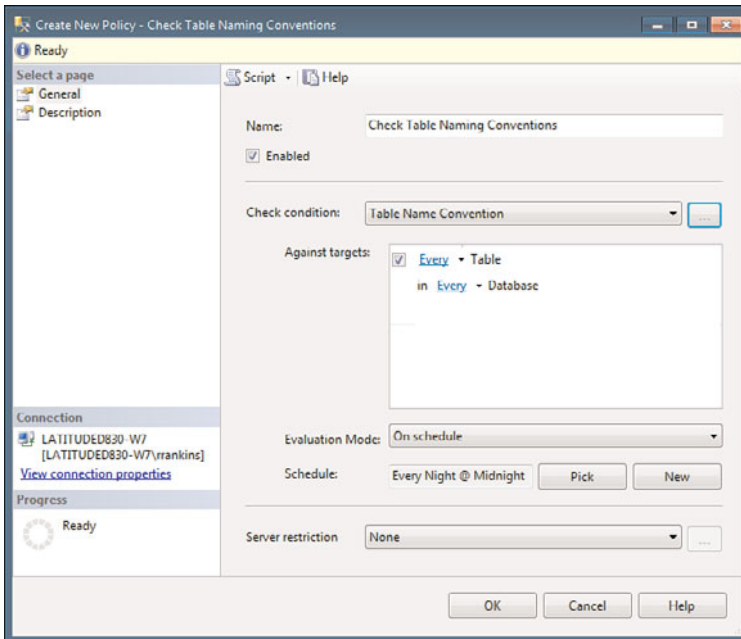

FIGURE 22.4 The Create New Policy dialog.

- Before you close the Create New Policy dialog, ensure that the policy is enabled (the Enabled check box is selected) and then click on the Description page. The Description page allows you to categorize your policy, but it also allows you to display a custom text message when a policy is violated and a hyperlink where the DBA/developer can go for more information about the policy.
- Click OK to finalize the creation of the new policy.

An Alternative to Creating Policies

As you can imagine, for complex policies you might need to create many conditions. In some cases it may be easier to create a table, database, or server configured to conform to the policy you want to create and then right-click on the specific object and select Facets. This brings up the View Facets page. Click on the Export Current State as Policy button. This exports a policy and a single condition to which the existing object will conform.

Figure 22.5 illustrates the dialog that prompts you for a name for your policy and condition as well as where you want to store the policy. You can store it in the file system and then import it to a Central Management Server or other servers where you want the policy

to be evaluated, or you can import it directly to a server. Note that this policy will contain conditions specific to the object you use as a template; for example, if you use the AdventureWorks2008 database, the policy will test for the condition where the database name is equal to AdventureWorks2008. For this feature to be useful, you likely need to edit the conditions to ensure that they are generic and evaluate exceptions correctly.

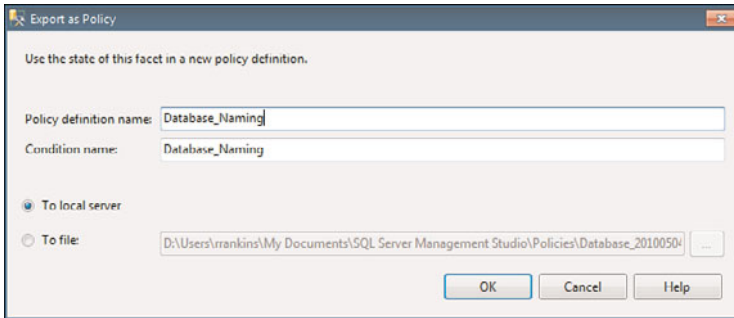

FIGURE 22.5 Exporting a policy based on an existing object.

Creating a Category

After you create a policy, it should be categorized. Categorization allows you to group policies into administrative or logical units and then allow database objects to subscribe to specific categories. It is worth mentioning that server objects can't subscribe to policies.

To create a category, click on the Description page in the Create New Policy dialog. Policies can be placed in the default category or a specific category, or you can create a new category. Specifying a category is illustrated in Figure 22.6.

You can also create categories by right-clicking on Policy Management and selecting Manage Categories.

If you choose to create a new category, click on the New button. This presents a dialog that allows you to name the category. By default, this policy is parked in the new category.

You can also select which category you want policies to belong to by selecting a specific category in the drop-down box. After you categorize your policies, you can select which categories you want your database to subscribe to. Right-click on the Policy Management folder and select Manage Categories. The Manage Policy Categories dialog (illustrated in Figure 22.7) appears. Check the categories to which you want all databases on your server to subscribe and deselect the ones that you do not want your server database to be subscribed to by default.

Other than the default category, DBAs can select which category (and policies belonging to that category) they want their databases to subscribe to. For example, if you have third-party software that does not follow your naming standards, you should ensure that the policies that enforce your naming standards are not in the default category. Then selectively have each of your user databases on your server subscribe to these databases.

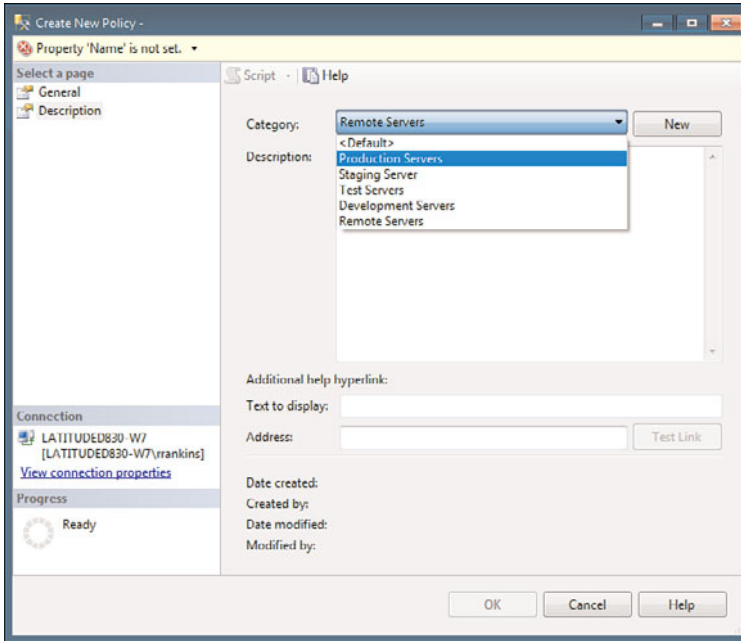

FIGURE 22.6 The category selection dialog.

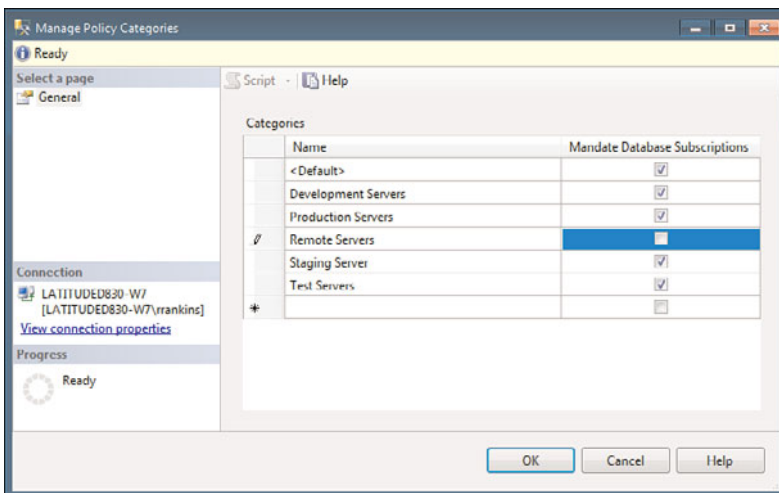

FIGURE 22.7 The Manage Policy Categories dialog.

Evaluating Policies

After you create an organization's policies and categories, you need to evaluate them to determine which of your servers and databases are out of compliance. There are three management points that can be leveraged to evaluate policies:

- ▶ For the first alternative, right-click on a server, server object, database, or database object in SQL Server Management Studio 2008 and select Policies and then Evaluate.
- ▶ For the second alternative, expand the Management folder, expand Policy Management, right-click on Policies, and select Evaluate. In the Evaluate Policies page displayed, check the policy or policies you want to evaluate and click the Evaluate button. It is also possible to select an individual policy. To do so, in the Policy folder, right-click on it and select Evaluate.
- ▶ Finally, the preferred way to evaluate all your servers, or a group of your servers, is to connect to display the Registered Servers list in SSMS. Expand the Central Management Servers node and right-click on the name of a Central Management Server and select Evaluate Policies. The policies you select to evaluate are evaluated on all SQL Servers defined on that Central Management Server—for example, all member servers in all Server Groups. If you select a Server Group, all member servers in that Server Group are evaluated. To evaluate the policies, you need to right-click on the Central Management Server, Server Group, or even Member Server and select Evaluate Policies.

When you right-click on the Central Management Server or Server Group and select Evaluate Policies, you are presented with a dialog that prompts you for a source, with a Choose Source prompt. For Select Source, enter the server name into which you have imported your policies or browse to a file share. Then highlight all the policies you want to import and click on the Close button to close the dialog.

After the policies are imported, you can select the individual policies you want to run and click Evaluate. The policies are then evaluated on the member servers, and the results are displayed in the Evaluation Results pane, as illustrated in Figure 22.8.

The Evaluation Results pane displays servers where a policy has failed. In the Target Details section, there is a View hyperlink, which allows you to browse to get more details on why the individual target server and policy target failed compliance to the policy you evaluated.

Importing and Exporting Policies

In some situations a DBA might want to export one or many policies with their conditions from one or many SQL Server systems and import them to another SQL Server instance or system. Fortunately, you can perform this task easily with an export and import wizard that generates or reads the policy definitions as XML files.

Follow these steps to export a policy with SQL Server Management Studio:

1. In Object Explorer, expand the Management folder, expand the Policy Management node, and then expand the Policies folder.
2. Within the Policies folder, right-click a desired policy to export and then select Export Policy.
3. In the Export Policy dialog, specify a name and path for the policy and click Save.

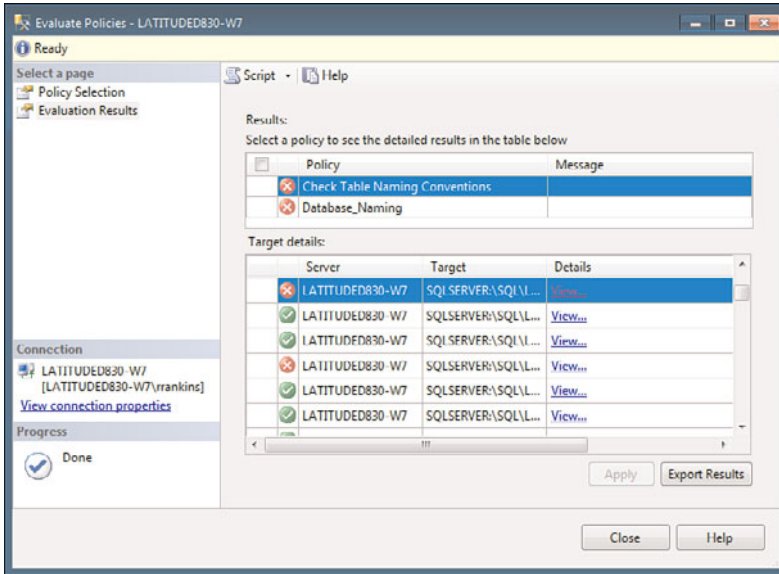

FIGURE 22.8 The Evaluation Results pane.

Importing a policy from an XML file is just as simple. Follow these steps to import a policy with SQL Server Management Studio:

1. In Object Explorer, expand the Management folder, expand the Policy Management node, and then select Policies.
2. Right-click on the Policies folder and select Import.
3. The import screen has three options you need to be aware of:
 - a. First, provide the path of the file to import.
 - b. Second, enable the option Replace Duplicate Items When Imported.
 - c. Finally, in the Policy State drop-down box, specify the state of the policy being imported. The options include Preserve Policy State on Import, Enable All Policies on Import, and Disable All Policies on Import.

Sample Templates and Real-World Examples

The following sections illustrate the sample policy templates included with SQL Server 2008 and real-world examples for using Policy-Based Management.

Sample Policy Templates

SQL Server 2008 includes a plethora of predefined sample policies, which can be leveraged by importing them into a SQL Server 2008 system. The policies available for import are located in the default installation drive at C:\Program Files\Microsoft SQL

Server\100\Tools\Policies. As mentioned earlier, you can import the desired policies by right-clicking the Policies node and selecting Import. The sample templates are categorized by SQL Server feature such as Database Engine, Reporting Services, and Analysis Services.

Evaluating Recovery Models

Recovery models determine how SQL Server uses the transaction log. On OLTP systems, the most appropriate recovery model is generally the Full Recovery model. For OLAP systems, the most appropriate recovery model is generally the simple recovery model. For most development environments, the most appropriate recovery model is also the simple recovery model.

For mission-critical databases, or databases where point-in-time recovery is important, having a transaction log backed up every five minutes may be required. Policy-Based Management can be used to determine whether the appropriate recovery model is in place for each user database for each server type. Central Management Servers could be created for each server type and a policy can be created to ensure that the appropriate recovery model is in place across all servers managed within a management server.

Implementing Surface Area Configuration Checks

SQL Server 2005 shipped with the SQL Server Surface Area Configuration (SAC) tool. This tool allowed you to enable or disable various components and services on individual SQL 2005 Servers. This feature was deprecated in SQL Server 2008 because the Microsoft team felt that the better way to handle these configuration tasks was through Policy-Based Management.

If you want to implement the Surface Area Configuration feature in SQL Server 2008 to configure components and services, import the following policies:

- ▶ Surface Area Configuration for Database Engine 2005 and 2000 Features.xml
- ▶ Surface Area Configuration for Database Engine 2008 Features.xml
- ▶ Surface Area Configuration for Service Broker Endpoints.xml
- ▶ Surface Area Configuration for SOAP Endpoints.xml

SQL Server Health Checks

One of the SQL Server Support Engineers has posted blog entries on how to perform server health checks using Policy-Based Management. You can access his blog using this URL: <http://blogs.msdn.com/bartd/archive/2008/09/11/defining-complex-server-health-policies-in-sql-2008.aspx>.

The main part of the SQL Server health check revolves around ensuring the disk response times are less than 100ms. The Policy uses ExecutesSQL to query the dynamic management view `sys.dm_io_virtual_file_stats` to ensure that the disk response time is within this limit. You can extend this policy to query other DMVs for other health checks—for example, the use of excessive parallelism or checking to ensure that cumulative wait stats have not exceeded desired boundaries.

Ensuring Object Naming Conventions

Your company may have standards for naming objects. For example, stored procedures must start with the prefix `usp`, tables must start with the prefix `tbl`, and functions must start with the prefix `ufn`. Policy-Based Management can be used to ensure that all objects are compliant with this policy. This policy can be implemented to execute as `On Change Prevent`, which prevents the creation of such noncompliant objects.

Checking Best Practices Compliance

You can implement policies that check for SQL Server best practices. For example, databases can be configured with the `autoclose` and `autoshrink` options. Although these options have their place on some systems, they are not recommended to be enabled in production environments because the `autoclose` option causes a time delay while the database is opened by a connection trying to access it. This can lead to timeouts. The `autoshrink` option can lead to fragmentation and is in general not recommended. A policy can check for these settings and other settings to ensure that all your databases are following best practices.

Policy-Based Management Best Practices

Following are some best practices to consider when implementing Policy-Based Management in SQL Server 2008:

- ▶ When deploying Policy-Based Management in your environment, you should be very careful about using `On Change Prevent`. For example, a policy that prevents stored procedure creation with the `sp_` prefix prevents the enabling of replication on a SQL Server.
- ▶ When you create a policy that you want enforced on all user databases, you should place this policy in the default category so that it is subscribed to all databases. Otherwise, you need to manually subscribe all databases to the categories that contain the policies you want enforced.
- ▶ You should make use of multiple Configuration Servers or Server Groups to group your SQL Servers according to logical groupings on which you want to group your policies.
- ▶ Importing policies into centralized SQL Server 2008 servers makes it easier to deploy groups of policies against groups of servers using Central Management Servers—for example, to store data warehouse policies on Server A. You should use this server as a source when selecting policies to evaluate against your data warehouse servers registered in the Data Warehousing Central Management Server.
- ▶ You might find that your environment contains third-party user applications/databases that are not in compliance with the policies you have created for your enterprise. Policy-Based Management uses the `opt-in` metaphor such that all policies are enforced by default. For databases on which you do not want the policy to be enforced, you need to tag the database, perhaps with an extended property or a

specially named table that the server exception category or target will detect and exempt that server or database from the policy.

- ▶ You should use the `ExecuteWSQL` task to issue WMI queries to extend conditions and policies beyond the SQL Server environment—for example, to check what other services may be running on a server hosting SQL Server.

Summary

Policy-Based Management is a new component in SQL Server 2008 that allows you to manage your SQL 2000, 2005, and 2008 servers by creating policies that can be used to enforce compliance to best practices or to report on out-of-compliance servers. It provides a highly granular, flexible, and extensible toolset that allows you to manage all aspects of your SQL Server. Properly used, it is a great tool to enforce standardization in your environment and to ease the management burden.

The next part of this book, Part IV, “Database Administration,” explores the tasks involved in creating and managing databases and database objects, just the sorts of things you want to apply many of your best practices and policies against.

This page intentionally left blank

CHAPTER 23

Creating and Managing Databases

A *database* is a collection of tables and related objects that help protect and organize data. It must exist before you can create all database objects, including tables, indexes, and stored procedures. This chapter focuses on how to create a sound database that can house database objects and how to manage the database after the objects are created. The creation and management of the various database objects is discussed in the remaining chapters in Part IV, “Database Administration.”

NOTE

It is important to remember that SQL Server actually uses its own set of databases that are installed by default when SQL Server is installed. These databases are referred to as *system databases*. The databases that users create are aptly named *user databases*. The system databases include *master*, *model*, *msdb*, *tempdb*, and *resource*. Each of these databases performs a key function in the operation of SQL Server. For example, the *master* database contains an entry for every user database created and contains server-wide information critical to the operation of SQL Server. The *model* database is basically a template database for any newly created databases. Each system database is based on a structure similar to user databases and contain database objects like those contained in user databases. The system databases are discussed in detail in Chapter 7, “SQL Server System and Database Administration.”

IN THIS CHAPTER

- ▶ What’s New in Creating and Managing Databases
- ▶ Data Storage in SQL Server
- ▶ Database Files
- ▶ Creating Databases
- ▶ Setting Database Options
- ▶ Managing Databases

What's New in Creating and Managing Databases

SQL Server 2008 offers several new features that provide improved security and manageability. The primary security enhancement is the capability to encrypt an entire database using Transparent Data Encryption (TDE). This transparent data encryption applies to the data files and log files that make up a database. It allows for an entire database to be secure via encryption without the need to change existing applications or the individual database objects. Transparent Data Encryption is covered in Chapter 12, "Data Encryption."

The manageability improvements in SQL Server 2008 are centered around data compression and enhanced database mirroring. The data compression improvements help reduce the amount of space that your database files occupy. The enhancements in database mirroring include automatic page repair, improved performance, and enhanced supportability via additional performance counters and new dynamic management views. Database mirroring is discussed in more detail in Chapter 20, "Database Mirroring."

Data Storage in SQL Server

A database is a storage structure for database objects. It is made up of at least two files. One file, referred to as a *data file*, stores the database objects, such as tables and indexes. The second file, referred to as the *transaction log file*, records changes to the data. A data file or log file can belong to only one database.

SQL Server stores data on the data file in 8KB blocks, known as pages. A *page* is the smallest unit of input/output (I/O) that SQL Server uses to transfer data to and from disk. An 8KB page is equal to $1024 \text{ bytes} \times 8$, or 8192 bytes. There is some overhead associated with each data page, so the maximum number of bytes of data that can be stored on a page is 8060 bytes. The overhead on a data page includes a 96-byte page header that contains system information about the page. This system information includes the page number, page type, and amount of free space on the page.

Generally, a row of data in a SQL Server database is limited to the 8060-byte maximum. With SQL Server 2008, there are some exceptions to this 8060-byte limit if the table contains columns that have the data types *text/image*, *varchar*, *nvarchar*, *varbinary*, or *sql_variant*. With these data types, SQL Server can store the data in a separate data structure when the size of the row exceeds the 8060-byte limit. When the 8060-byte limit is exceeded, SQL Server stores a pointer to the separate data structure so that the information in these columns can be accessed.

In an effort to reduce internal operations and increase I/O efficiency, SQL Server, when allocating space to a table or an index, allocates space in extents. An *extent* is eight contiguous pages, or 64KB of storage. There are actually two types of extents. Every table or index is initially allocated space in a *mixed extent*. As the name implies, mixed extents store pages from more than one object. When an index or a table is first created, it is assigned an index allocation map (IAM), which is used to track space usage for the object, and at least one data page. The IAM and data page are assigned to a mixed extent in an effort to save

space because dedicating an extent to a table with a few small rows would be wasteful. Up to eight initial pages are assigned this way. When an object requires more than eight pages of storage, all further space is allocated from uniform extents. A *uniform extent* stores pages for only a single index or table. This allows SQL Server to optimize read and write operations and reduce fragmentation because the data is stored in units of 64KB (that is, eight pages) as opposed to individual 8KB pages being scattered throughout the data file.

For more detailed information on the internal storage structures and how to manage them in SQL Server databases, see Chapter 38, “Database Design and Performance.”

Database Files

SQL Server maps a database over a set of operating system files visible to the SQL Server machine. Microsoft recommends that the files be located on a storage area network (SAN), on an iSCSI-based network, or on a locally attached disk. These three storage options provide the best performance and reliability for a SQL Server database. You have an option of storing database files on a network, but this option is turned off by default. You can use the trace flag 1807 to enable network-based database files, but it is generally not recommended that you do so.

Each database can contain a maximum of 32,767 files. Each database file serves a different purpose for the database engine. These files have a standard layout that allows SQL Server to organize and read the data within the files. SQL Server needs to keep track of the allocated space in each data file; it does so by allocating special pages in the first extent of each file. Because the data stored on these pages is dense and the files are accessed often, they are usually found in memory; therefore, they can be retrieved quickly.

The first page (page 0) in every file is the file header page. This page contains information about the file, such as the database to which the file belongs, the filegroup it is in, the minimum size, and its growth increment.

The second page (page 1) in each file is the page free space (PFS) page. The PFS page keeps track of the other pages in the database file. The PFS uses 1 byte for each page. This byte keeps track of whether the page is allocated, whether it is empty, and, if it is not empty, how full the page is. A single PFS page can keep track of 8,000 contiguous pages. Additional PFS pages are created as needed.

The third page (page 2) in each file is the global allocation map (GAM) page. This page tracks allocated extents. Each GAM page tracks 64,000 extents, and additional GAM pages are allocated as needed. The GAM page contains 1 bit for each extent, which is set to 0 if the extent is allocated to an object and to 1 if it is free.

The fourth page (page 3) is the secondary GAM (SGAM) page. The SGAM page tracks allocated mixed extents. Each SGAM page tracks 64,000 mixed extents, and additional SGAM pages are allocated as needed. A bit set to 1 for an extent indicates a mixed extent with pages available.

Primary Files

The *primary data file* is the data file that keeps track of all the other data files used by the database. It is an operating system file that typically has the file extension `.mdf`. SQL Server does not require that it have this `.mdf` extension, but it is recommended for consistency. The primary data file is the first file created for a database. Each database must have only one primary file. This file stores data for any database objects mapped to it, and it contains references to any other database files created.

In many cases, the primary data file is the only data file. There is no requirement to have more than one data file, and often, a database contains only one primary data file (for example, `C:\mssql\mydb.mdf`) and only one log file (for example, `C:\mssql\mydb_log.ldf`).

Secondary Files

You can create zero or more secondary data files in a database. These files, by default, are identified with the `.ndf` extension, but the extension can be different. Secondary data files provide an opportunity to spread the data that SQL Server stores over more than one physical file. This capability can be particularly useful for larger databases and can help with performance and management of database files. Consider, for example, a situation in which a database server has four physical drives available for the data file(s). Each drive is 1GB in size, but the database you are creating is 2GB. In this example, the database will not fit on one drive. A solution to this problem is to create a primary data file on one of the drives and a secondary data file on each of the three remaining drives. SQL Server automatically spreads the 2GB database across the four data files located on four separate drives.

Secondary files also provide some added flexibility for backing up or copying databases. This is most apparent with large databases. For example, let's say you have a 100GB database, and it contains only a primary data file. If you want to move this database to another environment, you must have a drive that is at least 100GB to store the primary data file. If you want to copy the database to a server that has 10 50GB drives, you cannot do it. You have the space across all 10 drives, but you do not have a single drive that can hold the primary data file. If, however, you create the database with several secondary files, you have the option of placing each of the secondary files on a separate drive.

TIP

You can use the `sys.master_files` catalog view to list the database files for all the databases. For example, `SELECT db_name(database_id), * from sys.master_files order by 1` returns all the database files, ordered by the name of the database they belong to. You can change the sort order for the `SELECT` statement and order it by `physical_name` to quickly locate a database file and find which database is using that file.

Using Filegroups

Filegroups allow you to align certain database objects with specific data files. Tables, indexes, and large object (LOB) data can be assigned to a filegroup. A filegroup can be associated with one or more data files. The alignment of data and indexes to filegroups can provide performance benefits and improve manageability. Each database has at least one filegroup, called the *primary filegroup*. This filegroup, by default, contains the primary data file and any other secondary data files that have not been specifically aligned with another filegroup. Any database object that you create without specifying a filegroup is created in the primary filegroup.

Additional filegroups can be created and aligned with secondary data files. There is no requirement to have more than one filegroup, but additional filegroups give you added flexibility. Filegroups can be aligned with data files that can be stored on separate disk drives to improve data access. This improvement is facilitated by concurrent disk access across the disk drives assigned to the filegroups.

TIP

If too many outstanding I/Os are causing bottlenecks in the disk I/O subsystem, you might want to consider spreading the files across more disk drives. Performance Monitor can identify I/O bottlenecks by monitoring the `PhysicalDisk` object and `Disk Queue Length` counter. You should consider spreading the files across multiple disk drives if the `Disk Queue Length` counter is greater than two times the number of spindles on the disk. For more information on monitoring SQL Server performance, see Chapter 39, “Monitoring SQL Server Performance.”

For example, you could create a filegroup called `UserData_FG`, consisting of three files spread over three physical drives. You could create another filegroup named `Index_FG`, with a single file, on a fourth drive. Then, when you create the tables, you can create them on the `UserData_FG` filegroup. You can create indexes on the `Index_FG` filegroup. This reduces contention between tables because the data is spread over three disks and can be accessed independently of the indexes. If more storage is required in the future, you can easily add additional files to the index or data filegroup, as appropriate.

You can create filegroups at the time the database is created, or you can add them after the database is created. When you create filegroups along with the database, the definition for the filegroup is contained in the `CREATE DATABASE` statement. Following is an example of a `CREATE DATABASE` statement with filegroup definitions:

```
CREATE DATABASE [mydb] ON PRIMARY
( NAME = N'mydb',
  FILENAME = N'C:\mssql12008\data\mydb.mdf',
  SIZE = 2048KB, FILEGROWTH = 1024KB ),
FILEGROUP [Index_FG]
```

```

( NAME = N'mydb_index1',
  FILENAME = N'I:\mssql12008\data\mydb_index1.ndf' ,
  SIZE = 2048KB , FILEGROWTH = 1024KB ),
FILEGROUP [UserData_FG]
( NAME = N'mydb_userdata1',
  FILENAME = N'D:\mssql12008\data\mydb_userdata1.ndf' ,
  SIZE = 2048KB , FILEGROWTH = 1024KB ),
( NAME = N'mydb_userdata2',
  FILENAME = N'E:\mssql12008\data\mydb_userdata2.ndf' ,
  SIZE = 2048KB , FILEGROWTH = 1024KB ),
( NAME = N'mydb_userdata3',
  FILENAME = N'F:\mssql12008\data\mydb_userdata3.ndf' ,
  SIZE = 2048KB , FILEGROWTH = 1024KB )
LOG ON
( NAME = N'mydb_log',
  FILENAME = N'L:\mssql12008\log\mydb_log.ldf' ,
  SIZE = 1024KB , FILEGROWTH = 10%)

```

This example creates a database named `mydb` that has three filegroups. The first filegroup, `PRIMARY`, contains the `.mdf` file. `Index_FG` contains one file: `I:\mssql12008\data\mydb_index1.ndf`. The third filegroup, `UserData_FG`, contains three data files located on the `D:`, `E:`, and `F:` drives. This example demonstrates the relationship between databases, filegroups, and the underlying operating system files. (The T-SQL for creating a database is discussed in detail later in this chapter.)

After you create a database with multiple filegroups, you can then create a database object on a specific filegroup. In the preceding example, you could use the filegroup named `UserData_FG` to hold user-defined tables, and you could use the filegroup named `Index_FG` for the database indexes. You assign database objects at the time you create the object. The following example demonstrates the creation of a user-defined table on the `UserData_FG` filegroup and the creation of an index for that table on the `Index_FG` filegroup:

```

CREATE TABLE dbo.Table1
  (TableId int NULL,
   TableDesc varchar(50) NULL)
ON [UserData_FG]

CREATE CLUSTERED INDEX [CI_Table1_TableID] ON [dbo].[Table1]
  ([TableId] ASC)
ON [Index_FG]

```

Any objects not explicitly created on a filegroup are created on the default filegroup. The `PRIMARY` filegroup is the default filegroup when a database is created. You can change the default filegroup, if necessary. If you want to change the default group to another group, you can use the `ALTER DATABASE` command. For example, the following command changes the default filegroup for the `mydb` database:

```
ALTER DATABASE [mydb] MODIFY FILEGROUP [UserData_FG] DEFAULT
```

You can also change the default filegroup by right-clicking the database in the Object Explorer, choosing Properties, and selecting the Filegroups page. Then you select the check box labeled Default to make the given filegroup the default. Figure 23.1 shows the filegroups for the AdventureWorks2008 database, with the primary filegroup selected as the default.

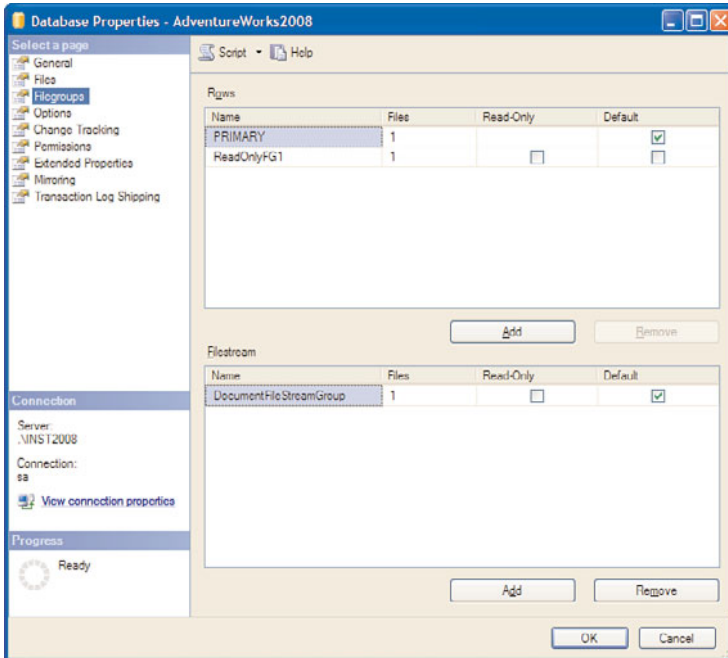

FIGURE 23.1 Setting the default filegroup in SQL Server Management Studio (SSMS).

When creating filegroups, you should keep in mind the following restrictions:

- ▶ You can't move a data file to another filegroup after it has been added to the database.
- ▶ Filegroups apply only to data files and not to log files.
- ▶ A data file can be part of only one filegroup and cannot be spread across multiple filegroups.
- ▶ You can have a maximum of 32,767 filegroups for each database.

NOTE

Using SANs and RAID arrays for the database disk subsystem diminishes the need for filegroups. SAN and RAID systems typically have many disks mapped to a single data drive. This inherently allows for concurrent disk access without requiring the creation of a filegroup with multiple data files.

Using Partitions

Partitioning in SQL Server 2008 allows for a single table or index to be aligned to more than one filegroup. This capability was introduced in SQL Server 2005. Prior to SQL Server 2005, you could use filegroups to isolate a table or an index to a single filegroup, but the table or index could not be spread across multiple filegroups or data files. The ability to spread a table or an index across multiple filegroups is particularly useful for large tables. You can partition a table across multiple filegroups and have data files live on separate disk drives to improve performance. Table partitioning is discussed in more detail in Chapter 24, “Creating and Managing Tables.”

Transaction Log Files

A *transaction* is a mechanism for grouping a series of database changes into one logical operation. SQL Server keeps track of each transaction in a file called the *transaction log*. This log file usually has the extension `.ldf`, but it can have a different extension. Typically, there is only one log file. You can specify multiple log files, but these files are accessed sequentially. If multiple files are used, SQL Server fills one file before moving to the next. You realize no performance benefit by using multiple files, but you can use them to extend the size of the log.

NOTE

The transaction log file is not a text file that can be read by opening the file in a text editor. The file is proprietary, and you cannot easily view the transactions or changes within it. However, you can use the undocumented `DBCC LOG (database name)` command to list the log contents. The output is relatively cryptic, but it can give you some idea of the type of information that is stored in the log file.

Because the transaction log file keeps track of all changes applied to a database, it is very important for database recovery. The transaction log is your friend: it can prevent significant data loss and provide recovery that is not possible without it. Consider, for example, a case in which a database is put in simple recovery mode. In short, this causes transaction detail to be automatically removed from the transaction log. This option is often selected because the transaction log is seen as taking too much disk space. The problem with simple mode is that it limits your ability to recover transactions. If a catastrophic failure occurs, you can restore your last database backup, but that may be it. If that backup was taken the night before, all the database work done that day is lost.

If your database is not in simple mode (Full or Bulk-Logged), and the transaction log is intact, you have much better recovery options. For example, if you back up your transaction log periodically (for example, every hour) and a catastrophic error occurs, your data loss is limited. You still need to restore your last database backup, but you have the option of applying all the database changes stored in your transaction log. With hourly backups, you should lose no more than an hour's worth of work. This topic is covered in detail in Chapter 14, “Database Backup and Restore.”

How the Transaction Log Works

SQL Server utilizes a write-ahead log. As changes are made to data through transactions, those changes are written immediately to the transaction log when the transaction is complete. The write-ahead log guarantees that all data modifications are written to the log prior to being written to disk. By writing each change to the transaction log before it is written to the database, SQL Server can increase I/O efficiency to the data files and ensure data integrity in case of system failure.

To fully understand the write-ahead log, you must first understand the role of SQL Server's cache or memory as it relates to database updates. SQL Server does not write updates directly to the data page on disk. Instead, SQL Server writes a change to a copy of the data page that has been placed in memory. Pages changed in memory and not yet written to disk are called *dirty pages*. The same basic approach is used for transaction log updates. The update to the log is performed in the log cache first, and it is written to disk at a later time. The time when the updates are actually written from cache to disk is called a *checkpoint*. The checkpoint occurs periodically, and SQL Server ensures that dirty pages are not written to disk before the corresponding log entry is written to disk.

The write-ahead log was designed for performance reasons, and it is critical for the recovery process after a system failure. If the system fails, an automatic recovery process is initiated when SQL Server restarts. This recovery process can use the checkpoint marker in the log file as a starting point for recovery. SQL Server examines all transactions after the checkpoint. If they are committed transactions, they are rolled forward; if they are incomplete transactions, they are rolled back, or undone.

NOTE

Changes were made in SQL Server 2005 that improve the availability of the database during the recovery process. These changes have been carried forward to SQL Server 2008. In versions prior to SQL Server 2005, the database was not available until it was completely recovered and the roll-forward and roll-back processes were complete. In versions following SQL Server 2005, the database is made available right after the roll-forward process. The roll-back or undo process can occur while users are in the database. This feature, known as Fast Recovery, is available only with the Enterprise Edition of SQL Server 2008.

For more detailed information on this topic, see Chapter 31, "Transaction Management and the Transaction Log."

Creating Databases

Database creation is a relatively straightforward operation that you can perform by using T-SQL statements or SSMS. Because the data and log files are created at the time the database is created, the time it takes for the database to be created depends on the size and number of files you specify when you create the database. If there is not enough disk space to create any of the files specified, SQL Server returns an error, and none of the files are created.

NOTE

Enhancements that were added in SQL Server 2005 and still exist in SQL Server 2008 have reduced the amount of time it takes to create a database. The reduction in creation time is attributed to a change in the way the database files are initialized. The initialization of the file with binary zeros is now deferred until the file is accessed via SQL queries. This results in much faster database creation and expansion. For example, we created a database with a 1GB data file on a machine running SQL Server 2008. The database was created in approximately 1 second. The same database was then created in SQL Server 2000, running on the same machine. The creation of the database on SQL Server 2000 took approximately 36 seconds. This new feature will make a lot of folks who create and support large databases very happy.

Using SSMS to Create a Database

The Object Explorer in SSMS makes creating a database simple. You right-click the Databases node and select New Database. The New Database dialog appears, as shown in Figure 23.2. The General page is selected by default. It allows you to select the essential information needed to create a database, including the database name, database owner, and location of the database files.

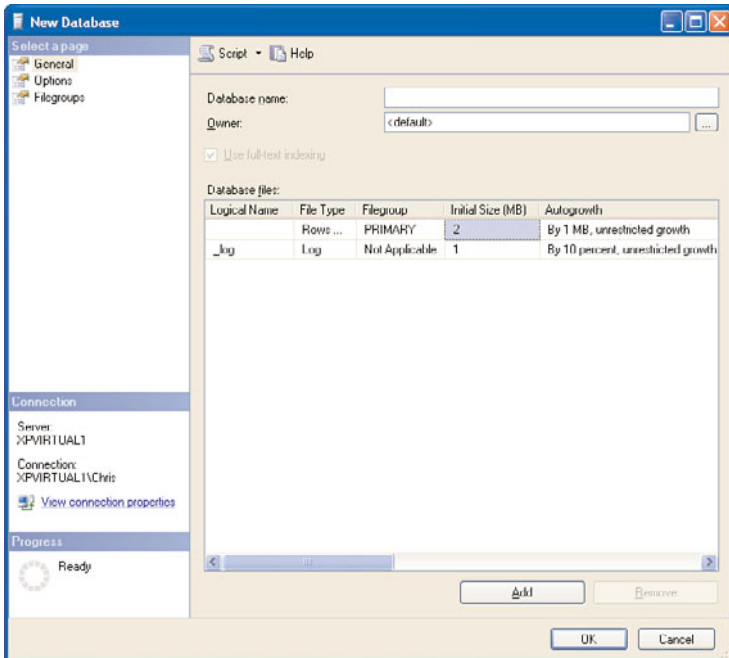

FIGURE 23.2 Creating a database by using SSMS.

Some related information is populated when you enter the database name. For example, the logical name of the database files is populated using the database name. The data file

(which is identified with the file type Data) is named the same as the database. The log file (file type Log) has a database name with the suffix `_log`. The logical filename can be changed, but it must be unique within the database.

The location of the database files is an important decision. The location for each file is entered in the Path column in the Database Files grid. This column, located on the right side of the Database Files grid, includes an ellipsis that can help you navigate the directory structure on your server. When you select the location of these files, you should keep in mind the following:

- ▶ **Disk space**—Databases, by nature, grow over time. You need to make sure the location where you place your database files has sufficient space for growth.
- ▶ **Performance**—The location of your database files can affect performance. Generally, the data and log files should be placed on separate disk drives (with separate controllers) to maximize performance.
- ▶ **Organization**—Choosing a common location or directory for your database files can help keep things organized. For example, you could choose to place your data files in directories named `\mssql\data\` and `\mssql\log` instead of using the long pathname that SQL Server uses by default.

There are several restrictions related to the database files specified. Each filename must be unique and cannot be used by another database. The files specified for a database must be located on a local drive of the machine where SQL Server is installed, a SAN drive, or an iSCSI-based network drive. Finally, you need to make sure the path specified exists on the drive prior to creating the database.

NOTE

The default path for the database files is populated based on database settings values specified in the Server Properties dialog. To open this dialog, you right-click the server in the Object Explorer and choose Properties. When the Server Properties dialog appears, you choose the Database Settings page, where you see the database default locations. If the database default locations for the log and data files are not specified, the paths to the master database files are used. You can determine the paths to the master database files by looking at the startup parameters for the SQL Server instance. You can view these startup parameters within the SQL Server Configuration Manager. After you open this application, you right-click the SQL Server service and select Properties. On the Advanced tab of the Properties dialog that appears, you find the setting named Startup Parameters. The `-d` parameter identifies the location of the data file for the master database. The `-l` parameter identifies the location of the log file for the master database.

The remaining pages in the New Database dialog allow you to set database options, utilize filegroups, and set extended properties. The Options page contains many settings discussed in the “Setting Database Options” section later in this chapter. Three settings at the top of the Options page deserve special attention: Collation, Recovery Model, and Compatibility Level. Figure 23.3 shows the Options page.

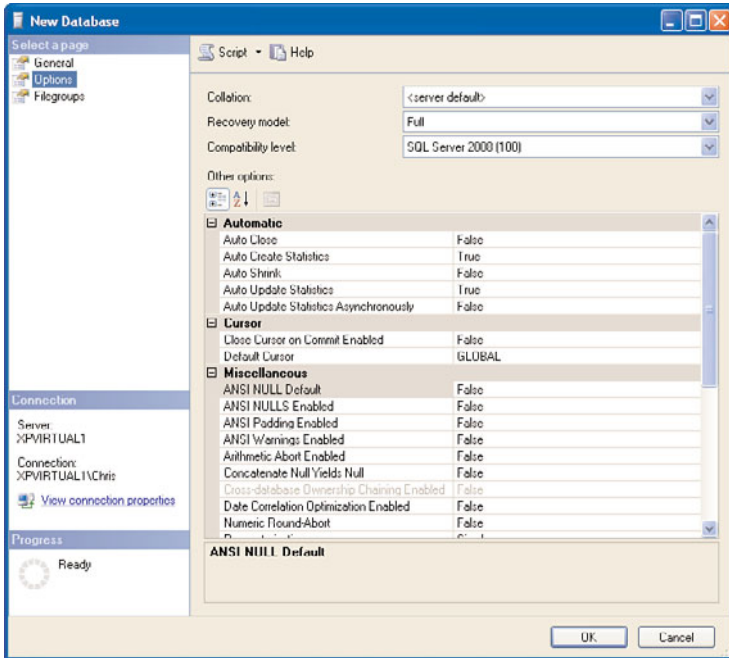

FIGURE 23.3 The Options page for creating a database.

Collation specifies how strings are sorted and compared. The selection of collation is language dependent and addresses differences in the way characters are ordered. The default collation for a database is based on the server default, which is set during the installation of SQL Server. The server default for many U.S.-based installations is `SQL_Latin1_General_CP1_CI_AS`. The collation name provides some insight into how the collation will work. For example, `CI` is an acronym for Case Insensitive, and `AS` indicates that the collation will be Accent Sensitive. The following `SELECT` statement can be used to list all the available collations and relates details about how the collation behaves:

```
SELECT * from ::fn_helpcollations()
```

The Recovery Model setting is critical in determining how much data can be recovered in the event of a media failure. The default is Full, which provides the greatest level of recovery. With Full recovery, all changes to the database (inserts, updates, and deletions) are written to the transaction log, and so are any changes that may have occurred using `BCP` or `BULK INSERT`. If a failure occurs on one of the database files, you can restore the database by using the last full backup. All the changes captured in the transaction log since the last full backup can be reapplied to the database as well.

The Bulk-Logged recovery setting is similar to Full recovery but has some differences in the way that operations (`BCP` or `BULK INSERT`) are logged. With Bulk-Logged recovery, you can still restore all the transaction log backups to recover your database to a point in time.

NOTE

When either Full recovery or Bulk-Logged settings is selected, it is important to set up a job or maintenance plan that performs periodic backups of the transaction log. A backup of the transaction log removes data from the log and keeps the size of the transaction log manageable. If regular backups of the transaction log are not made, the transaction log will continue to grow as every change in the database is written to it.

Simple recovery mode offers the simplest backup/recovery model but the greatest possibility of losing changes to the database. This is based on the fact that changes recorded in the transaction log are automatically truncated when the database is placed in Simple recovery mode. Recovery with Simple mode is limited to using full or differential database backups that have been taken. Simple recovery mode is a good option for read-only databases and for development databases that can afford the loss of changes since the last database backup. All the recovery models are discussed in detail in Chapter 14.

The last setting on the Options page that deserves special attention is Compatibility Level. The Compatibility Level determines the level of backward compatibility the database engine uses. For many newly created databases in SQL Server 2008, the default of SQL Server 2008 (100) will suffice. With this setting, all the new features available with SQL Server 2008 are utilized. In some situations, however, you might want a SQL Server 2008 database to behave as though it were a SQL Server 2005 database or SQL Server 2000 database. You can accomplish this by setting Compatibility Level to SQL Server 2005 (90) or SQL Server 2000 (80). Generally, you select older compatibility levels to allow code that was developed for prior versions of SQL Server to work as it did with those versions.

NOTE

The Compatibility Level setting is intended to allow a database to behave as if it were running in a previous version of SQL Server by providing similar query behavior or by allowing deprecated features to still work as they did in the previous version. However, setting the Compatibility Level to a prior version does not prevent new SQL Server 2008 features from being implemented in the database. The intent of this functionality is to provide a means for moving a database and application developed for a previous release of SQL Server to SQL Server 2008 and allow it to work as it did while enabling you to start taking advantage of new features and capabilities as you migrate the system to SQL Server 2008.

Using T-SQL to Create Databases

Instead of using SSMS, you can use T-SQL to create a database. The T-SQL command to do this is `CREATE DATABASE`. The `CREATE DATABASE` syntax is extensive and is best illustrated with an example. Listing 23.1 shows a sample script to create a database called `mydb`. This script was generated using the Script option available on the New Database screen.

LISTING 23.1 Using T-SQL to Create a Database

```

CREATE DATABASE [mydb] ON PRIMARY
( NAME = N'mydb', FILENAME = N'C:\mssql2008\data\mydb.mdf' ,
  SIZE = 2048KB , FILEGROWTH = 1024KB )
LOG ON
( NAME = N'mydb_log', FILENAME = N'C:\mssql2008\log\mydb_log.ldf',
  SIZE = 1024KB , FILEGROWTH = 10%)
GO

```

The database created in Listing 23.1 is relatively simple. It is named `mydb` and contains one data file and one log file. The data file is created on the `PRIMARY` filegroup; it is named `mydb.mdf` and is created in the `C:\mssql2008\data` folder. The `mydb.mdf` file is initially created with a size of 2048KB, or 2MB. If the database utilizes the entire 2MB, the file can be expanded by the amount specified in the `FILEGROWTH` parameter. In this case, the file can grow in 1MB increments. (Managing file growth is discussed in the section “Managing Databases,” later in this chapter.)

The log file is defined using the `LOG ON` clause in the `CREATE DATABASE` command. The `mydb` database created in Listing 23.1 has a log file named `mydb_log.ldf` that is also created in the `C:\mssql2008\data` folder. The initial size of the file is 1MB, and it can expand by 10% of the current log file size. You need to use caution with large databases when using a percentage to define `FILEGROWTH`. For example, you may have problems if you have a large database that has a 30GB log file and a `FILEGROWTH` of 10%. If the database file is set to autogrow, and the 30GB log file is full, it attempts to expand the log file by 3GB. An expansion of this size could be detrimental to performance, and the disk drive where the log file is located might not have that much disk space remaining.

You can specify many of the other options that define a database after the database is created by using the `ALTER DATABASE` statement. The T-SQL scripting option available on the `CREATE DATABASE` screen generates the basic `CREATE DATABASE` syntax shown in Listing 23.1, and then it generates a series of `ALTER DATABASE` commands that further define the database. These options are discussed in the next section.

Setting Database Options

You can use an abundance of database options to refine the behavior of a database. These options fall into the following categories, which are part of the option specification:

- Auto Options

- Cursor Options

- Database Availability Options

- Date Correlation Optimization Options

- External Access Options

- Parameterization Options

- Recovery Options
- Service Broker Options
- Snapshot Isolation Options
- SQL Options

For each category, you can set one or more options. You can find a full list of options for each category in the section “Setting Database Options” in SQL Server Books Online. Some of the options are discussed in further detail in the chapters of this book that relate to the database options. For example, the recovery options are discussed in detail in Chapter 14, the Service Broker options are discussed in Chapter 49, “SQL Server Service Broker” (on the CD), and database mirroring options are discussed in Chapter 20, “Database Mirroring.”

The following section focuses on the database options displayed on the Options page in SSMS.

The Database Options

You can access many of the most common database options via the Options page of the Database Properties dialog. To get to this dialog, you right-click a database in the SSMS Object Explorer and select Properties. When the dialog appears, you select the Options page from the list on the left side of the Database Properties dialog. Figure 23.4 shows the Options page for the AdventureWorks2008 database. The options listed under Other Options can be listed alphabetically or by category. The default display mode is by category.

The default settings for these options suffice for most installations. However, some options deserve special attention. The options listed under the Automatic category are among these options. The Auto Close option could cause problems in prior versions of SQL Server. This option is intended for desktop implementations in which the database does not need to be online all the time. When users are not accessing the database and this option is selected, the database files are closed. When the first user accesses the database, the database is brought back online. The problem in prior versions was that the synchronous operation of opening and closing the database files caused performance problems. This issue has been addressed in SQL Server 2008 because the operations are now performed asynchronously. The Auto Close option defaults to `true` only for SQL Server 2008 Express Edition and should generally be left set to `false` for all other versions.

The Auto Create Statistics and Auto Update Statistics options also deserve special attention in situations in which the creation or updating of statistics is affecting performance. Generally, the creation or updating of statistics improves performance. These statistics enable the Query Optimizer to make the best decisions when determining the access path to the data. In some rare circumstances, there may be performance problems at the time statistics are created or updated automatically. When these situations arise, you can turn off the Auto Statistics options and schedule the statistics operations to occur during off-hours.

Enabling the Auto Shrink option is a good idea for keeping a nonproduction database as small as possible. This option automatically performs a database shrink operation against the database files when more than 25% of a file contains unused space. The default setting

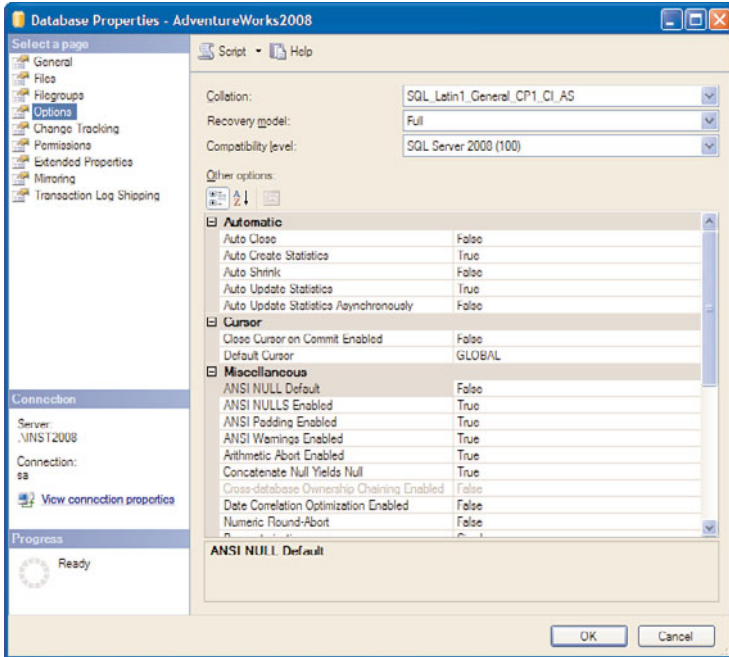

FIGURE 23.4 Database options in SSMS.

is false because this option can cause performance problems (related to the timing of the shrink operation) in a production database. Because the operation is automatic, it can run at any time, including times when there may be heavy production load.

The Page Verify option in the Recovery category was enhanced in SQL Server 2005. That enhancement came in the form of a new CHECKSUM option. This CHECKSUM option is the default; it causes a checksum calculation to occur across the entire database page. Prior to the availability of the CHECKSUM option, page verification was done with TORN_PAGE_DETECTION. Both of these options help detect damaged database pages, but CHECKSUM is the method that Microsoft recommends. The CHECKSUM calculation can be complicated but it basically tells SQL Server to calculate a number based on the contents of each data / index page. The CHECKSUM value is stored in the page header when it is written to disk. When the page is read from the disk, the checksum is computed again and compared to the value in page header to help ensure that the contents of each page are valid.

Database Read-Only and Restrict Access are two other commonly used options in the State category. You can set Database Read-Only to true to prevent updates from occurring in the database. Databases used for reference and not updated are perfect candidates for this option. The Restrict Access options are handy when you're executing system maintenance or mass updates in which you want to restrict users from accessing the database. Single User allows only one user to access the database. The Restricted option allows only members of db_owner, dbcreator, and sysadmin to access the database. With the

Restricted option, there is no limit on the number of users in these groups that can access the database.

You can easily set up the options reviewed in this section as well as the other options mentioned by using the Database Properties dialog. The current value for each option is shown in the right-hand column. To set an option to another value, you click the current value, and a drop-down arrow appears. When you click the drop-down arrow, you can select from the list of valid values for the option. After making all your option changes, you can click OK for the changes to take effect immediately, or you can click the Script button to generate the T-SQL code to change the options. The T-SQL code used to change the options is discussed in the next section.

Using T-SQL to Set Database Options

If you prefer to use T-SQL, or if the option you need to set doesn't appear in the Database Properties dialog, you can use the ALTER DATABASE command to set options. For example, the following command sets AUTO_UPDATE_STATISTICS to OFF in the AdventureWorks2008 database:

```
ALTER DATABASE [AdventureWorks2008] SET AUTO_UPDATE_STATISTICS OFF WITH NO_WAIT
```

You can also change some of the options by using the system stored procedure sp_dboption. This feature is scheduled to be removed in a future release of SQL Server but is still available in this release. You might still be using this procedure based on prior releases, and old habits are hard to break. Following is an example of one of the sp_dboption commands many people have been using for years:

```
EXEC sp_dboption 'AdventureWorks2008', 'single user', 'TRUE'
```

This command sets the AdventureWorks2008 database to single-user mode. Setting a database to single-user mode is useful when you're performing certain database operations. For example, you might use sp_dboption to set a database to single-user mode prior to renaming the database with the sp_renamedb system procedure. It is important to break old habits and move on to using the ALTER DATABASE command. The single-user option and database name change have both been integrated into the ALTER DATABASE syntax. The following example shows how to set the single-user mode option and change the database name by using ALTER DATABASE:

```
ALTER DATABASE [AdventureWorks2008] SET SINGLE_USER WITH NO_WAIT
GO
ALTER DATABASE [AdventureWorks2008] MODIFY NAME = [AdventureWorks2008_New]
GO
```

As you can see, using ALTER DATABASE is fairly straightforward and offers a consistent approach for modifying a database and its options.

TIP

Databases can be brought offline in SQL Server 2008 using SSMS or the T-SQL `ALTER DATABASE` command. When databases are offline no one can access them and the related database files can be moved. For example, you use the following T-SQL command to take the AdventureWorks2008 database offline:

```
ALTER DATABASE [AdventureWorks2008] SET OFFLINE WITH NO_WAIT
```

You can also specify an option with the `ALTER DATABASE` command that sets the database into an emergency state. This state marks the database as read-only, logging is disabled, and access to the database is limited to members of the `sysadmin` fixed server role. This option quickly prevents normal users from getting at the database but leaves the database available for inquiry for administrators. This is particularly useful when a database had been marked as suspect and is inaccessible. An example of setting a database to the emergency state follows:

```
ALTER DATABASE [AdventureWorks2008] SET emergency WITH NO_WAIT.
```

The offline option and emergency options can be invaluable when you want to quickly prevent or limit access to you database.

Retrieving Option Information

You can retrieve database settings by using several different methods. You can use the Database Properties dialog in SSMS (as described in the preceding section) to display commonly accessed options. You can also use the `DATABASEPROPERTYEX` function or the `sp_dboption` system stored procedure to display individual database options. As mentioned previously, `sp_dboption` is slated for removal in a future release, so the `DATABASEPROPERTYEX` function is preferred. This function accepts input values for the database name and the option for which you want to retrieve the value. The following is an example of a `SELECT` statement you can use to retrieve the Auto Shrink option for the AdventureWorks2008 database:

```
SELECT DATABASEPROPERTYEX ('AdventureWorks2008', 'IsAutoShrink')
```

This function returns a value of 1 or 0 for Boolean values—with 1 being “on” or “true”—and returns the actual value for non-Booleans. Table 23.1 lists the valid properties for the `DATABASEPROPERTYEX` function.

TABLE 23.1 **DATABASEPROPERTYEX** Properties

Property	Explanation
Collation	This is the default collation name for the database.
ComparisonStyle	This is the Windows comparison style of the collation.

TABLE 23.1 DATABASEPROPERTYEX Properties

Property	Explanation
IsAnsiNullDefault	The database follows SQL-92 rules for allowing null values.
IsAnsiNullsEnabled	All comparisons to a null evaluate to unknown.
IsAnsiPaddingEnabled	Strings are padded to the same length before comparison or insertion.
IsAnsiWarningsEnabled	Error or warning messages are issued when standard error conditions occur.
IsArithmeticAbortEnabled	Queries are ended when an overflow or divide-by-zero error occurs during query execution.
IsAutoClose	The database shuts down cleanly and frees resources after the last user exits.
IsAutoCreateStatistics	Existing statistics are automatically updated when the statistics become out-of-date because the data in the tables has changed.
IsAutoShrink	Database files are candidates for automatic periodic shrinking.
IsAutoUpdateStatistics	The AUTO_UPDATE_STATISTICS database option is enabled.
IsCloseCursorsOnCommitEnabled	Cursors that are open when a transaction is committed are closed.
IsFulltextEnabled	The database is full-text enabled.
IsInStandBy	The database is online as read-only, with the restore log allowed.
IsLocalCursorsDefault	Cursor declarations default to LOCAL.
IsMergePublished	The tables in a database can be published for merge replication, if replication is installed.
IsNullConcat	The null concatenation operand yields NULL.
IsNumericRoundAbortEnabled	Errors are generated when loss of precision occurs in expressions.
IsParameterizationForced	The PARAMETERIZATION database SET option is FORCED.

TABLE 23.1 **DATABASEPROPERTYEX** Properties

Property	Explanation
IsPublished	The tables of the database can be published for snapshot or transactional replication, if replication is installed.
IsQuotedIdentifiersEnabled	Double quotation marks can be used on identifiers.
IsRecursiveTriggersEnabled	Recursive firing of triggers is enabled.
IsSubscribed	The database is subscribed to a publication.
IsSyncWithBackup	The database is either a published database or a distribution database and can be restored without disrupting transactional replication.
IsTornPageDetectionEnabled	The SQL Server database engine detects incomplete I/O operations caused by power failures or other system outages.
LCID	This is the Windows locale ID (LCID) for the collation.
Recovery	This is the recovery model for the database.
SQLSortOrder	This indicates the SQL Server sort order ID supported in earlier versions of SQL Server.
Status	This is the database status.
Updateability	This indicates whether data can be modified.
UserAccess	This indicates which users can access the database.
Version	This is the internal version number of the SQL Server code with which the database was created. It is for internal use only by SQL Server tools and in upgrade processing.

If you would like to retrieve all the options set for a database, you have a couple of choices. The option that has been around for a while is `sp_helpdb`. You can pass to this system stored procedure the database name, and it returns several pieces of information about the database, including the options set. The database options are returned in the first result set from `sp_helpdb` in a column named `Status`. The database options are displayed in a comma-delimited format in the `Status` column. All Boolean options that are set to `ON` are returned in the `Status` column, and all non-Boolean values are returned with the value to which they are set.

The syntax for `sp_helpdb` is as follows:

```
sp_helpdb database_name
```

The `sys.databases` catalog view is another good resource for displaying all the database options. This catalog view has a separate column for each of the database options and is much easier to read than the `sp_helpdb` output. The view also has the added flexibility of allowing you to choose a set of options to return. The following example shows a `SELECT` statement that uses the `sys.databases` catalog view to return a common set of options:

```
select name, is_auto_close_on, is_auto_shrink_on,
       is_auto_create_stats_on, is_auto_update_stats_on
from sys.databases
where name = 'AdventureWorks2008'
```

The results from this `SELECT` statement return Boolean values in each column, indicating whether the option is set to `on` or `off`. The number of columns available for selection is extensive and similar to those options available with the `DATABASEPROPERTYEX` function.

TIP

Selecting the column you want from the `sys.databases` catalog view is easier when you use the Object Explorer. To set it, you go to the master database and expand the Views node, followed by the System Views node. When you see the `sys.databases` view listed under System Views, you expand the columns for the `sys.databases` view to see a list of all the available columns. You can then drag the options you want to view into a database query window for use in a `SELECT` statement.

You can also use the new IntelliSense feature available in the SQL Server 2008 query window. When creating a `SELECT` statement that retrieves from the `sys.databases` catalog view (or any other catalog view), you are given a drop-down list of available columns when you reference the view in the select list. See chapter 4 for a more in-depth discussion of the object explorer and IntelliSense.

Managing Databases

After you create a database, you have the ongoing task of managing it. At the database level, this task generally involves manipulating the file structure and setting options appropriate for the usage of the database.

Managing File Growth

As discussed earlier in this chapter, SQL Server manages file growth by automatically growing files by preset intervals when a need for additional space arises. However, this is a very loose definition of the word *manages*. What actually happens is that when the database runs out of space, it suspends all update activity, checks whether it is allowed additional space, and if space is available, it increases the file size by the value defined by `FILEGROWTH`. When the database fills up again, the whole process starts over.

When all the files in a filegroup are full and are configured to autogrow, SQL Server automatically expands one file at a time in a round-robin fashion to accommodate more data. For example, if a filegroup consists of multiple files, and no free space is available in any file in the filegroup, the first file is expanded by the specified file-growth setting. When the first file is full again, and there is no more free space elsewhere in the filegroup, the second file is expanded. When the second file is full, and there is no more free space elsewhere in the filegroup, the third file is expanded, and so on.

Because FILEGROWTH can be defined as small as 64KB, automatically increasing the file size can be detrimental to performance if it happens too frequently. When you think of managing file growth, you can think of the database administrator proactively monitoring the size of files and increasing the size before SQL Server runs out of space when allocating new extents. That's not to say automatic file growth is a bad thing; it is, in fact, a great "safety valve" to accommodate unpredictable data growth or a lack of attention on the part of the administrator.

Expanding Databases

As previously discussed, databases can be expanded automatically, or you can intervene and expand them manually. The manual expansion can be accomplished by adding more files to the database or by increasing the size of the existing files. The database expansions can be accomplished with either SSMS or T-SQL.

To expand the size of the data files using SSMS, you right-click the database in the Object Explorer and select Properties. When the Database Properties dialog appears, you select the Files page to list all the files associated with the database. The Initial Size (MB) column displays the current disk allocation for each file. You can enter the new size directly into the column or use the up arrow to increase the size. After establishing the new size, you can simply click OK to expand the database file, or you can script the change by using the Script button at the top of the Database Properties window.

You can also use the Files page of the Database Properties dialog in SSMS to add files to a database. You do this by clicking the Add button, which adds a new file entry row into the Database Files grid. You must supply a logical name for the new file, which typically contains the database name. In addition, you must supply the other data values in the row, including the file type, filegroup, initial size, autogrowth parameters, and path to the file.

The T-SQL ALTER DATABASE command is another option you can use for expanding a database. Listing 23.2 shows an ALTER DATABASE example that increases the size of a data file in the AdventureWorks2008 database to 200MB.

LISTING 23.2 Using T-SQL to Increase the Size of a Database File

```
ALTER DATABASE [AdventureWorks2008]
  MODIFY FILE ( NAME = N'AdventureWorks2008_Data', SIZE = 200MB )
GO
```

You can also use the ALTER DATABASE command to add a new file to a database. Listing 23.3 shows an example that adds a new data file to the AdventureWorks2008 database.

LISTING 23.3 Using T-SQL to Add a New Database File

```
ALTER DATABASE [AdventureWorks2008]
  ADD FILE ( NAME = N'AdventureWorks2008_Data2',
  FILENAME = N'C:\Program Files\Microsoft SQL
  Server\MSSQL.1\MSSQL\DATA\AdventureWorks2008_Data2.ndf',
  SIZE = 2048KB , FILEGROWTH = 1024KB ) TO FILEGROUP [PRIMARY]
GO
```

Shrinking Databases

Shrinking database files is a bit more involved than expanding them. Generally, you do database shrink operations manually, using DBCC commands. SQL Server does have the AUTOSHRINK database option, but it is usually reserved for development databases and should not be used in production. The reason it is not recommended for production is that the AUTOSHRINK operation can run at peak usage time and affect performance. AUTOSHRINK is executed when more than 25% of a file contains unused space. This event can occur, for example, after a large deletion.

If you want to shrink a database manually, you can do so by using DBCC SHRINKDATABASE, DBCC SHRINKDATAFILE, or SSMS. The following sections describe these three methods.

NOTE

Generally, you should avoid shrinking database files if you believe that the files are going to grow to the same larger size again. The continual expansion of a database can affect performance while the expansion is occurring. Also, if a database file is repeatedly shrunk and expanded, the database file itself can become fragmented within the file system, which can degrade I/O performance for the file.

Using DBCC SHRINKDATABASE to Shrink Databases

The DBCC SHRINKDATABASE statement attempts to shrink all the files in a database and leave a specified target percentage of free space. The following is an example of the DBCC SHRINKDATABASE syntax and running the command against the AdventureWorks2008 database:

```
DBCC SHRINKDATABASE
( 'database_name' | database_id | 0
  [ ,target_percent ]
  [ , { NOTRUNCATE | TRUNCATEONLY } ]
)
[ WITH NO_INFOMSGS ]
--Shrink Example
DBCC SHRINKDATABASE (AdventureWorks2008, 25)
```

The first parameter of the `DBCC SHRINKDATABASE` command is the *database_name* or *database_id*, and the second parameter is the desired percentage that will be left free. In the preceding example, an attempt will be made to shrink the database file and leave 25% free space in the files. This operation is done one data file at a time, and the log files are treated as one unit and shrunk together.

There are quite a few things to consider when you use the `DBCC SHRINKDATABASE` command. The following are some of the most important considerations:

- ▶ `DBCC SHRINKDATABASE` does not shrink a file smaller than its minimal size. The minimal size is the size of the file when it was initially created or the size of the file after it was explicitly resized. Explicit resizing can be accomplished with the `DBCC SHRINKFILE` command.
- ▶ The `TRUNCATEONLY` option frees any unused space at the end of a file but does not attempt any page movement within the file. The target percentage is ignored when this option is specified.
- ▶ The `NOTRUNCATE` option attempts to move pages in the files to push all free space to the end of the file. This option does not actually return the space to the operating system, and the physical file does not end up smaller when this option is used.
- ▶ If neither the `NOTRUNCATE` nor `TRUNCATEONLY` options are specified, this is equivalent to running `DBCC SHRINKDATABASE WITH NOTRUNCATE` followed by `DBCC SHRINKDATABASE WITH TRUNCATEONLY`. The first part attempts to push all the free space to the end of the file; then the free space is released to the operating system, and the file ends up smaller.
- ▶ The database files can never be shrunk to a size smaller than the data contained within them.

For smaller databases, the `DBCC SHRINKFILE` command is often considered to be a good choice because it is all inclusive and applies to all the database files. For larger databases or situations in which you need more control, you should consider using the `DBCC SHRINKFILE` command, which is discussed in the next section.

Using `DBCC SHRINKFILE` to Shrink Databases

The `DBCC SHRINKFILE` command operates on individual database files. For databases that contain many database files, you must execute multiple commands to shrink the entire database. This task requires some extra work, but the increased control is often worth the effort. This, combined with the fact that you can shrink a file below its minimum specified size, makes it a very good option.

The following example shows the syntax for the `DBCC SHRINKFILE` command and a simple example for the `AdventureWorks2008` database:

```
DBCC SHRINKFILE
(
    { ' file_name ' | file_id }
```

```

    { [ , EMPTYFILE]
    | [ [ , target_size ] [ , { NOTRUNCATE | TRUNCATEONLY } ] ]
    }
)
[ WITH NO_INFOMSGS ]
-- sample shrink command
USE [AdventureWorks2008]
GO
DBCC SHRINKFILE (N'AdventureWorks2008_Data' , 180)
GO
DBCC SHRINKFILE (N'AdventureWorks2008_Log' , 10)
GO

```

Note that with this option, a filename or an ID is supplied, rather than the database name. `DBCC SHRINKFILE` must be run in the database that the file belongs to. You specify `TARGET_SIZE` in megabytes; this is the desired size for the file after the shrink completes. If `TARGET_SIZE` is not specified or the target size is too small, the command tries to shrink the file as much as possible. The `EMPTYFILE` option migrates all data in the file to other files in the same filegroup. No further data can be placed on the file. The file can subsequently be dropped from the database. This capability can be useful when you want to migrate a data file to a new disk. The `NOTRUNCATE` and `TRUNCATEONLY` options for `DBCC SHRINKDATAFILE` work the same way as with `DBCC SHRINKDATABASE`. Refer to the previous section for details.

TIP

If you would like to shrink every database file by using the `DBCC SHRINKFILE` command, you can generate the commands by using a `SELECT` statement. The following `SELECT` is an example of this:

```

SELECT 'PRINT ''LOGICAL NAME: ' + rtrim(name) +
      ' FILENAME: ' + rtrim(filename) + '''' + char(10) +
      'go' + char(10) +
      ' DBCC SHRINKFILE (' + convert(varchar(8),fileid) + ',1)' +
      char(10) + 'go' + char(10)
from sysfiles order by fileid

```

The results from this `SELECT` produce the `DBCC SHRINKFILE` commands for all the files in the database that it is run against. You can then paste the results into another query window and execute them. This particular example uses a fixed target size of 1MB, but you can adjust this size in the `SELECT` statement. You could also modify this `SELECT` statement so that it uses the `sys.master_files` catalog view instead of using `sysfiles`.

Shrinking the Log File

The data file most likely to grow beyond a normal size and require periodic shrinking is the transaction log file. If a user process issues a large update transaction, the log file grows to the size needed to hold the records generated by the transaction. This could be significantly larger than the normal growth of the transaction log.

As with data files, shrinking of the log file in SQL Server 2008 can take place only from the end of the log file. However, you must first back up or truncate the log to remove the inactive log records and reduce the size of the logical log. You can then run the `DBCC SHRINKFILE` or `DBCC SHRINKDATABASE` command to release the unused space in the log file.

Transaction log files are divided logically into segments, called virtual log files. The Database Engine chooses the size of the virtual log files dynamically while it is creating or extending log files. Transaction log files can only be shrunk to a virtual log file boundary. It is therefore not possible to shrink a log file to a size smaller than the size of a virtual log file, even if the space is not being used. The size of the virtual log files in a transaction log increase as the size of the log file increases. For example, a database defined with a log file of 1GB may have virtual log files 128MB in size. Therefore, the log can be shrunk to only about 128MB.

Because of the overhead incurred when the autoshrink process attempts to shrink database files, it is not recommended that you enable this option for the transaction log because it could be triggered numerous times during the course of a business day. It is better to schedule the shrinking of the log file to be performed during normal daily maintenance, when production system activity is at a minimum.

Using SSMS to Shrink Databases

In addition to shrinking a database by using T-SQL, you can do so through SSMS. In the Object Explorer, you right-click the database you want to shrink, and then you choose Tasks, followed by Shrink. You can then select either Database or Files. Selecting the Database option displays the Shrink Database dialog (see Figure 23.5). The currently allocated size and free space for the database are shown. You have the option of selecting the Shrink Action and checking the Reorganize Files Before Releasing Unused Space check box.

You can click the Script button to generate the T-SQL that will be used to perform the database shrink operation. When you do, a `DBCC SHRINKDATABASE` command is generated.

If you want to shrink database files, you choose the Files option instead of Database. Figure 23.6 shows the Shrink File dialog displayed when you select Files. You can shrink one database file at a time using this window. If you choose the shrink option Release Unused Space, SMSS uses the `DBCC SHRINKFILE` command with the `TRUNCATEONLY` option. If you choose the Reorganize Pages Before Releasing Unused Space option, SMSS uses the `DBCC SHRINKFILE` command without the `TRUNCATEONLY` or `NOTRUNCATE` option. As mentioned earlier, this causes page movement to free as much space as possible. A `TRUNCATE` operation then releases the free space back to the operating system.

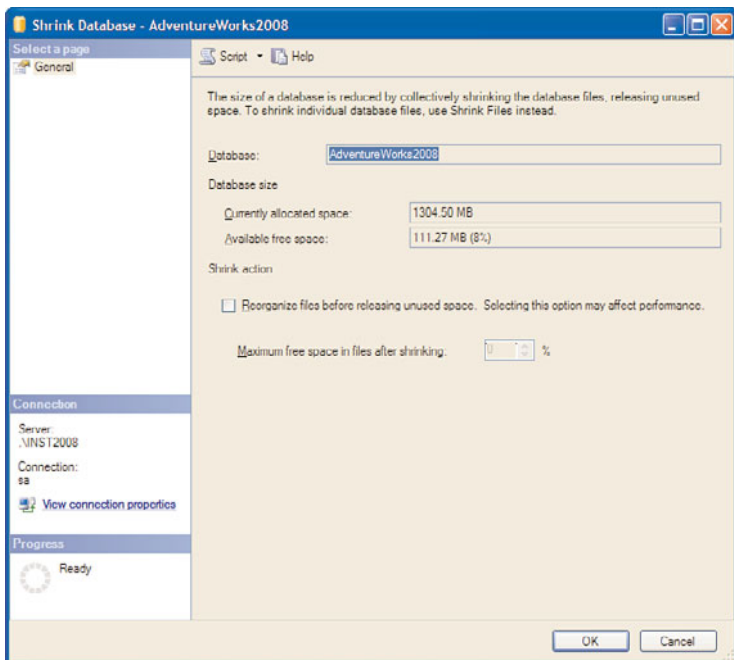

FIGURE 23.5 Shrinking an entire database using SSMS.

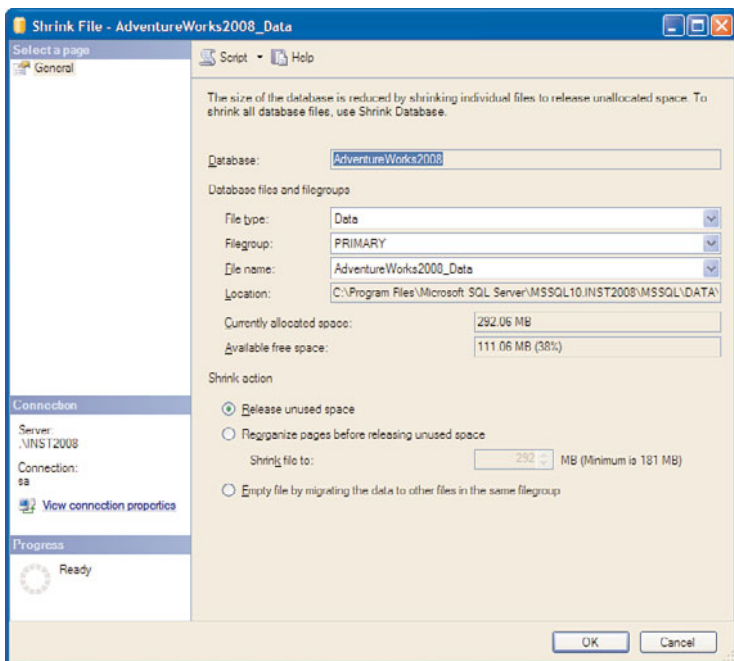

FIGURE 23.6 Shrinking database files in SSMS.

Moving Databases

Sometimes you need to move a database or database file. There are several ways to accomplish this task:

- ▶ Make a database backup and then restore it to a new location.
- ▶ Alter the database, specifying a new location for the database file.
- ▶ Detach the database and then reattach the database, specifying an alternate location.

Restoring a Database Backup to a New Location

The database backup option is fairly straightforward. You make a backup of the database and then write it to a file or files. The file is restored, and any changes to the location of the database files are made at that time. Backup and restoration are discussed in detail in Chapter 14.

You can easily detach a database by right-clicking the database in the Object Explorer and choosing Tasks and then Detach. When the database is detached, you can move the file(s) to the desired location. You can then right-click on the database's node and select Attach. The Attach Databases screen that appears allows you to select the .mdf file and change the file location for any of the related database files. The steps involved in detaching and attaching a database are discussed in detail in the later section "Detaching and Attaching Databases."

Using ALTER DATABASE

The ALTER DATABASE option for moving user database files was added in SQL Server 2005. This option involves the following steps:

1. Take the database offline.
2. Manually move the file(s) to the new location.
3. Run the ALTER DATABASE command to set the FILENAME property to the new file location.
4. Bring the database online.

The following example uses the ALTER DATABASE command to move the log file for the AdventureWorks2008 database to the root of the C: drive.

```
ALTER DATABASE AdventureWorks2008
MODIFY FILE (NAME = AdventureWorks2008_Log,
FILENAME = 'C:\AdventureWorks2008_log.ldf')
```

CAUTION

Use caution when specifying the `FILENAME` parameter to move a database log file. If the `FILENAME` setting specified in the `ALTER DATABASE` command is incorrect and the file does not exist, the command still completes successfully. When the database is brought back online, a message stating that the file can't be found appears, and a new log file is created for you. This invalidates the old log file.

Detaching and Attaching Databases

A convenient way to move or copy database files is to detach and attach databases. Detaching database files removes the database from an instance of SQL Server but leaves the database files intact. After the database is detached, the files associated with the database (that is, `.mdf`, `.ndf`, and `.ldf` files) can be copied or moved to an alternate location. You can then reattach the relocated files by using the `CREATE DATABASE` command with the `FOR ATTACH` option.

TIP

The process of detaching and attaching a database is extremely fast. It is therefore a good alternative to `BACKUP` and `RESTORE` when you're copying a database to another location. The catch with detaching a database is that all users must be disconnected from the database, and the database is unavailable during the detach and copy of the database files.

To detach a database, you right-click the database in Object Explorer and select `Tasks and then Detach`. Figure 23.7 shows an example of the `Detach Database` dialog box for detaching the `AdventureWorks2008` database. You can specify several options, including a handy option (called `Drop Connections`) to kill any user processes (SPIDs) that may still be connected to the database when the detach operation is running. If you do not select the `Drop Connections` option, and users are still connected to the database, the detach operation fails.

Other options available during the detach operation are also useful. The `Update Statistics` option updates out-of-date statistics for all the database tables before you detach the database. The statistics update can take some time on larger databases, so this slows down the overall detach operation. The other option, `Keep Full Text Catalogs`, is new to SQL Server 2008. It allows you to detach any full-text catalogs associated with the database. These detached full-text catalogs are then reattached along with the database when the files are attached. See chapter 56 for a more in-depth discussion of full-text catalogs.

The attach operation is simple to execute through SMSS. In Object Explorer, you simply right-click the database's node and select the `Attach` option. The `Attach Databases` dialog box appears, allowing you to specify the database file(s) you want to attach. You need to click the `Add` button to be able to select a database file for restoration. When you select the main `.mdf` file associated with the database, the associated file information for the other related database files is populated as well.

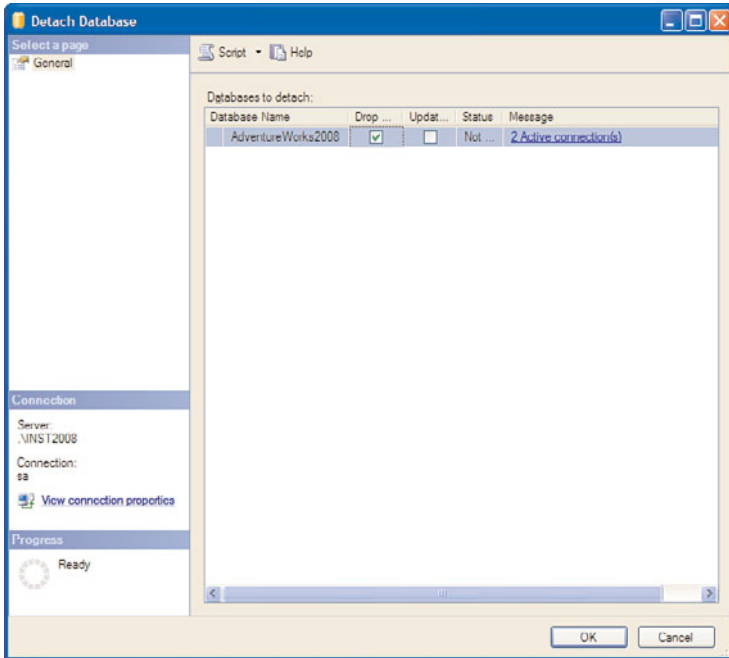

FIGURE 23.7 Detaching a database by using SSMS.

23.8 shows the Attach Databases dialog box for the AdventureWorks2008 database. The top portion of the dialog box lists the main (.mdf) database file selected for the AdventureWorks2008 database. The bottom portion lists the related files. You have an option to attach the database with a different name by changing the Attach As name located at the top of the screen. You can also edit the database details at the bottom of the screen and enter the location of the database files that will be attached. The Current File Path column displays the original file locations determined from the .mdf file. If the files were moved to a new location, this is the place to change the current file path to the new location.

You can also accomplish the detach and attach operations by using T-SQL. You perform the detach operation with the `sp_detach_db` system stored procedure. You perform the attach operation with the `CREATE DATABASE` command, using the `FOR ATTACH` option. The following is an example of T-SQL commands for detaching and attaching the AdventureWorks2008 database:

```
--Detach the database
EXEC master.dbo.sp_detach_db
  @dbname = N'AdventureWorks2008', @keepfulltextindexfile=N'false'
GO
--Attach the database
CREATE DATABASE [AdventureWorks2008] ON
 ( FILENAME = 'C:\Program Files\Microsoft SQL
```

```
Server\MSSQL.1\MSSQL\Data\AdventureWorks2008_Data.mdf' ),
( FILENAME = 'C:\Program Files\Microsoft SQL
Server\MSSQL.1\MSSQL\Data\AdventureWorks2008_log.LDF' )
FOR ATTACH
```

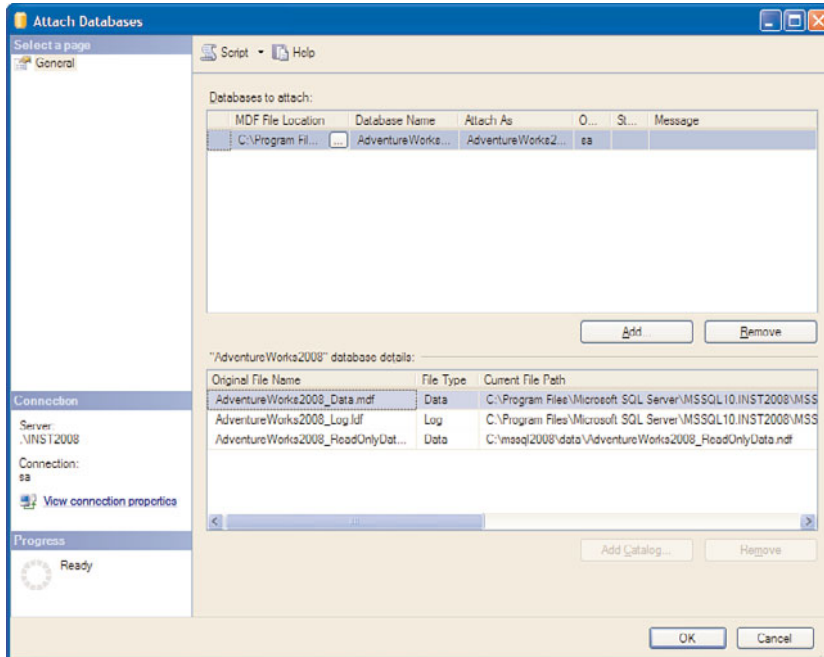

FIGURE 23.8 Attaching a database by using SSMS.

NOTE

You can use the `sp_attach_db` procedure to attach a database, but Microsoft recommends that you use the `CREATE DATABASE ... FOR ATTACH` command instead. The `sp_attach_db` procedure has been deprecated and is slated for removal in a future release of SQL Server.

SQL Server 2008 has the capability to attach a database without all the log files. You do this by using the `ATTACH_REBUILD_LOG` clause when creating the database. When you use this clause, SQL Server rebuilds the log files for you. This capability is useful on large databases that may have large logs that are not needed in the environment where the database files are attached. For example, a `READ_ONLY` database would not need the log files that may be associated with its production counterpart. The following example uses the `ATTACH_REBUILD_LOG` clause to create a copy of the AdventureWorks2008 database:

```
CREATE DATABASE [AdventureWorks2008Temp] ON
( FILENAME = 'C:\Temp\AdventureWorks2008_Data.mdf' )
```

FOR ATTACH_REBUILD_LOG

Summary

The steps involved in creating and managing databases are by no means limited to the topics in this chapter. A database consists of many database objects and has a myriad of other features discussed throughout this book. The next chapter, “Creating and Managing Tables,” delves into one of the most basic elements of a database: the table.

CHAPTER 24

Creating and Managing Tables

Tables are logical constructs used for the storage and manipulation of data in databases. Tables contain *columns*, which describe data, and *rows*, which are instances of table data. Basic relational database design determines the table and column names as well as the distribution of columns within tables.

This chapter gives you the administrative knowledge you need to create tables and manage them within your enterprise. It focuses on the basic constructs for tables and the table-level features that can make your tables robust and efficient objects to house your data.

What's New in SQL Server 2008

Most of the new table-oriented features available with SQL Server 2008 are related to the columns that define a table. Columns can now be defined with several new data types that further expand the type of data that SQL Server can store and manage. Some of these new types, such as the FILESTREAM storage and the geometry and geography data types take SQL Server beyond the typical relational model. FILESTREAM storage provides a reference point to a flat file in the operating system where the data actually resides, and the geometry and geography data types bring you into the world of spatial data storage.

The *hierarchyid* data type is system-provided. You use *hierarchyid* as a data type to create tables with a hierarchical structure or to reference the hierarchical structure of

- ▶ Creating Temporary Tables

data in another location. You use `hierarchyid` functions to query and perform work with hierarchical data by using Transact-SQL (T-SQL).

There have also been additions to more traditional relational data types. For example, SQL Server 2008 now offers separate data types for date and time. The new `date` data type contains only the date, whereas the new `time` data type contains only the time portion. In the past, the `datetime` or `smalldatetime` data types combined the date and time components into a single data type. Other date and time data type enhancements are discussed later in the chapter.

SQL Server 2008 also introduces new ways to organize or access columns. Sparse columns and column sets are example of this. A *sparse column* is a column where the majority of the column's values contain null values. A sparse column is an ordinary column but is given the `SPARSE` keyword when it is added to a table so that the SQL Server Database Engine can optimize the storage of these types of columns. The related *column set* is another type of column that is XML-typed and identifies all the sparse columns added to a table. These data types and all the new data types are discussed later in this chapter.

The good news is that the management of tables and their related columns has remained relatively unchanged in SQL Server 2008. You will find that the facilities available in the SQL Server Management Studio are as familiar and as easy to use as they were in SQL Server 2005.

NOTE

This chapter uses examples from Bigpubs2008 database and the Adventureworks2008 database. Instructions for installing the BigPubs2008 database are located in the Introduction chapter at the beginning of this book.

Creating Tables

SQL Server 2008 supports the creation of tables using T-SQL, the SQL Server Management Studio (SSMS) Object Explorer and the SSMS Database Diagram Editor. Regardless of the tool you choose, creating a table involves naming the table, defining the columns, and assigning properties to the columns. The visual tools (such as Object Explorer and database diagrams) are usually the best starting point for creating tables. These tools offer drop-down boxes that allow you to choose the data types for your columns and check boxes that allow you to define their nullability.

This chapter first looks at the visual tools and then delves into the specific parameters related to the underlying T-SQL statements that ultimately create a table.

Using Object Explorer to Create Tables

The Object Explorer in SSMS has a `Tables` node under each database listed. You can add tables via the Object Explorer by right-clicking this `Tables` node. Figure 24.1 shows the `New Table` option displayed after you right-click the `Tables` node in Object Explorer. The

top-right side of the screen shown in Figure 24.1 is the table creation screen that allows you to enter the column name and data type and to set the Allow Nulls option.

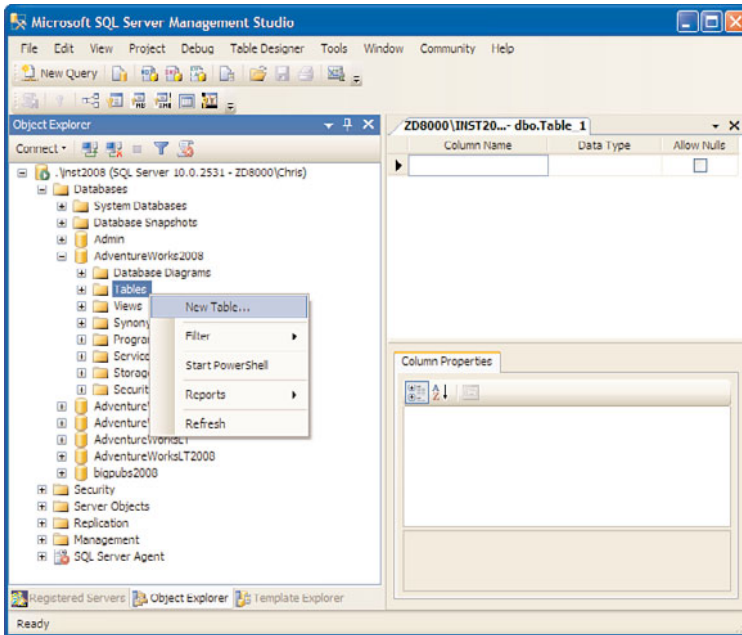

FIGURE 24.1 Using Object Explorer to create a table.

The data entry area under Column Name is a free-form area where you can define a column name. You can select the data type from the Data Type drop-down, which displays the data types available with SQL Server. The Allow Nulls option is Boolean in nature and is either checked or not checked. For each column selected, a Column Properties section is displayed in SSMS, providing a myriad of additional properties that you can assign to each column. These properties are discussed in more detail in the “Defining Columns” section, later in this chapter.

Using Database Diagrams to Create Tables

You can use the database diagrams for a more robust visual representation of your tables. You view them from within SSMS, and they give you the distinct advantage of being able to display multiple tables and the relationships between these tables. The Database Diagram Editor behaves similarly to other data modeling tools that allow you to move related tables around in the diagram and group them accordingly.

Figure 24.2 shows several screens related to database diagrams. The left side of Figure 24.2 shows the Object Explorer and the resulting New Database Diagram option that is displayed if you right-click the Database Diagrams node. The right side of the screen shows the diagram design window. In this example, the existing Department table from

the AdventureWorks2008 database was added to the diagram, and a new Printer table was added as well. The printer table was added by right-clicking in the diagram design window and selecting the New Table option.

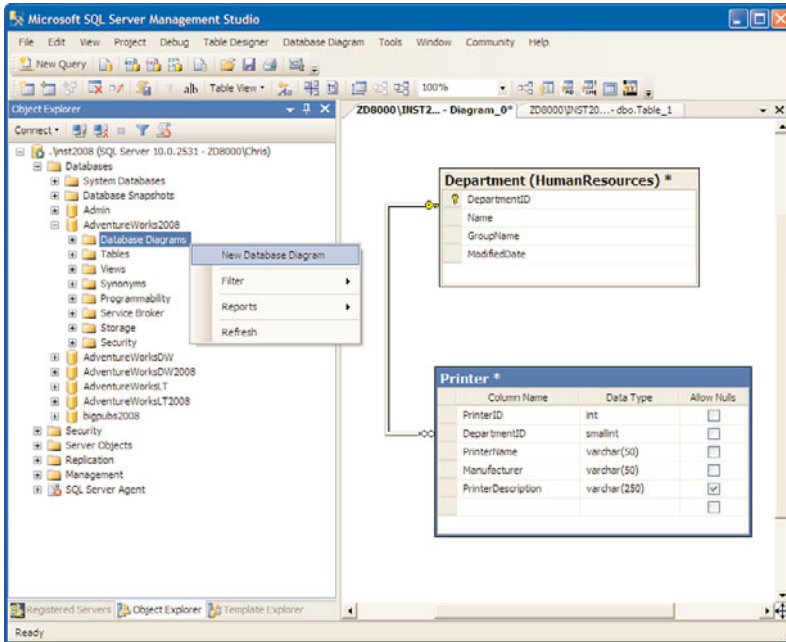

FIGURE 24.2 Using database diagrams to create a table.

The column names and related attributes for the new Printer table in Figure 24.2 were added using the table entry fields. The data entry screen for the table is similar to the one provided with the Object Explorer. You enter column names, along with their associated data types and nullability option.

The advantage of database diagrams is that you can define relationships and show them with a visual representation. This visual view provides a much easier way to view the table structures in a database. In the example shown in Figure 24.2, the line drawn between the Department and Printer tables represents a relationship between these two tables. You define such a foreign key relationship in the database diagram by dragging the related column from one table to the other related table. Table relationships and constraints are discussed later in this chapter, in the section “Defining Table Constraints.”

Using T-SQL to Create Tables

Ultimately, all the tables created with the visual tools can also be created by using T-SQL. As with many of the SSMS tools, database objects can be resolved or scripted into T-SQL statements. Let’s examine the T-SQL syntax to better understand some of the table creation options; then we can discuss the definition of the columns in each table.

The full T-SQL `CREATE TABLE` syntax is extensive. It includes options to define table constraints, indexes, and index options. SQL Server Books Online shows the full syntax and describes each of these options in detail. Listing 24.1 shows the basic T-SQL syntax; the first part of the syntax is listed in Books Online. This syntax is enough to enable you to create a table with its associated column definitions.

LISTING 24.1 Basic T-SQL **CREATE TABLE** Syntax

```
CREATE TABLE
    [ database_name . [ schema_name ] . | schema_name . ] table_name
    ( { <column_definition> | <computed_column_definition> }
      [ <table_constraint> ] [ ,...n ] )
    [ ON { partition_scheme_name ( partition_column_name ) | filegroup
      | "default" } ]
    [ { TEXTIMAGE_ON { filegroup | "default" } } ]
[ ; ]

<column_definition> ::=
column_name <data_type>
    [ COLLATE collation_name ]
    [ NULL | NOT NULL ]
    [
        [ CONSTRAINT constraint_name ] DEFAULT constant_expression ]
    [ [ IDENTITY [ ( seed ,increment ) ] [ NOT FOR REPLICATION ] ]
    ]
    [ ROWGUIDCOL ] [ <column_constraint> [ ...n ] ]

<data type> ::=
[ type_schema_name . ] type_name
    [ ( precision [ , scale ] | max |
      [ { CONTENT | DOCUMENT } ] xml_schema_collection ) ]
```

The number of options in this basic syntax can be daunting, but the reality is that you can exclude many of the options and execute a relatively simple statement. Listing 24.2 is an example of a simple statement you can use to create a table. This listing shows a `CREATE TABLE` statement that you can use to create the Printers table that was shown in Figure 24.2.

LISTING 24.2 A Basic T-SQL **CREATE TABLE** Example

```
CREATE TABLE Printer
(
    PrinterID int NOT NULL,
    DepartmentID smallint NOT NULL,
    PrinterName varchar(50) NOT NULL,
```

```

Manufacturer varchar(50) NOT NULL,
PrinterDescription varchar(250) NULL
)

```

The `CREATE TABLE` statement in Listing 24.2 specifies the table to create, followed by an ordered list of columns to add to the table. The following section describes the specifics related to defining the columns.

TIP

SSMS provides several methods for generating the T-SQL code to create tables. Therefore, you rarely need to type the `CREATE TABLE` statements from scratch. Instead, you can use the friendly graphical user interface (GUI) screens that enable you to define the table, and then you can generate the T-SQL script. For example, you can right-click a new table in the database diagram and select `Generate Change Script` to generate the associated T-SQL for the table.

One of the important considerations during table creation is schema assignment. *Schemas* allow you to logically group objects (including tables) and define ownership, independent of the individual users in the database. Schema enhancements introduced in SQL Server 2005 are still available in SQL Server 2008 and can play a significant role in the definition of tables in a database. Consider, for example, the `AdventureWorks2008` database that ships with SQL Server 2008. The tables in this database have been assigned to schemas that group the tables according to their functional areas. The schemas in the `AdventureWorks2008` database include `Sales`, `Purchasing`, `Person`, `Production`, `HumanResources`, and `dbo`. Some sample tables in the `Person` schema include the `Person` and `Address` tables. The `Purchasing` schema includes tables that relate to purchasing, including the `PurchaseOrderHeader` and `Vendor` tables.

The designation of a schema in the `CREATE TABLE` statement is relatively simple. Listing 24.3 includes a three-part table name for the creation of a `Printer` table in the `HumanResources` schema. The database name (`AdventureWorks2008`) is the first part of the name, followed by a schema name (`HumanResources`). The last part of Listing 24.3 shows a sample `SELECT` statement against the `Printer` table that is owned by the `HumanResources` schema. The schema name must precede the table, when referenced. The only exception to this rule is tables that belong to the default schema assigned to the user executing the query.

LISTING 24.3 Using T-SQL `CREATE TABLE` in a Schema

```

CREATE TABLE AdventureWorks2008.HumanResources.Printer
(
    PrinterID int NOT NULL,
    DepartmentID smallint NOT NULL,
    PrinterName varchar(50) NOT NULL,

```

```

    Manufacturer varchar(50) NOT NULL,
    PrinterDescription varchar(250) NULL
)
go
select * from HumanResources.Printer

```

The creation of schemas and assignment of tables to schemas requires some forethought. This task, which is permission oriented, is discussed in more detail in Chapter 11, “Security and User Administration.”

Defining Columns

A *table* is defined as a collection of columns. Each column represents an attribute of the database table and has characteristics that define its scope and the type of data it can contain. In defining a column, you must assign a name and a data type. For consistency and readability, the column names should adhere to a naming convention that you define for your environment. Naming conventions often use a set of standard suffixes that indicate the type of data the column will contain. For example, you can add the `Date` suffix to a column name (for example, `OrderDate`) to identify it as a column that contains date/time data, or you can add the suffix `ID` (for example, `PrinterID`) to indicate that the column contains a unique identifier.

When creating and naming columns, you need to keep the following restrictions in mind:

- ▶ You can define up to 1,024 columns (nonsparse + computed) for each table. This number is increased to 30,000 columns if the table has a defined column set using sparse columns.
- ▶ Column names must be unique within a table.
- ▶ A row can hold a maximum of 8,060 bytes. Some data types can be stored off the 8KB data page to allow a row to exceed this limit.
- ▶ A data type must be assigned to each column.

These restrictions provide a framework for a column definition. The next consideration in defining a column is the data type. The following section discusses the various data types.

Data Types

SQL Server 2008 has an extensive list of data types to choose from, including some that are new to SQL Server 2008. New data types include `date`, `time`, `datetime2`, `datetimeoffset`, `filestream`, and `geometry`. Each data type is geared toward a specific type of data that will be stored in the column. Table 24.1 provides a complete list of the data types available in SQL Server 2008.

TABLE 24.1 Table Data Types

Data Type	Range/Description	Storage
bigint	-2^{63} (-9,223,372,036,854,775,808) to 2^{63-1} (9,223,372,036,854,775,807)	8 bytes
binary (n)		Binary data with a length of n bytes The number of bytes defined by n, up to 8,000
bit	An integer data type that can take a value of 1, 0, or NULL	1 byte for every eight columns that are defined as bits on the table
char	Up to 8,000 characters	1 byte per character
date	0001-01-01 through 9999-12-31	3 bytes
datetime through	8 bytes; accurate to December 31, 9999	January 1, 1753, 3.33 milliseconds
datetime2 through	8 bytes; accurate to December 31, 9999	January 1, 0001, 100 nanoseconds
datetimeoffset through	10 bytes December 31, a time zone offset	January 1, 0001, 9999; includes
decimal	Based on the precision	-10^{38+1} to 10^{38-1}
float	$-1.79E + 38$ to $-2.23E - 38$, 0 and $2.23E - 38$ to $1.79E + 38$	4 or 8 bytes, depending on the allocation mantissa
geography representing	round-earth data such as GPS latitude and longitude coordinates	.NET CLR data type
geometry CLR data type representing	data in a Euclidean (flat) coordinate system	.NET
hierarchyid levels	Up to 892 bytes	User defined nodes and
image	Variable-length binary data	Up to 2^{31-1} (2,147,483,647) bytes
int	-2^{31} (-2,147,483,648) to 2^{31-1} (2,147,483,647)	4 bytes

TABLE 24.1 Table Data Types

Data Type	Range/Description	Storage
money	-922,337,203,685,477.5808 to 922,337,203,685,477.5807	8 bytes
nchar	Up to 4,000 Unicode characters	Two times the number of characters entered
ntext	Up to 2^{30-1} (1,073,741,823) characters	Two times the number of characters entered
numeric (p,s) 10^{38-1}	Based on the precision	-10^{38+1} through
nvarchar(n)		Up to 4,000 Unicode characters Two times the number of characters entered
nvarchar(max)	Unicode characters up to the maximum storage capacity of	Two times the number plus 2 bytes, up to 2^{30-1}
real	$-1.18E - 38$, 0 and $1.18E - 38$ to $3.40E + 38$	4 bytes
smalldatetime		January 1, 1900, through June 6, 2079 4 bytes; accurate to 1 minute
smallint to 2^{15-1} (32,767)	2 bytes	-2^{15} (-32,768)
smallmoney 214,748.3647	4 bytes	-214,748.3648 to
sql_variant values of	Up to 8,016 bytes various SQL Server 2008-supported data types, except text, ntext, image, timestamp, and sql_variant	A data type that stores
text	Up to 231-1	2,147,483,647) characters Up to 2,147,483,647 bytes
time	00:00:00.0000000 to 23:59:59.9999999	5 bytes
timestamp/rowversion generated, unique binary	numbers within a database; generally used for version stamping rows	Automatically 8 bytes

TABLE 24.1 Table Data Types

Data Type	Range/Description	Storage
tinyint	0 to 255	1 byte
uniqueidentifier unique identifier	16 bytes (GUID)	A 16-byte globally
varbinary(n)		Binary data with a length of n bytes. The number of bytes defined by n, up to 8,000.
varbinary(max)	Binary data up to the maximum storage capacity	Two times the number of characters entered plus 2 bytes, up to 2 ³⁰⁻¹
varchar (n)	1 byte per character	Up to 8,000 characters
varchar (max)	Non-Unicode characters up to the maximum storage capacity	1 byte per character; maximum 2 ³¹⁻¹ bytes
xml	XML instances or a variable of XML type	2GB

The data type you select is important because it provides scope for the column. For example, if you define a column as type `int`, you can be assured that only integer data will be stored in the column and that character data will not be allowed. The advantages of data typing are fairly obvious but sometimes overlooked.

You should avoid defining most of your columns with a single data type, such as `varchar`. As mentioned earlier in this chapter, the visual tools provide a great way for you to select a data type: you simply select a data type from a drop-down selection box that lists the available data types.

TIP

The Object Explorer has a categorized list of all the system data types. To get to it, you open the Programmability node under your database and then expand the Types node. You then see a node named System Data Types that lists all the data type categories, including Exact Numbers, Approximate Numbers, and Date and Time. The data types for each category are listed under each category node. If you mouse over the particular data type, you see a brief description, including the valid range of values.

Several data types in SQL Server 2008 deserve special attention. Some of these data types are new to SQL Server 2008 and some of them were introduced in SQL Server 2005. The following sections discuss these data types.

New Date/Time Data Types

Several new date/time data types were added in SQL Server 2008. These data types were added to enhance SQL Server's date/time capabilities. The `date` and `time` data types were added to separate these two date/time components. The `date` data type contains only the month, day, and year components, whereas the `time` data type contains only the time components. The separation of `date` and `time` was planned for SQL Server 2005 but never made it to the final release.

The precision and scale of date/time data types has been expanded in SQL Server 2008 as well. The `datetime2` data type is similar to the `datetime` data type, but it has a larger range of dates (January 1, 0001, through December 31, 9999), and the time portion of this data type contains fractional seconds with seven digits of precision. The `datetime` data type is accurate only to within 3 milliseconds, whereas the new `datetime2` data type is accurate to 100 nanoseconds.

Finally, SQL Server introduces time zone support in a new data type named `datetimeoffset`. This data type has precision in fractional seconds (like `datetime2`), but it also contains an extra date/time component that defines the time zone offset for the date. The time zone offset is two digits that represent the offset hours and two digits that represent the offset minutes. The offset is used against the UTC date. The following example shows how this new data type can be used:

```
select CAST('2009-07-08 11:33:22.1234567-04:00' AS datetimeoffset(7))
```

The xml Data Type

The `xml` data type (introduced in SQL Server 2005) enables you to store XML documents and XML fragments in a SQL Server database. (An XML fragment is an XML instance that is missing a single top-level element.) Use of the `xml` data type is discussed in more detail in Chapter 47, "Using XML in SQL Server 2008."

The hierarchyid Data Type

The `hierarchyid` data type is new in SQL Server 2008. The `hierarchyid` data type is a variable-length system data type used to represent a position in a tree hierarchy. A column of type `hierarchyid` does not automatically represent a tree. It is up to the application to generate and assign `hierarchyid` values in such a way that the desired relationship between rows is reflected in the values. For more information and examples for using the `hierarchyid` data type, see Chapter 42, "What's New for Transact-SQL in SQL Server 2008."

Spatial Data Types

SQL Server 2008 introduces support for storing geographical data with the inclusion of new spatial data types. Spatial data types provide a comprehensive, high-performance, and extensible data storage solution for spatial data, enabling organizations of any scale to integrate geospatial features into their applications and services.

Spatial data types can be used to store and manipulate location-based information and come in the form of two new data types: `geography` and `geometry`. The `geography` data type is a .NET CLR data type that provides a storage structure for geodetic data, sometimes

referred to as round earth data because it assumes a roughly spherical model of the world. It provides a storage structure for spatial data that is defined by latitude and longitude coordinates using an industry standard ellipsoid such as WGS84, the projection method used by Global Positioning System (GPS) applications. The `geometry` data type is a .NET CLR data type that supports the planar model/data, which assumes a flat projection and is therefore sometimes called flat earth. `geometry` data is represented as points, lines, and polygons on a flat surface, such as maps and interior floor plans where the curvature of the earth does not need to be taken into account.

For more information on and examples using spatial data types, see Chapter 42.

Large-Value Data Types

Three large-value data types added in SQL Server 2005 allow you to store a significant amount of data in a single column. They allow you to store up to 2^{31} bytes of non-Unicode data and 2^{30} bytes of Unicode data. All these data types have the `(max)` designator: `varchar(max)`, `nvarchar(max)`, and `varbinary(max)`. The `varchar`, `nvarchar`, and `varbinary` data types were available prior to SQL Server 2005, but the `max` parameter gave these types additional scope.

The great thing about these data types is that they are much easier to work with than large object (LOB) data types. LOB data types (which include `text`, `ntext`, and `image`) require special programming when retrieving and storing data. The large-value data types do not have these restrictions. They can be used much like their smaller counterparts `varchar(n)`, `nvarchar(n)`, and `varbinary(n)` that are defined without the `max` keyword. So if you want to select data from a `varchar(max)` column, you can simply execute a `SELECT` statement against it, regardless of the amount of data stored in it. Consider, for example, the following `SELECT` statement, executed against a `varchar(max)` column named `DocumentSummary` in the `AdventureWorks2008.Production.Document` table:

```
select Title, substring(DocumentSummary,1,30) 'DocumentSummary'
from production.document
where LEFT(DocumentSummary,30) like 'Reflector%'
```

```
/* results from previous select statement
```

Title	DocumentSummary
Front Reflector Bracket Installation	Reflectors are vital safety co

```
*/
```

This works fine with the `varchar(max)` column, but the `LEFT` function used in the `WHERE` clause would cause an error if the column were a `text` column instead.

The large-value data types can be stored in the data row or in a separate data page, based on the setting of the `sp_tableoption 'large value types out of row'` option. If the option is set to `OFF`, up to 8,000 characters can be stored in this column in the actual data row. If the option is set to `ON`, data for this column is stored in a separate data page if its length would result in the data row exceeding 8,060 bytes. The actual location of the column data is transparent to any user accessing the table.

Large Row Support

In SQL Server 2000, there was a strict limit of 8,060 bytes that could be stored in a single row. If the total amount of data exceeded this limit, the update or insert would fail. Enhancements were made in SQL Server 2005 to dynamically manage rows that exceed the 8,060-byte limit. This dynamic behavior is designed for columns that are defined as `varchar`, `nvarchar`, `varbinary`, or `sql_variant`. If the values in these columns cause the total size of the row to go beyond the 8,060-byte limit, SQL Server moves one or more of the variable-length columns to pages in the `ROW_OVERFLOW_DATA` allocation unit. A pointer to this separate storage location, rather than the actual data, is kept in the data row. If the data row shrinks below the 8,060-byte limit at a later time, SQL Server dynamically moves the data from the `ROW_OVERFLOW_DATA` allocation unit back into the data page.

The following example creates a table that has columns that could exceed the 8,060-byte limit, with a total of 9,000 characters:

```
CREATE TABLE t1
(col1 varchar(4000), col2 varchar(5000))

insert t1
select replicate('x', 4000), replicate('x', 5000)
```

If you execute the `CREATE TABLE` statement, you do not get any warning message related to the 8,060-byte limit. After the table is created, you can execute an insert into the table that exceeds the 8,060-byte limit. The insert succeeds, and the dynamic allocation previously described is handled automatically.

User-Defined Data Types

User-defined data types allow you to create custom data types that are based on the existing system data types. These data types are also called *alias data types* in SQL Server 2008. You create a user-defined data type and give it a unique name that you can then use in the definitions of tables. For example, you can create a user-defined data type named `ShortDescription`, defined as `varchar(20)`, and assign it to any column. This promotes data type consistency across your tables.

You can create user-defined data types by using T-SQL in a couple of different ways. Using the `sp_addtype` system stored procedure and using the new `CREATE TYPE` command are two possibilities. The `sp_addtype` system stored procedure is slated to be removed in a future version of SQL Server, so using the `CREATE TYPE` command is preferred. The following example shows how to create the `ShortDescription` user-defined data type:

```
CREATE TYPE [dbo].[ShortDescription] FROM [varchar](20) NOT NULL
```

After a user-defined data type is created, you can use it in the definition of tables. The following is an example of a table created with the new `ShortDescription` user-defined data type:

```
CREATE TABLE [dbo].CodeTable
(TableId int identity,
 TableDesc ShortDescription)
```

When you look at the definition of the `CodeTable` table in Object Explorer, you see the `TableDesc` column displayed with the `ShortDescription` data type as well as the underlying data type `varchar(20)`.

You can use the Object Explorer to create user-defined data types as well. To do so, you right-click the `User-Defined Data Types` node, then select `Programmability`, and then select `Types`. Then you choose the `New User-Defined Data Type` option, and you can create a new user-defined data type through a friendly GUI screen. If you create a user-defined data type in the model database, this user-defined data type is created in any newly created database.

CLR User-Defined Types

SQL Server 2008 continues support for user-defined types (UDTs) implemented with the Microsoft .NET Framework common language runtime (CLR). CLR UDTs enable you to extend the type system of the database and also enable you to define complex structured types.

A UDT may be simple or structured and of any degree of complexity. A UDT can encapsulate complex, user-defined behaviors. You can use CLR UDTs in all contexts where you can use a system type in SQL Server, including in columns in tables, in variables in batches, in functions or stored procedures, as arguments of functions or stored procedures, or as return values from functions.

A UDT must first be implemented as a managed class or structure in any one of the CLR languages and compiled into a .NET Framework assembly. You can then register it with SQL Server by using the `CREATE ASSEMBLY` command, as in the following example:

```
CREATE ASSEMBLY latlong FROM 'c:\samplepath\latlong.dll'
```

After registering the assembly, you can create the CLR UDTs by using a variation of the `CREATE TYPE` command shown previously:

```
CREATE TYPE latitude EXTERNAL NAME latlong.latitude
CREATE TYPE longitude EXTERNAL NAME latlong.longitude
```

When a CLR UDT is created, you can use it in the definition of tables. The following example shows a table created with the new `latitude` and `longitude` UDTs:

```
CREATE TABLE [dbo].StoreLocation
  (StoreID int NOT NULL,
   StoreLatitude latitude,
   StoreLongitude longitude)
```

For more details on programming and defining CLR UDTs, see Chapter 45, “SQL Server and the .NET Framework.”

Column Properties

Name and data type are the most basic properties of a column, but many other properties can be defined for a column. You do not have to specify these properties to be able to create the columns, but you can use them to further refine the type of data that can be stored within a column. Note that many of the available column properties relate to indexes and constraints that are beyond the scope of this section. The following sections describe some of the column properties you are most likely to encounter.

The NULL and NOT NULL Keywords

When you are defining tables, it is always good idea to explicitly state whether a column should or should not contain nulls. You do this by specifying the NULL or NOT NULL keywords after the column data type. If the nullability option is not specified, the SQL Server default is to allow nulls unless the ANSI_NULL_DFLT_OFF option is enabled for the session or no setting is specified for the session, and the ANSI_NULL_DEFAULT option for the database is set to OFF. Because of this uncertainty, it is best to always explicitly specify the desired nullability option for each column. Listing 24.4 creates a new table named PrinterCartridge that has the NULL or NOT NULL property specified for each column.

LISTING 24.4 Defining Column **NULL** Properties by Using **CREATE TABLE**

```
CREATE TABLE dbo.PrinterCartridge
(
    CartridgeId int NOT NULL,
    PrinterID int NOT NULL,
    CartridgeName varchar(50) NOT NULL,
    CartridgeColor varchar(50) NOT NULL,
    CartrideDescription varchar(255) NULL,
    InstallDate datetime NOT NULL
)
GO
```

NOTE

It is beyond the scope of this section to debate whether columns should ever allow nulls. In some organizations, nulls are heavily used, and in others they are not allowed. There is no right answer, but it is important for a development team to be aware of the existence of nulls so that it can create appropriate code to handle them.

Identity Columns

A property commonly specified when creating tables is IDENTITY. This property automatically generates a unique sequential value when it is assigned to a column. It can be assigned only to columns that are of the following types:

- ▶ decimal
- ▶ int
- ▶ numeric
- ▶ smallint
- ▶ bigint
- ▶ tinyint

Only one identity column can exist for each table, and that column cannot allow nulls.

When implementing the `IDENTITY` property, you supply a seed and an increment. The *seed* is the starting value for the numeric count, and the *increment* is the amount by which it grows. A seed of 10 and an increment of 10 would produce values of 10, 20, 30, 40, and so on. If not specified, the default seed value is 1, and the increment is 1. Listing 24.5 adds an `IDENTITY` value to the `PrinterCartridge` table used in the previous example.

LISTING 24.5 Defining an Identity Column by Using **CREATE TABLE**

```
IF EXISTS (SELECT * FROM dbo.sysobjects
WHERE id = OBJECT_ID(N'dbo.PrinterCartridge')
AND OBJECTPROPERTY(id, N'IsUserTable') = 1)
DROP TABLE dbo.PrinterCartridge

CREATE TABLE dbo.PrinterCartridge
(
    CartridgeId int IDENTITY (1000, 1) NOT NULL,
    PrinterID int NOT NULL,
    CartridgeName varchar(50) NOT NULL,
    CartridgeColor varchar(50) NOT NULL,
    CartridgeDescription varchar(255) NULL,
    InstallDate datetime NOT NULL
)
GO

insert PrinterCartridge
(PrinterID, CartridgeName, CartridgeColor, CartridgeDescription, InstallDate)
values (1, 'inkjet', 'black', 'laser printer cartridge', '8/1/09')

select CartridgeId, PrinterID, CartridgeName
from PrinterCartridge

/* results from previous SELECT statement
CartridgeId PrinterID CartridgeName
-----
1000          1          inkjet
*/
```

In this listing, the seed value has been set to 1000, and the increment has been set to 1. An insert into the PrinterCartridge table and a subsequent SELECT from that table follows the CREATE TABLE statement in the listing. Notice that the results of the SELECT show a value of 1000 for the identity column CartridgeID. This is the seed or starting point that is defined.

ROWGUIDCOL Columns

An alternative to an identity column is a column defined with the ROWGUIDCOL property. Like the IDENTITY property, the ROWGUIDCOL property is autogenerating and unique. The difference is that the ROWGUIDCOL option generates column values that will be unique on any networked database anywhere in the world. The identity column generates values that are unique only within the table that contains the column.

You can have only one ROWGUIDCOL column per table. You must create this ROWGUIDCOL column with the uniqueidentifier data type, and you must assign a default of NEWID() to the column to generate the unique value. Keep in mind that users can manually insert values directly into columns defined as ROWGUIDCOL. These manual inserts could cause duplicates in the column, so a UNIQUE constraint should be added to the column as well to ensure uniqueness.

Listing 24.6 shows the creation of a table with a ROWGUIDCOL column. Several rows are inserted into the newly created table, and those rows are selected at the end of the listing.

LISTING 24.6 Defining a **ROWGUIDCOL** Column

```
CREATE TABLE SomeUniqueTable
  (UniqueID UNIQUEIDENTIFIER          DEFAULT NEWID(),
   EffectiveDate datetime )
GO
INSERT INTO SomeUniqueTable (EffectiveDate) VALUES ('7/1/09')
INSERT INTO SomeUniqueTable (EffectiveDate) VALUES ('8/1/09')
GO
select * from SomeUniqueTable
/* Results from previous select statement
UniqueID                               EffectiveDate
-----
614181BC-D7B9-4108-B2BD-C2F39E999424  2009-07-01 00:00:00.000
62368A2D-3557-4727-9DD3-FBCA38705B1B  2009-08-01 00:00:00.000
*/
```

You can see that the ROWGUIDCOL values are fairly large. They are 16-byte binary values that are significantly larger than most of the data types used for identity columns. For example, an identity column defined as data type int occupies only 4 bytes. You need to consider the storage requirements for ROWGUIDCOL when you select this data type.

Computed Columns

A *computed column* is a column whose value is calculated based on other columns. Generally speaking, the column is a virtual column because it is calculated on the fly, and no value is stored in the database table. With SQL Server 2008, you have an option of actually storing the calculated value in the database. You do so by marking the column as persisted. If the computed column is persisted, you can create an index on this column as well.

Listing 24.7 includes several statements that relate to the creation of a computed column. It starts with an ALTER TABLE statement that adds a new computed column named SetRate to the Sales.CurrencyRate table in the AdventureWorks2008 database. The new rate column is based on an average of two other rate columns in the table. A SELECT statement is executed after that; it returns several columns, including the new SetRate computed column. The results are shown after the SELECT. Finally, an ALTER TABLE statement is used to change the newly added column so that its values are stored in the database. This is accomplished with the ADD PERSISTED option.

LISTING 24.7 Defining a Computed Column

```
--Add a computed column to the Sales.CurrencyRate Table named SetRate
ALTER TABLE Sales.CurrencyRate
  ADD SetRate AS ( (AverageRate + EndOfDayRate) / 2)
go
--Select several columns including the new computed column
select top 5 AverageRate, EndOfDayRate , SetRate
  from sales.currencyrate

/*Results from previous SELECT statement
AverageRate          EndOfDayRate          SetRate
-----
1.00                1.0002                1.0001
1.5491              1.55                  1.5495
1.9379              1.9419                1.9399
1.4641              1.4683                1.4662
8.2781              8.2784                8.2782
*/

--Alter the computed SetRate column to be PERSISTED
ALTER TABLE Sales.CurrencyRate
  alter column SetRate ADD PERSISTED
```

NOTE

You can use the `sp_spaceused` stored procedure to check the space allocated to the `Sales.CurrencyRate` table. You need to check the size before the column is persisted, and then you need to check the space allocated to the table after the column is persisted. As you would expect, the space allocated to the table is increased only after the column is persisted.

FILESTREAM Storage

SQL Server 2008 introduces FILESTREAM storage for storing unstructured data, such as documents, images, and videos. In previous versions of SQL Server, there were two ways of storing unstructured data. One method was to store it in the database as a binary large object (BLOB) in an `image` or `varbinary(max)` column. The other method was to store the data outside the database, separate from the structured relational data, storing a reference or pathname to the unstructured data in a `varchar` column in a table. Neither of these methods is ideal for unstructured data.

FILESTREAM storage helps to solve the issues with using unstructured data by integrating the SQL Server Database Engine with the NTFS file system for storing the unstructured data, such as documents and images, on the file system with the database storing a pointer to the data. Although the actual data resides outside the database in the NTFS file system, you can still use T-SQL statements to insert, update, query, and back up FILESTREAM data, while maintaining transactional consistency between the unstructured data and corresponding structured data with same level of security.

To specify that a column should store data on the file system when creating or altering a table, you specify the FILESTREAM attribute on a `varbinary(max)` column. This causes the Database Engine to store all data for that column on the file system, but not in the database file. After you complete these tasks, you can use Transact-SQL and Win32 to manage the FILESTREAM data.

NOTE

To use FILESTREAM storage, you must first enable FILESTREAM storage at the Windows level as well as at the SQL Server Instance level. You can enable FILESTREAM at the Windows level during installation of SQL Server 2008 or at any time using SQL Server Configuration Manager. After you enable FILESTREAM at the Windows level, you next need to enable FILESTREAM for the SQL Server Instance. You can do this either through SQL Server Management Studio or via T-SQL. For more information on enabling and using FILESTREAM storage, see Chapter 42.

Sparse Columns and Column Sets

SQL Server 2008 provides a new space-saving storage option referred to as *sparse columns*. Sparse columns are ordinary columns that provide optimized storage for null values. If the value of a column defined as a sparse column is NULL, it doesn't consume any space at all.

You can define a column as a sparse column by specifying the `SPARSE` keyword after the data type in the `CREATE TABLE` or `ALTER TABLE` statement, as shown in Listing 24.8.

LISTING 24.8 Specifying a Sparse Column in a Create Table Statement

```
CREATE TABLE DBO.SPARSE_TABLE
(ID INT IDENTITY(1,1),
 FIRST_NAME VARCHAR (50),
 MIDDLE_NAME VARCHAR (50) SPARSE NULL,
 LASTNAME VARCHAR (50)
)
```

The space savings of sparse columns come with a trade-off, however, requiring extra space for storing non-null values in the sparse column. Fixed-length and precision data types require 4 extra bytes, and variable-length data types require 2 extra bytes. For this reason, you should consider using sparse columns only when the space saved is at least 20% to 40%.

SQL Server stores sparse columns in a single XML column that appears to external applications and end users as a normal column. Storing the sparse columns in a single XML column allows up to 30,000 sparse columns in a single table, exceeding the limitation of 1,024 columns if sparse columns are not used. In addition, because sparse columns have many null-valued rows, they are good candidates for filtered indexes. A filtered index on a sparse column can index only the rows that have non-null values stored in the column. This creates smaller and more efficient indexes. (For more information on filtered indexes, see Chapters 25, “Creating and Managing Indexes,” and 34, “Data Structures, Indexes, and Performance.”)

Sparse columns can be of any SQL Server data type and behave like any other column with the following restrictions:

- ▶ A sparse column must be nullable and cannot have the `ROWGUIDCOL` or `IDENTITY` properties. A sparse column cannot be of the following data types—`text`, `ntext`, `image`, `timestamp`, user-defined data type, `geometry`, or `geography`—or have the `FILESTREAM` attribute.
- ▶ A sparse column cannot have a default value.
- ▶ A sparse column cannot be bound to a rule.
- ▶ A computed column cannot be marked as sparse.
- ▶ A sparse column cannot be part of a clustered index or a unique primary key index.

When the number of sparse columns in a table is large, and operating on them individually is cumbersome, you may want to define a column set. A column set is an untyped XML representation that combines all the sparse columns of a table into a structured set. A column set is like a calculated column in that the column set is not physically stored in the table, but the column set is directly updatable. Applications may see some perfor-

mance improvement when they select and insert data by using column sets on tables that have lots of columns.

To define a column set, use the `<column_set_name> FOR ALL_SPARSE_COLUMNS` keywords in the `CREATE TABLE` or `ALTER TABLE` statements, as shown in Listing 24.9.

LISTING 24.9 Defining a Column Set

```
CREATE TABLE emp_info
(ID INT IDENTITY(1,1),
 FIRST_NAME VARCHAR (50),
 MIDDLE_NAME VARCHAR (50) SPARSE NULL ,
 LASTNAME VARCHAR (50),
 HOMEPHONE VARCHAR(10) SPARSE NULL,
 BUSPHONE VARCHAR(10) SPARSE NULL,
 CELLPHONE VARCHAR(10) SPARSE NULL,
 FAX VARCHAR(10) SPARSE NULL,
 EMAIL VARCHAR(30) SPARSE NULL,
 WEBSITE VARCHAR(30) SPARSE NULL,
 CSet XML COLUMN_SET FOR ALL_SPARSE_COLUMNS
)
```

A column set is created as an untyped XML column and is treated as any other XML column with a maximum XML data size limit of 2GB. Only one column set per table is allowed. You cannot add a column set to a table if the table already contains sparse columns.

To specify a column as a sparse column using SQL Server Management Studio (SSMS), set the `Is Sparse` property to `Yes` in the column properties for the selected column (see Figure 24.3). Similarly, if a column needs to be declared as column set, set the `Is Columnset` property to `Yes` in the column properties.

For more information on using and working with sparse columns and column sets, see Chapter 42.

Defining Table Location

As databases scale in size, the physical location of database objects, particularly tables and indexes, becomes crucial. Consider two tables, `Authors` and `Titles`, that are always queried together. If they are located on the same physical disk, contention for hardware resources may slow performance. SQL Server addresses this issue by enabling you to specify where a table (or an index) is stored.

The mechanism for specifying the physical table location is the filegroup. Filegroups are aligned to physical data files. By default, each database has a primary filegroup and a data file that matches the name of the database. You can create additional filegroups and align them to other data files. When these filegroups are created, SQL Server enables you to create your database tables on a specific filegroup.

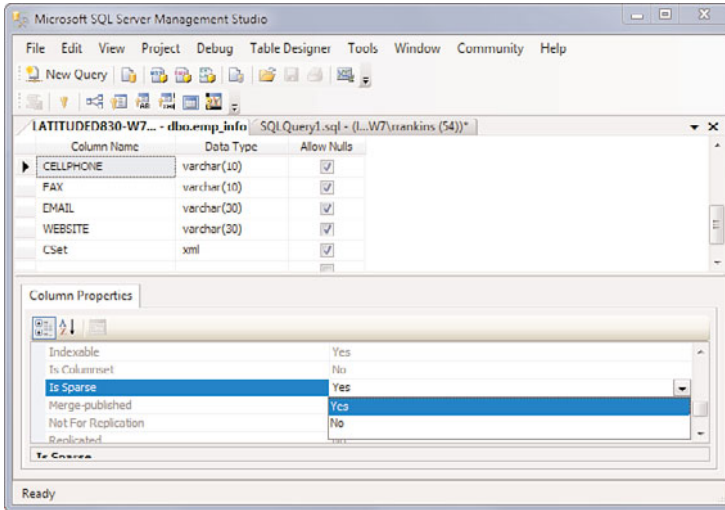

FIGURE 24.3 Setting a column as a sparse column.

NOTE

Using partitioned tables is a way to specify table location. This SQL Server 2008 feature allows you to divide a table into partitions and align those partitions with filegroups. This concept is discussed in detail in the “Using Partitioned Tables” section, later in this chapter.

The placement of tables on separate filegroups has some distinct advantages, including performance benefits. You can achieve performance improvements by storing filegroups on different disks. You can also achieve some manageability improvements by using filegroups because you can back up and manipulate filegroups separately. This capability is particularly important for large tables.

You specify the location of a table by using the `ON` clause during table creation. Listing 24.10 shows an example of creating two filegroups in the `BigPubs2008` database, followed by the creation of two new tables on those filegroups. Note that the filegroups must exist before the tables are created. For more information on filegroups, see Chapter 23, “Creating and Managing Databases.”

LISTING 24.10 An Example of Creating Tables on Specific Filegroups

```
--Add the filegroups
ALTER DATABASE BigPubs2008 ADD FILEGROUP FG1
ALTER DATABASE BigPubs2008 ADD FILEGROUP FG2
GO
--Add files to the filegroups
ALTER DATABASE BigPubs2008 ADD FILE
```

```
( NAME = FG1_File,  
  FILENAME = 'c:\BigPubs2008FG1.ndf',  
  SIZE = 2MB) TO FILEGROUP FG1
```

```
go
```

```
ALTER DATABASE BigPubs2008 ADD FILE
```

```
( NAME = FG2_File,  
  FILENAME = 'c:\BigPubs2008FG2.ndf',  
  SIZE = 2MB) TO FILEGROUP FG2
```

```
go
```

```
CREATE TABLE [dbo].[authors_NEW](  
  [au_id] [dbo].[id] NOT NULL,  
  [au_lname] [varchar](40) ,  
  [au_fname] [varchar](20) ,  
  [phone] [char](12),  
  [address] [varchar](40) NULL,  
  [city] [varchar](20) NULL,  
  [state] [char](2) NULL,  
  [zip] [char](5) NULL,  
  [contract] [bit] NOT NULL,
```

```
) ON FG1
```

```
go
```

```
CREATE TABLE [dbo].[titles_NEW](  
  [title_id] [dbo].[tid] NOT NULL,  
  [title] [varchar](80) NOT NULL,  
  [type] [char](12) NOT NULL,  
  [pub_id] [char](4) NULL,  
  [price] [money] NULL,  
  [advance] [money] NULL,  
  [royalty] [int] NULL,  
  [ytd_sales] [int] NULL,  
  [notes] [varchar](400) NULL,  
  [pubdate] [datetime] NOT NULL,
```

```
) ON FG2
```

Defining Table Constraints

Constraints provide a means to enforce data integrity. In addition to NULL/NOT NULL, discussed earlier in this chapter, SQL Server provides five constraint types: PRIMARY KEY, FOREIGN KEY, UNIQUE, CHECK, and DEFAULT. These constraints help further define the type of data you can store in tables.

Constraints are covered in detail in Chapter 26, “Implementing Data Integrity.” This chapter introduces the basic means for adding constraints to a table. You can add constraints at the time of table creation, or you can add them after a table has been created, by using the ALTER TABLE statement.

Listing 24.11 shows a CREATE TABLE statement that has an example of each one of the five constraint types listed. The PRIMARY KEY constraint is created at the bottom of the script and is named PK_TitleHistory. The FOREIGN KEY constraint is created on the title_id column and is named FK_titles_titleHistory. The UNIQUE constraint is part of the primary key and can be identified with the UNIQUE keyword. The CHECK constraint is created on the price column; it checks to make sure the price is greater than zero. Finally, a DEFAULT constraint is created on the modify_user column; it sets the user to the value of system if no explicit value is specified.

LISTING 24.11 Example of Creating Constraints with **CREATE TABLE**

```
CREATE TABLE dbo.TitleHistory(
    title_id dbo.tid
        CONSTRAINT FK_titles_titleHistory
            REFERENCES titles (title_id)NOT NULL ,
    change_date datetime NOT NULL,
    title varchar(80) NOT NULL,
    type char(12) NOT NULL,
    price money NULL
        CONSTRAINT CK_TitleHistory_Price CHECK (Price>0),
    modify_user nchar(10) NOT NULL
        CONSTRAINT DF_TitleHistory_modify_user DEFAULT (N'system'),
    CONSTRAINT PK_TitleHistory UNIQUE CLUSTERED
( title_id ASC,
  change_date ASC ) )
```

You can create the same constraints as in Listing 24.11 by using the ALTER TABLE statement. This means you can first create the table (without the constraints) and then add the constraints afterward. Listing 24.12 shows the creation of the same titleHistory table, with the constraints added later via the ALTER TABLE statement.

LISTING 24.12 Example of Creating Constraints with **ALTER TABLE**

```
IF EXISTS (SELECT * FROM dbo.sysobjects
WHERE id = OBJECT_ID(N'[dbo].[TitleHistory]')
AND OBJECTPROPERTY(id, N'IsUserTable') = 1)
DROP TABLE [dbo].[TitleHistory]

CREATE TABLE dbo.TitleHistory(
    title_id dbo.tid NOT NULL,
```

```
change_date datetime NOT NULL,  
title varchar(80) NOT NULL,  
type char(12) NOT NULL,  
price money NULL,  
modify_user nchar(10) NOT NULL )  
GO  
  
--PRIMARY KEY/UNIQUE CONSTRAINT  
ALTER TABLE dbo.TitleHistory  
ADD CONSTRAINT PK_TitleHistory UNIQUE CLUSTERED  
(  
    title_id ASC,  
    change_date ASC  
)WITH (SORT_IN_TEMPDB = OFF, ONLINE = OFF)  
go  
--FOREIGN KEY CONSTRAINT  
ALTER TABLE dbo.TitleHistory WITH CHECK  
ADD CONSTRAINT FK_titles_titleHistory FOREIGN KEY( title_id)  
REFERENCES dbo.titles (title_id)  
GO  
--CHECK CONSTRAINT  
ALTER TABLE dbo.TitleHistory WITH CHECK  
ADD CONSTRAINT CK_TitleHistory_Price CHECK ((Price>(0)))  
GO  
--DEFAULT CONSTRAINT  
ALTER TABLE dbo.TitleHistory  
ADD CONSTRAINT DF_TitleHistory_modify_user  
DEFAULT (N'system') FOR modify_user
```

Modifying Tables

You often need to modify database tables after you create them. Fortunately, you can use several tools to accomplish this task. These tools are the same set of tools you can use to add, modify, and delete tables: the SSMS Object Explorer, Table Designer, Database Diagram Editor, and T-SQL. The following sections touch on each of these tools but focus most heavily on the use of T-SQL.

Regardless of the method you use, you must always exercise caution when modifying tables, particularly in a production environment. Table relationships and the impact to data that may already exist in a table are key considerations in modifying a table. A visual tool such as a database diagram can assist you in determining the impact to related tables

and can be used to generate the T-SQL script. The following section looks at the underlying T-SQL that can be used to modify a table, and then we delve into the visual tools that can simplify your life and generate some of the T-SQL for you.

Using T-SQL to Modify Tables

You can modify tables in many different ways, including making changes to the columns, constraints, and indexes associated with a table. Some of the changes have a bigger impact on the database than others. Some modifications require that the modified table be dropped and re-created to effect the change. Fortunately, you can use the T-SQL `ALTER TABLE` statement to mitigate the database impact and help streamline many of the most common modifications. You can make the following types of changes by using the `ALTER TABLE` statement:

- ▶ Change a column property, such as a data type or `NULL` property.
- ▶ Add new columns or drop existing columns.
- ▶ Add or drop constraints.
- ▶ Enable or disable `CHECK` and `FOREIGN KEY` constraints.
- ▶ Enable or disable triggers.
- ▶ Reassign partitions.
- ▶ Alter an index associated with a constraint.

The following sections discuss a few examples of these types of changes to familiarize you with the `ALTER TABLE` command. The full syntax for the `ALTER TABLE` command is extensive, and you can find it in [SQL Server Books Online](#).

Changing a Column Property

You can use the `ALTER COLUMN` clause of the `ALTER TABLE` command to modify column properties, including the `NULL` property or the data type of a column. Listing 24.13 shows an example of changing the data type of a column.

LISTING 24.13 Changing the Data Type of a Column by Using **ALTER TABLE**

```
alter table titles
  alter column notes varchar(400) null
```

You must be aware of several restrictions when you modify the data type of a column. The following rules apply when altering columns:

- ▶ You cannot modify a text, image, ntext, or timestamp column.
- ▶ The column cannot be the `ROWGUIDCOL` for the table.
- ▶ The column cannot be a computed column or be referenced by a computed column.

- ▶ The column cannot be a replicated column.
- ▶ If the column is used in an index, the column length can only be increased in size. In addition, it must be of `varchar`, `nvarchar`, or `varbinary` data type, and the data type cannot change.
- ▶ If statistics have been generated using `CREATE STATISTICS`, the statistics must first be dropped before the column can be altered.
- ▶ The column cannot have a `PRIMARY KEY` or `FOREIGN KEY` constraint or be used in a `CHECK` or `UNIQUE` constraint. The exception is that a column with a `CHECK` or `UNIQUE` constraint, if defined as variable length, can have the length altered.
- ▶ A column with a default defined for it can have only the length, nullability, or precision and scale altered.
- ▶ If a column has a schema-bound view defined on it, the same rules that apply to columns with indexes apply.

TIP

Changing some data types can result in changing the data. For example, changing from `nchar` to `char` could result in any extended characters being converted. Similarly, changing precision and scale could result in data truncation. Other modifications, such as changing from `char` to `int`, might fail if the data doesn't match the restrictions of the new data type. Before you change data types, you should always validate that the data conforms to the desired new data type.

Adding and Dropping Columns

You add columns to a table by using the `ADD COLUMN` clause. Listing 24.14 illustrates the addition of a new column named `ISBN` to the `titles` table.

LISTING 24.14 Adding a Column by Using **ALTER TABLE**

```
ALTER TABLE titles
  add ISBN int null
```

When you use the `ALTER TABLE` statement to add a column, the new column is added at the end of the table. In most cases, this location is acceptable. The location of the column in the table generally has no bearing on the use of the table. There are, however, situations in which it is desired to have the new column added in the middle of the table. The `ALTER TABLE` statement does not work for this situation. To add a column in the middle of the table, you need to create a new version of the table with a different name and the columns in the desired order, copy the data from the old table, drop the old table, and

rename the new table with the old table name. Alternatively, you can also accomplish this by using SSMS, as described in the following section.

There are also some issues you need to consider with regard to the null option specified for a new column. In the case of a column that allows nulls, there is no real issue: SQL Server adds the column and allows a NULL value for all rows. If NOT NULL is specified, however, the column must be an identity column or have a default specified. Note that even if a default is specified, if the column allows nulls, the column is not populated with the default if no value is provided for the column. You use the WITH VALUES clause as part of the default specification to override this and populate the column with the default.

With some restrictions, columns can also be dropped from a table. Listing 24.15 shows the syntax for dropping a column. You can specify to drop multiple columns, separated by commas.

LISTING 24.15 Dropping a Column by Using **ALTER TABLE**

```
alter table titles
drop column ISBN
```

The following columns cannot be dropped:

- ▶ A column in a schema-bound view
- ▶ An indexed column
- ▶ A replicated column
- ▶ A column used in a CHECK, FOREIGN KEY, UNIQUE, or PRIMARY KEY constraints
- ▶ A column associated with a default or bound to a default object
- ▶ A column bound to a rule

NOTE

Be careful when using ALTER TABLE to modify columns that hold existing data. When you add, drop, or modify columns, SQL Server places a schema lock on the table, preventing any other access until the operation completes. Changes to columns in tables that have many rows can take a long time to complete and generate a large amount of log activity.

As mentioned earlier, the ALTER TABLE statement is not the only T-SQL statement you can use to modify tables. You accomplish some table changes by using T-SQL that drops and re-creates the tables that are being modified. The following sections look at some examples of these types of changes.

Using Object Explorer and the Table Designer to Modify Tables

The Object Explorer in SSMS is your window into the various tables available for modification in a database. You expand the Tables node in the Object Explorer tree and right-click the table you would like to modify. Then you select the Design option, and a Table Designer window appears, showing all the table columns. In addition, a Table Designer menu option appears at the top of the SSMS window. The Table Designer menu includes many options, including Insert Columns, Delete Columns, and Remove Primary Key. The full list of available options is shown in Figure 24.4. A Table Designer window for the BigPubs2008.Authors table is shown as the active tab on the right side of Figure 24.4.

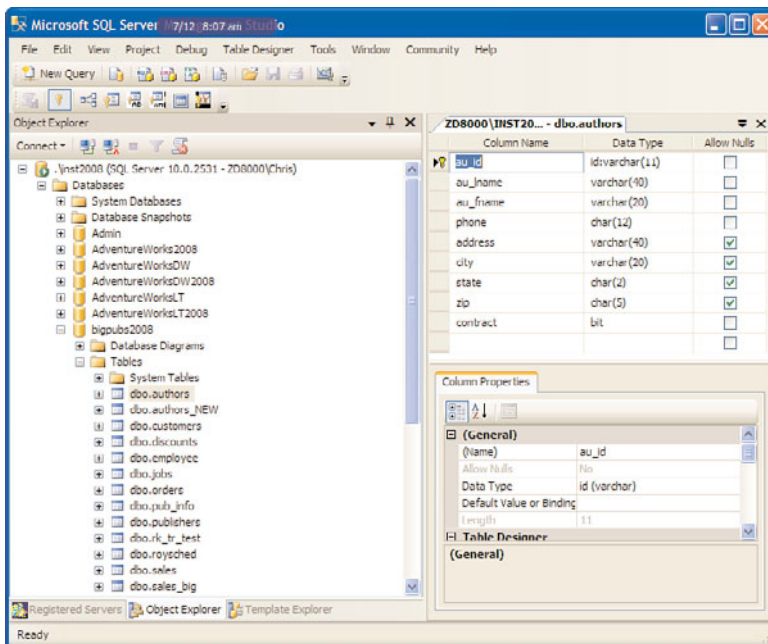

FIGURE 24.4 The Table Designer.

To illustrate the power of the Table Designer, let's add a new column to the authors table. You can add the column to the middle of the table, just prior to the address column. You do this by highlighting the entire address row in the Table Designer grid and then selecting Table Designer, Insert Column. A new data entry row is added to the Table Designer grid, where you can specify the name of the new column, the data type, and a null option. For this example, you can name the new column Gender, with a data type of char(1) and the setting ALLOW NULLS. Figure 24.5 shows the Table Designer grid with the newly added Gender column highlighted. In addition, the figure shows the Table Designer menu options with the newly enabled Generate Change Script option selected.

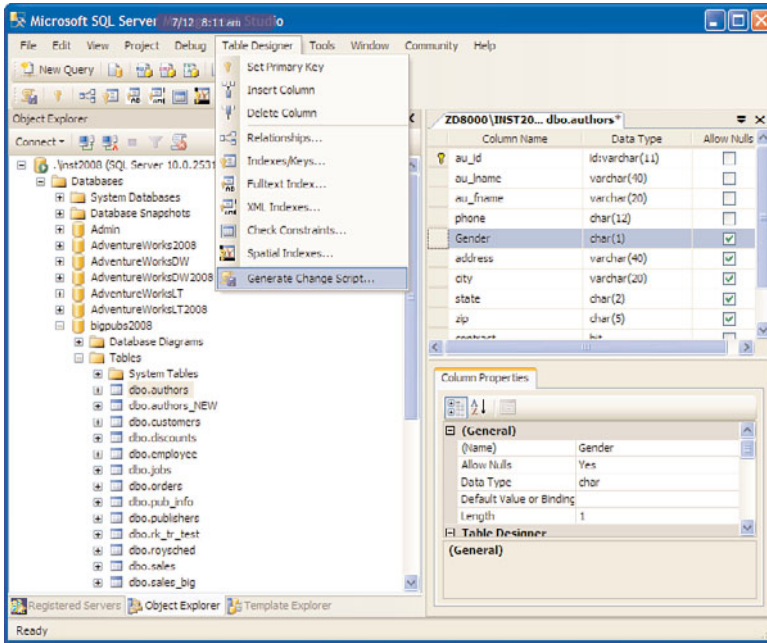

FIGURE 24.5 Inserting a column in Table Designer.

You do not need to use the Generate Change Script option for changes you make in the Table Designer. You can close the Table Designer tab where you made your changes, and the Table Designer makes the changes for you behind the scenes. Sometimes, though, you might want to script the changes and see exactly what is going to happen to the database. Clicking the Script button is also the preferred method for deploying changes to other environments. You can save a script in a change repository and execute it in your target environments. This approach ensures that you have a repeatable, well-documented means for making table changes.

Listing 24.16 shows the contents of a script that would be generated based on the new Gender column you added to the authors table. For the sake of space, some of the initial script options and the triggers associated with the authors table have been removed from the script. The important point to note is how extensive this script is. A new temporary authors table is created, and it includes the new column; the data from the authors table is copied into the temporary table; and then the table is renamed. In addition, the script must manage the constraints, indexes, and other objects associated with the authors table. The good news is that Table Designer does most of the work for you.

LISTING 24.16 Changing Script Generated from the Table Designer

```
ALTER TABLE dbo.authors
    DROP CONSTRAINT DF__authors__phone__04C40F4
GO
```

```
CREATE TABLE dbo.Tmp_authors
(
    au_id dbo.id NOT NULL,
    au_lname varchar(40) NOT NULL,
    au_fname varchar(20) NOT NULL,
    phone char(12) NOT NULL,
    Gender char(1) NULL,
    address varchar(40) NULL,
    city varchar(20) NULL,
    state char(2) NULL,
    zip char(5) NULL,
    contract bit NOT NULL
) ON [PRIMARY]
GO
ALTER TABLE dbo.Tmp_authors ADD CONSTRAINT
    DF__authors__phone__04C4C0F4 DEFAULT ('UNKNOWN') FOR phone
GO
IF EXISTS(SELECT * FROM dbo.authors)
    EXEC('INSERT INTO dbo.Tmp_authors (au_id, au_lname,
        au_fname, phone, address, city, state, zip, contract)
        SELECT au_id, au_lname, au_fname, phone, address,
            city, state, zip, contract
        FROM dbo.authors WITH (HOLDLOCK TABLOCKX)')
GO
ALTER TABLE dbo.titleauthor
    DROP CONSTRAINT FK__titleauth__au_id__14070484
GO
DROP TABLE dbo.authors
GO
EXECUTE sp_rename N'dbo.Tmp_authors', N'authors', 'OBJECT'
GO
ALTER TABLE dbo.authors ADD CONSTRAINT

GO

```

You will find that you can make most of the changes you want to make by using the Table Designer. To make other changes, you can use the same approach you just used to add a column. This approach involves making the changes via the Table Designer menu options and then using the option to script the change. This is a great way to evaluate the impact of your changes and to save those changes for later execution.

Using Database Diagrams to Modify Tables

Database diagrams offer an excellent visual view of your database tables that you can also use to modify tables. You do this by adding the table you want to modify to a new or existing database diagram. Oftentimes, it is best to also add all the related tables to the diagram as well. You can easily do this by right-clicking the table and choosing the Add Related Tables option.

With a database diagram, you have the same options that you have with the Table Designer, plus you have diagramming options. Both the Table Designer and Database Diagrams menus are shown when a database diagram is in focus. These menus disappear if you change the tabbed window to a Database Engine query window, so remember that you must select the diagram window to be able to display the menu options.

Figure 24.6 shows a database diagram for the `HumanResources.Department` table, along with its related table. The Table Designer menu is selected to show that it is available when you work with a database diagram. You must have one of the tables selected to enable all the menu options. In Figure 24.6, the `Department` table has been highlighted, and a new `ModifiedUser` column has been added to the end of the table. Figure 24.6 also shows that the Database Diagram menu is available for selection. This menu includes options to add tables to the diagram and manipulate the tables within the diagram.

The same scripting options are available with a database diagram as are available in the Table Designer. You can make your changes from within the diagram and then choose the Generate Change Script menu option. Listing 24.17 shows the change script generated based on the addition of the `ModifiedUser` column to the end of the `Department` table. As expected, this change is accomplished with an `ALTER TABLE` statement.

LISTING 24.17 The Change Script Generated from a Database Diagram

```

ALTER TABLE HumanResources.Department ADD
    ModifiedUser varchar(20) NULL
GO

```

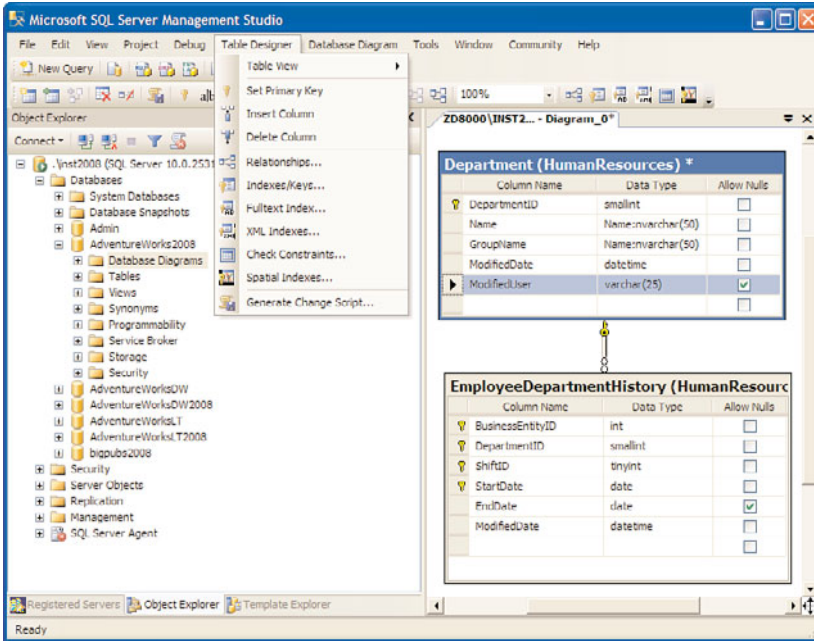

FIGURE 24.6 Modifying tables by using a database diagram.

The use of the `ALTER TABLE` statement in this listing brings us full circle, back to our initial method for making table modifications. Using all the tools discussed in this section together will usually give you the best results.

Dropping Tables

There are several different methods for dropping (or deleting) a table. You can right-click the table in the SSMS Object Explorer and select `Delete`, you can right-click a table in a database diagram and choose `Delete Tables from Database`, or you can use the old-fashioned method of utilizing T-SQL. Here's an example of the T-SQL `DROP TABLE` statement:

```
DROP TABLE [HumanResources].[Department]
```

You can reference multiple tables in a single `DROP TABLE` command by separating the table names with commas. Any triggers and constraints associated with the table are also dropped when the table is dropped.

A big consideration when dropping a table is the table's relationship to other tables. If a foreign key references the table that you want to drop, the referencing table or foreign key constraint must be dropped first. In a database that has many related tables, dropping elements can get complicated. Fortunately, a few tools can help you through this. The system stored procedure `sp_helpconstraint` is one of these tools. This procedure lists all

the foreign key constraints that reference a table. Listing 24.18 shows an execution of this stored procedure for the `Sales.Store` table in the `AdventureWorks2008` database. The procedure results include information about all the constraints on the table. The results to focus on are those that follow the heading `Table Is Referenced by Foreign Key`. The partial results shown in Listing 24.18 for the `Sales.Store` table indicate that `FK_StoreContact_Store_CustomerID` must be dropped first before you can drop the `Sales.Store` table.

LISTING 24.18 Using `sp_helpconstraint` to Find Foreign Key References

```
sp_helpconstraint [Sales.Store]

/*partial results of sp_helpconstraint execution
Table is referenced by foreign key
-----
AdventureWorks2008.Sales.StoreContact: FK_StoreContact_Store_CustomerID
*/
```

Two other approaches are useful for identifying foreign key references prior to dropping a table. The first is using a database diagram. You can create a new database diagram and add the table that you are considering for deletion. After the table is added, you right-click the table in Object Explorer and select `Add Related Tables`. The related tables, including those that have foreign key references, are then added. You can then right-click the relationship line connecting two tables and select `Delete Relationships from Database`. When you have deleted all the foreign key relationships from the diagram, you can right-click the table you want to delete and select `Generate Change Script` to create a script that can be used to remove the foreign key relationship(s).

The other approach is to right-click the table in Object Explorer and choose `View Dependencies`. The dialog that appears gives you the option of viewing the objects that depend on the table or viewing the objects on which the table depends. If you choose the option to view the objects that depend on the table, all the dependent objects are displayed, but you can focus on the objects that are tables.

Using Partitioned Tables

In SQL Server 2008, tables are stored in one or more partitions. *Partitions* are organizational units that allow you to divide data into logical groups. By default, a table has only a single partition that contains all the data. The power of partitions comes into play when you define multiple partitions for a table that is segmented based on a key column. This column allows the data rows to be horizontally split. For example, a date/time column can be used to divide each month's data into a separate partition. These partitions can also be aligned to different filegroups for added flexibility, ease of maintenance, and improved performance.

The important point to remember is that you access tables with multiple partitions (which are called *partitioned tables*) the same way you access tables with a single partition. Data Manipulation Language (DML) operations such as `INSERT` and `SELECT` statements reference the table the same way, regardless of partitioning. The difference between these types of tables has to do with the back-end storage and the organization of the data.

Generally, partitioning is most useful for large tables. *Large* is a relative term, but these tables typically contain millions of rows and take up gigabytes of space. Often, the tables targeted for partitioning are large tables experiencing performance problems because of their size. Partitioning has several different applications, including the following:

- ▶ **Archival**—Table partitions can be moved from a production table to another archive table that has the same structure. When done properly, this partition movement is very fast and allows you to keep a limited amount of recent data in the production table while keeping the bulk of the older data in the archive table.
- ▶ **Maintenance**—Table partitions that have been assigned to different filegroups can be backed up and maintained independently of each other. With very large tables, maintenance activities on the entire table (such as backups) can take a prohibitively long time. With partitioned tables, these maintenance activities can be performed at the partition level. Consider, for example, a table that is partitioned by month: all the new activity (updates and insertions) occurs in the partition that contains the current month's data. In this scenario, the current month's partition would be the focus of the maintenance, thus limiting the amount of data you need to process.
- ▶ **Query performance**—Partitioned tables joined on partitioned columns can experience improved performance because the Query Optimizer can join to the table based on the partitioned column. The caveat is that joins across partitioned tables not joining on the partitioned column may actually experience some performance degradation. Queries can also be parallelized along the partitions.

Now that we have discussed some of the reasons to use partitioned tables, let's look at how to set up partitions. There are three basic steps:

1. Create a partition function that maps the rows in the table to partitions based on the value of a specified column.
2. Create a partition scheme that outlines the placement of the partitions in the partition function to filegroups.
3. Create a table that utilizes the partition scheme.

These steps are predicated on a good partitioning design, based on an evaluation of the data within the table and the selection of a column that will effectively split the data. If multiple filegroups are used, those filegroups must also exist before you execute the three steps in partitioning. The following sections look at the syntax related to each step, using simple examples. These examples utilize the `BigPubs2008` database.

Creating a Partition Function

A partition function identifies values within a table that will be compared to the column on which you partition the table. As mentioned previously, it is important that you know the distribution of the data and the specific range of values in the partitioning column before you create the partition function. The following query provides an example of determining the distribution of data values in the `sales_big` table by year:

```
--Select the distinct yearly values
SELECT year(ord_date) as 'year', count(*) 'rows'
FROM sales_big
GROUP BY year(ord_date)
ORDER BY 1
go
```

```
year          rows
-----
2005          30
2006        613560
2007        616450
2008        457210
```

You can see from the results of the `SELECT` statement that there are four years' worth of data in the `sales_big` table. Because the values specified in the `CREATE PARTITION FUNCTION` statement are used to establish data ranges, at a minimum, you would need to specify at least three data values when defining the partition function, as shown in the following example:

```
--Create partition function with the yearly values to partition the data
CREATE PARTITION FUNCTION SalesBigPF1 (datetime)
AS RANGE RIGHT FOR VALUES
('01/01/2006', '01/01/2007',
'01/01/2008')
GO
```

In this example, four ranges, or partitions, would be established by the three `RANGE RIGHT` values specified in the statement:

- ▶ **values < 01/01/2006**—This partition includes any rows prior to 2006.
- ▶ **values >= 01/01/2006 AND values < 01/01/2007**—This partition includes all rows for 2006.
- ▶ **values >= 01/01/2007 AND values < 01/01/2008**—This partition includes all rows for 2007.
- ▶ **values > 01/01/2008**—This includes any rows for 2008 or later.

This method of partitioning would be more than adequate for a static table that is not going to be receiving any additional data rows for different years than already exist in the

table. However, if the table is going to be populated with additional data rows after it has been partitioned, it is good practice to add additional range values at the beginning and end of the ranges to allow for the insertion of data values less than or greater than the existing range values in the table. To create these additional upper and lower ranges, you would want to specify five values in the `VALUES` clause of the `CREATE PARTITION FUNCTION`, as shown in Listing 24.19. The advantages of having these additional partitions are demonstrated later in this section.

LISTING 24.19 Creating a Partition Function

```
if exists (select 1 from sys.partition_functions where name = 'SalesBigPF1')
    drop partition function SalesBigPF1
go
--Create partition function with the yearly values to partition the data
Create PARTITION FUNCTION SalesBigPF1 (datetime)
    AS RANGE RIGHT FOR VALUES
    ('01/01/2005', '01/01/2006', '01/01/2007',
     '01/01/2008', '01/01/2009')
GO
```

In this example, six ranges, or partitions, are established by the five range values specified in the statement:

- ▶ **values < 01/01/2005**—This partition includes any rows prior to 2005.
- ▶ **values >= 01/01/2005 AND values < 01/01/2006**—This partition includes all rows for 2005.
- ▶ **values >= 01/01/2006 AND values < 01/01/2007**—This partition includes all rows for 2006.
- ▶ **values >= 01/01/2007 AND values < 01/01/2008**—This partition includes all rows for 2007.
- ▶ **values >= 01/01/2008 AND values < 01/01/2009**—This partition includes all rows for 2008.
- ▶ **values >= 01/01/2009**—This partition includes any rows for 2009 or later.

An alternative to the `RIGHT` clause in the `CREATE PARTITION FUNCTION` statement is the `LEFT` clause. The `LEFT` clause is similar to `RIGHT`, but it changes the ranges such that the `<` operands are changed to `<=`, and the `>=` operands are changed to `>`.

TIP

Using `RANGE RIGHT` partitions for `datetime` values is usually best because this approach makes it easier to specify the limits of the ranges. The `datetime` data type can store values only with accuracy to 3.33 milliseconds. The largest value it can store is 0.997 milliseconds. A value of 0.998 milliseconds rounds down to 0.997, and a value of 0.999 milliseconds rounds up to the next second.

If you used a `RANGE LEFT` partition, the maximum time value you could include with the year to get all values for that year would be `23:59:59.997`. For example, if you specified `12/31/2006 23:59:59.999` as the boundary for a `RANGE LEFT` partition, it would be rounded up so that it would also include rows with `datetime` values less than or equal to `01/01/2007 00:00:00.000`, which is probably not what you would want. You would redefine the example shown in Listing 24.19 as a `RANGE LEFT` partition function as follows:

```
CREATE PARTITION FUNCTION SalesBigPF1 (datetime)
AS RANGE LEFT FOR VALUES
('12/31/2004 23:59:59.997', '12/31/2005 23:59:59.997',
'12/31/2006 23:59: 59.997', '12/31/2007 23:59:59.997',
'12/31/2008 23:59:59.997')
```

As you can see, it's a bit more straightforward and probably less confusing to use `RANGE RIGHT` partition functions when dealing with `datetime` values or any other continuous-value data types, such as `float` or `numeric`.

Creating a Partition Scheme

After you create a partition function, the next step is to associate a partition scheme with the partition function. A partition scheme can be associated with only one partition function, but a partition function can be shared across multiple partition schemes.

The core function of a partition scheme is to map the values defined in the partition function to filegroups. When creating the statement for a partition scheme, you need to keep in mind the following:

- ▶ A single filegroup can be used for all partitions, or a separate filegroup can be used for each individual partition.
- ▶ Any filegroup referenced in the partition scheme must exist before the partition scheme is created.
- ▶ There must be enough filegroups referenced in the partition scheme to accommodate all the partitions. The number of partitions is one more than the number of values specified in the partition function.
- ▶ The number of partitions is limited to 1,000.
- ▶ The filegroups listed in the partition scheme are assigned to the partitions defined in the function based on the order in which the filegroups are listed.

Listing 24.20 creates a partition schema that references the partition function created in Listing 24.19. This example assumes that the referenced filegroups have been created for each of the partitions. (For more information on creating filegroups and secondary files, see Chapter 23.)

NOTE

If you would like to create the same filegroups and files used by the examples in this section, check out the script file called `Create_Filegroups_and_Files_for_Partitioning.sql` on the included CD in the code listings directory for this chapter. If you run this script, it creates all the necessary file groups and files referenced in the examples. Note that you need to edit the script to change the `FILENAME` value if you need the files to be created in a directory other than `C:\MSSQL2008\DATA`.

LISTING 24.20 Creating a Partition Scheme

```
--Create a partition scheme that is aligned with the partition function
CREATE PARTITION SCHEME SalesBigPS1
    AS PARTITION SalesBigPF1
    TO ([Older_data], [2005_data], [2006_data],
        [2007_data], [2008_data], [2009_data])
GO
```

Alternatively, if all partitions are going to be on the same filegroup, such as the `PRIMARY` filegroup, you could use the following:

```
Create PARTITION SCHEME SalesBigPS1
    as PARTITION SalesBigPF1
    ALL to ([PRIMARY])
go
```

Notice that `SalesBigPF1` is referenced as the partition function in Listing 24.20. This ties together the partition scheme and partition function. Figure 24.7 shows how the partitions defined in the function would be mapped to the filegroup(s). At this point, you have made no changes to any table, and you have not even specified the column in the table that you will partition. The next section discusses those details.

Creating a Partitioned Table

Tables are partitioned only when they are created. This is an important point to keep in mind when you are considering adding partitions to a table that already exists.

Sometimes, performance issues or other factors may lead you to determine that a table you have already created and populated may benefit from being partitioned.

The re-creation of large tables in a production environment requires some forethought and planning. The data in the table must be retained in another location for you to re-create the table. Bulk copying the data to a flat file and renaming the table are two possible solutions for retaining the data. After you determine the data retention method, you can re-create the table, with the new partition scheme. For simplicity's sake, the example in Listing 24.21 creates a new table named `sales_big_Partitioned` instead of using the

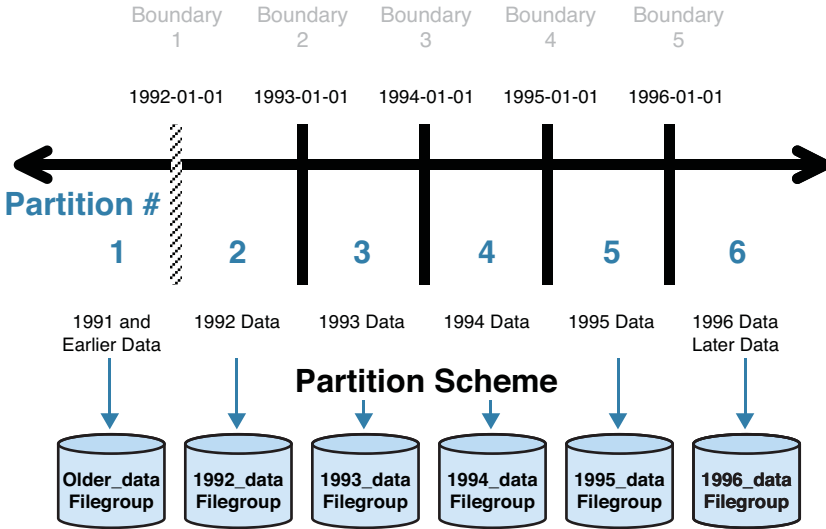

FIGURE 24.7 Mapping of partitions to filegroups, using a **RANGE RIGHT** partition function.

original sales_big table. The second part of Listing 24.21 copies the data from the sales_big table into the sales_big_Partitioned table.

LISTING 24.21 Creating a Partitioned Table

```
CREATE TABLE dbo.sales_big_Partitioned(
    sales_id int IDENTITY(1,1) NOT NULL,
    stor_id char(4) NOT NULL,
    ord_num varchar(20) NOT NULL,
    ord_date datetime NOT NULL,
    qty smallint NOT NULL,
    payterms varchar(12) NOT NULL,
    title_id dbo.tid NOT NULL
) ON SalesBigPS1 (ord_date) --this statement is key to Partitioning the table
GO

GO

--Insert data from the sales_big table into the new sales_big_partitioned table
SET IDENTITY_INSERT sales_big_Partitioned ON
GO
INSERT sales_big_Partitioned with (TABLOCKX)
(sales_id, stor_id, ord_num, ord_date, qty, payterms, title_id)
SELECT sales_id, stor_id, ord_num, ord_date, qty, payterms, title_id
FROM sales_big
```

```

go
SET IDENTITY_INSERT sales_big_Partitioned OFF
GO

```

The key clause to take note of in this listing is `ON SalesBigPS1 (ord_date)`. This clause identifies the partition scheme on which to create the table (`SalesBigPS1`) and the column within the table to use for partitioning (`ord_date`).

After you create the table, you might wonder whether the table was partitioned correctly. Fortunately, there are some catalog views related to partitions that you can query for this kind of information. Listing 24.22 shows a sample `SELECT` statement that utilizes the `sys.partitions` view. The results of the statement execution are shown immediately after the `SELECT` statement. Notice that there are six numbered partitions and that the estimated number of rows for each partition corresponds to the number of rows you saw when you selected the data from the unpartitioned `SalesBig` table.

LISTING 24.22 Viewing Partitioned Table Information

```

select convert(varchar(16), ps.name) as partition_scheme,
       p.partition_number,
       convert(varchar(10), ds2.name) as filegroup,
       convert(varchar(19), isnull(v.value, ''), 120) as range_boundary,
       str(p.rows, 9) as rows
from sys.indexes i
join sys.partition_schemes ps on i.data_space_id = ps.data_space_id
join sys.destination_data_spaces dds
     on ps.data_space_id = dds.partition_scheme_id
join sys.data_spaces ds2 on dds.data_space_id = ds2.data_space_id
join sys.partitions p on dds.destination_id = p.partition_number
                    and p.object_id = i.object_id and p.index_id = i.index_id
join sys.partition_functions pf on ps.function_id = pf.function_id
LEFT JOIN sys.Partition_Range_values v on pf.function_id = v.function_id
        and v.boundary_id = p.partition_number - pf.boundary_value_on_right
WHERE i.object_id = object_id('sales_big_partitioned')
      and i.index_id in (0, 1)
order by p.partition_number

/* Results from the previous SELECT statement
partition_scheme partition_number filegroup range_boundary rows
-----
SalesBigPS1          1 Older_Data          0
SalesBigPS1          2 2005_Data 2005-01-01 00:00:00 30
SalesBigPS1          3 2006_Data 2006-01-01 00:00:00 613560
SalesBigPS1          4 2007_Data 2007-01-01 00:00:00 616450
SalesBigPS1          5 2008_Data 2008-01-01 00:00:00 457210
SalesBigPS1          6 2009_Data 2009-01-01 00:00:00 0
*/

```

Adding and Dropping Table Partitions

One of the most useful features of partitioned tables is that you can add and drop entire partitions of table data in bulk. If the table partitions are set up properly, these commands can take place in seconds, without the expensive input/output (I/O) costs of physically copying or moving the data. You can add and drop table partitions by using the `SPLIT RANGE` and `MERGE RANGE` options of the `ALTER PARTITION FUNCTION` command:

```
ALTER PARTITION FUNCTION partition_function_name()
{ SPLIT RANGE ( boundary_value ) | MERGE RANGE ( boundary_value ) }
```

Adding a Table Partition

The `SPLIT RANGE` option adds a new boundary point to an existing partition function and affects all objects that use this partition function. When this command is run, one of the function partitions is split in two. The new partition is the one that contains the new boundary point. The new partition is created to the right of the boundary value if the partition is defined as a `RANGE RIGHT` partition function or to the left of the boundary if it is a `RANGE LEFT` partition function. If the partition is empty, the split is instantaneous.

If the partition being split contains data, any data on the new side of the boundary is physically deleted from the old partition and inserted into the new partition. In addition to being I/O intensive, a split is also log intensive, generating log records that are four times the size of the data being moved. In addition, an exclusive table lock is held for the duration of the split. If you want to avoid this costly overhead when adding a new partition to the end of the partition range, it is recommended that you always keep an empty partition available at the end and split it before it is populated with data. If the partition is empty, SQL Server does not need to scan the partition to see whether there is any data to be moved.

NOTE

Avoiding the overhead associated with splitting a partition is the reason the code in Listing 24.19 defined the `SalesBigPF1` partition function with a partition for 2009, even though there is no 2009 data in the `sales_big_partitioned` table. As long as you split the partition before any 2009 data is inserted into the table and the 2009 partition is empty, no data needs to be moved, so the split is instantaneous.

Before you split a partition, a filegroup must be marked to be the `NEXT USED` partition by the partition scheme that uses the partition function. You initially allocate filegroups to partitions by using a `CREATE PARTITION SCHEME` statement. If a `CREATE PARTITION SCHEME` statement allocates more filegroups than there are partitions defined in the `CREATE PARTITION FUNCTION` statement, one of the unassigned filegroups is automatically marked as `NEXT USED` by the partition scheme, and it will hold the new partition.

If there are no filegroups currently marked `NEXT USED` by the partition scheme, you must use `ALTER PARTITION SCHEME` to either add a filegroup or designate an existing filegroup to hold the new partition. This can be a filegroup that already holds existing partitions. Also, if a partition function is used by more than one partition scheme, all the partition schemes that use the partition function to which you are adding partitions must have a `NEXT USED` filegroup. If one or more do not have a `NEXT USED` filegroup assigned, the `ALTER PARTITION FUNCTION` statement fails, and the error message displays the partition scheme or schemes that lack a `NEXT USED` filegroup.

The following SQL statement adds a `NEXT USED` filegroup to the `SalesBigPS1` partition scheme. Note that in this example, the filegroup specified is a new filegroup, `2010_DATA`:

```
ALTER PARTITION SCHEME SalesBigPS1 NEXT USED '2010_Data'
```

Now that you have specified a `NEXT USED` filegroup for the partition scheme, you can go ahead and add the new range for 2010 and later data rows to the partition function, as in the following example:

```
--Alter partition function with the yearly values to partition the data
ALTER PARTITION FUNCTION SalesBigPF1 () SPLIT RANGE ('01/01/2010')
GO
```

Figure 24.8 shows the effects of splitting the 2009 table partition.

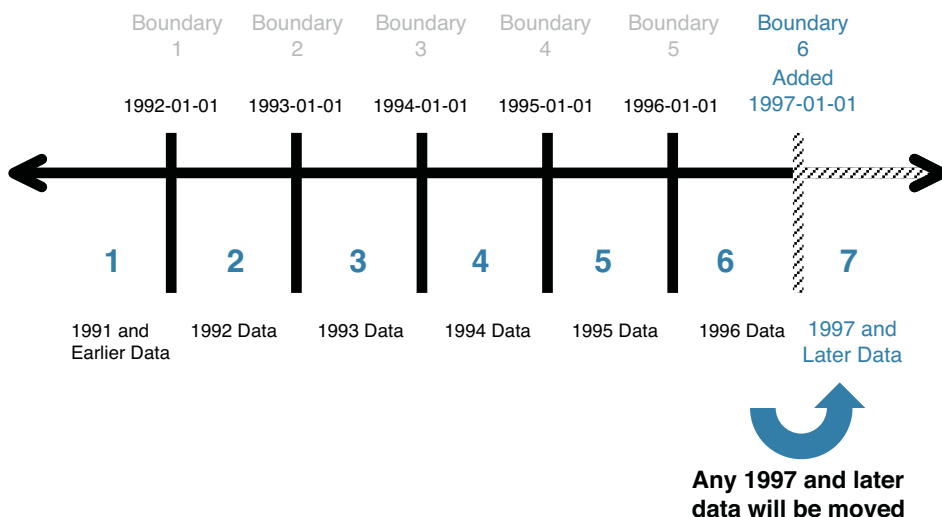

FIGURE 24.8 The effects of splitting a **RANGE RIGHT** table partition.

You can also see the effects of splitting the partition on the system catalogs by running the same query as shown earlier, in Listing 24.22:

```

/* New results from the SELECT statement in Listing 24.22
partition_scheme partition_number filegroup range_boundary rows
-----
SalesBigPS1          1 Older_Data          0
SalesBigPS1          2 2005_Data  2005-01-01 00:00:00  30
SalesBigPS1          3 2006_Data  2006-01-01 00:00:00 613560
SalesBigPS1          4 2007_Data  2007-01-01 00:00:00 616450
SalesBigPS1          5 2008_Data  2008-01-01 00:00:00 457210
SalesBigPS1          6 2009_Data  2009-01-01 00:00:00  0
SalesBigPS1          7 2010_Data  2010-01-01 00:00:00  0
*/

```

Dropping a Table Partition

You can drop a table partition by using the `ALTER PARTITION FUNCTION ... MERGE RANGE` command. This command essentially removes a boundary point from a partition function as the partitions on each side of the boundary are merged into one. The partition that held the boundary value is removed. The filegroup that originally held the boundary value is removed from the partition scheme unless it is used by a remaining partition or is marked with the `NEXT USED` property.

Any data that was in the removed partition is moved to the remaining neighboring partition. If a `RANGE RIGHT` partition boundary was removed, the data that was in that boundary's partition is moved to the partition to the left of boundary. If it was a `RANGE LEFT` partition, the data is moved to the partition to the right of the boundary.

The following command merges the 2005 partition into the `Old_Data` partition for the `sales_big_partitioned` table:

```
ALTER PARTITION FUNCTION SalesBigPF1 () MERGE RANGE ('01/01/2005')
```

Figure 24.9 demonstrates how the 2005 `RANGE RIGHT` partition boundary is removed and the data is merged to the left, into the `Old_Data` partition.

CAUTION

Splitting or merging partitions for a partition function affects all objects using that partition function.

You can also see the effects of merging the partition on the system catalogs by running the same query as shown in Listing 24.22:

```

/* New results from the SELECT statement in Listing 24.20
partition_scheme partition_number filegroup range_boundary rows
-----

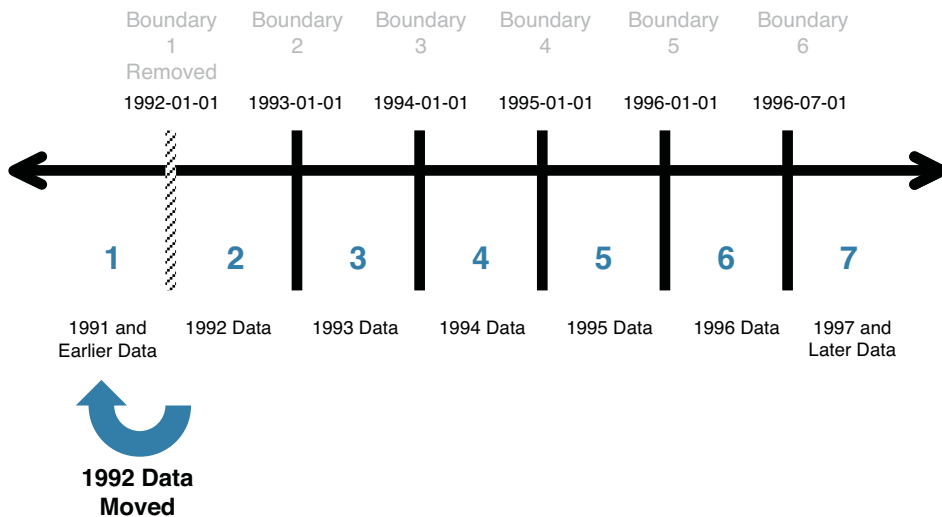

FIGURE 24.9 The effects of merging a **RANGE RIGHT** table partition.

Like the split operation, the merge operation occurs instantaneously if the partition being merged is empty. The process can be very I/O intensive if the partition has a large amount of data in it. Any rows in the removed partition are physically moved into the remaining partition. This operation is also very log intensive, requiring log space approximately four times the size of data being moved. An exclusive table lock is held for the duration of the merge.

If you no longer want to keep the data in the table for a partition you are merging, you can move the data in the partition to another empty table or empty table partition by using the `SWITCH PARTITION` option of the `ALTER TABLE` command. This option is discussed in more detail in the following section.

Switching Table Partitions

One of the great features of table partitions is that they enable you to instantly swap the contents of one partition to an empty table, the contents from a partition on one table to a partition in another table, or an entire table's contents into another table's empty partition. This operation performs changes only to metadata in the system catalogs for the affected tables/partitions, with no actual physical movement of data.

For you to switch data from a partition to a table or from a table into a partition, the following criteria must be met:

- ▶ The source table and target table must both have the same structure (that is, the same columns in the same order, with the same names, data types, lengths, precisions, scales, nullabilities, and collations). The tables must also have the same primary key constraints and settings for `ANSI_NULLS` and `QUOTED_IDENTIFIER`.
- ▶ The source and target of the `ALTER TABLE . . . SWITCH` statement must reside in the same filegroup.
- ▶ If you are switching a partition to a single, nonpartitioned table, the table receiving the partition must already be created, and it must be empty.
- ▶ If you are adding a table as a partition to an already existing partitioned table or moving a partition from one partitioned table to another, the receiving partition must exist, and it must be empty.
- ▶ If you are switching a partition from one partitioned table to another, both tables must be partitioned on the same column.
- ▶ The source must have all the same indexes as the target, and the indexes must also be in the same filegroup.
- ▶ If you are switching a nonpartitioned table to a partition of an already existing partitioned table, the nonpartitioned table must have a constraint defined on the column corresponding to the partition key of the target table to ensure that the range of values fits within the boundary values of the target partition.
- ▶ If the target table has any `FOREIGN KEY` constraints, the source table must have the same foreign keys defined on the corresponding columns, and those foreign keys must reference the same primary keys that the target table references.

If you are switching a partition of a partitioned table to another partitioned table, the boundary values of the source partition must fit within those of the target partition. If the boundary values do not fit, a constraint must be defined on the partition key of the source table to make sure all the data in the table fits into the boundary values of the target partition.

CAUTION

If the tables have `IDENTITY` columns, partition switching can result in the introduction of duplicate values in `IDENTITY` columns of the target table and gaps in the values of `IDENTITY` columns in the source table. You can use `DBCC_CHECKIDENT` to check the identity values of tables and correct them if necessary.

When you switch a partition, data is not physically moved. Only the metadata information in the system catalogs indicating where the data is stored is changed. In addition, all associated indexes are automatically switched, along with the table or partition.

To switch table partitions, you use the ALTER TABLE command:

```
ALTER TABLE table_name SWITCH [ PARTITION source_partition_number_expression ]
    TO target_table [ PARTITION target_partition_number_expression ]
```

You can use the ALTER TABLE...SWITCH command to switch an unpartitioned table into a table partition, switch a table partition into an empty unpartitioned table, or switch a table partition into another table's empty table partition. The code shown in Listing 24.23 creates a table to hold the data from the 2006 partition and then switches the 2006 partition from the sales_big_partitioned table to the new table.

LISTING 24.23 Switching a Partition to an Empty Table

```
CREATE TABLE dbo.sales_big_2006(
    sales_id int IDENTITY(1,1) NOT NULL,
    stor_id char(4) NOT NULL,
    ord_num varchar(20) NOT NULL,
    ord_date datetime NOT NULL,
    qty smallint NOT NULL,
    payterms varchar(12) NOT NULL,
    title_id dbo.tid NOT NULL
) ON '2006_data' -- required in order to switch the partition to this table
go
alter table sales_big_partitioned
    switch partition $PARTITION.SalesBigPF1 ('1/1/2006')
    to sales_big_2006
go
```

Note that Listing 24.23 uses the \$PARTITION function. You can use this function with any partition function name to return the partition number that corresponds with the specified partitioning column value. This prevents you from having to query the system catalogs to determine the specific partition number for the specified partition value.

You can run the query from Listing 24.22 to show that the 2006 partition is now empty:

partition_scheme	partition_number	filegroup	range_boundary	rows
SalesBigPS1	1	Older_Data		30
SalesBigPS1	2	2006_Data	2006-01-01 00:00:00	0
SalesBigPS1	3	2007_Data	2007-01-01 00:00:00	616450
SalesBigPS1	4	2008_Data	2008-01-01 00:00:00	457210
SalesBigPS1	5	2009_Data	2009-01-01 00:00:00	0
SalesBigPS1	6	2010_Data	2010-01-01 00:00:00	0

Now that the 2006 data partition is empty, you can merge the partition without incurring the I/O cost of moving the data to the `Older_data` partition:

```
ALTER PARTITION FUNCTION SalesBigPF1 () merge RANGE ('1/1/2006')
```

Rerunning the query in Listing 24.22 now returns the following result set:

partition_scheme	partition_number	filegroup	range_boundary	rows
SalesBigPS1	1	Older_Data		30
SalesBigPS1	2	2007_Data	2007-01-01 00:00:00	616450
SalesBigPS1	3	2008_Data	2008-01-01 00:00:00	457210
SalesBigPS1	4	2009_Data	2009-01-01 00:00:00	0
SalesBigPS1	5	2010_Data	2010-01-01 00:00:00	0

To demonstrate switching a table into a partition, you can update the date for all the rows in the `sales_big_2006` table to 2009 and switch it into the 2009 partition of the `sales_big_partitioned` table. Note that before you can do this, you need to copy the data to a table in the `2009_data` filegroup and also put a check constraint on the `ord_date` column to make sure all rows in the table are limited to values that are valid for the `2009_data` partition. Listing 24.24 shows the commands you use to create the new table and switch it into the 2009 partition of the `sales_big_partitioned` table.

LISTING 24.24 Switching a Table to an Empty Partition

```
CREATE TABLE dbo.sales_big_2009(
    sales_id int IDENTITY(1,1) NOT NULL,
    stor_id char(4) NOT NULL,
    ord_num varchar(20) NOT NULL,
    ord_date datetime NOT NULL
    constraint CK_sales_big_2009_ord_date
        check (ord_date >= '1/1/2009' and ord_date < '1/1/2010'),
    qty smallint NOT NULL,
    payterms varchar(12) NOT NULL,
    title_id dbo.tid NOT NULL
) ON '2009_data' -- required to switch the table to the 2009 partition
go
set identity_insert sales_big_2009 on
go
insert sales_big_2009 (sales_id, stor_id, ord_num,
                    ord_date, qty, payterms, title_id)
    select sales_id, stor_id, ord_num,
           dateadd(yy, 3, ord_date),
           qty, payterms, title_id
    from sales_big_2006
go
set identity_insert sales_big_2009 off
```

```

go
alter table sales_big_2009
    switch to sales_big_partitioned
    partition $PARTITION.SalesBigPF1 ('1/1/2009')
go

```

Rerunning the query from Listing 24.22 now returns the following result:

partition_scheme	partition_number	filegroup	range_boundary	rows
SalesBigPS1	1	Older_Data		30
SalesBigPS1	2	2007_Data	2007-01-01 00:00:00	616450
SalesBigPS1	3	2008_Data	2008-01-01 00:00:00	457210
SalesBigPS1	4	2009_Data	2009-01-01 00:00:00	613560
SalesBigPS1	5	2010_Data	2010-01-01 00:00:00	0

TIP

Switching data into or out of partitions provides a very efficient mechanism for archiving old data from a production table, importing new data into a production table, or migrating data to an archive table. You can use `SWITCH` to empty or fill partitions very quickly. As you've seen in this section, split and merge operations occur instantaneously if the partitions being split or merged are empty first. If you must split or merge partitions that contain a lot of data, you should empty them first by using `SWITCH` before you perform the split or merge.

Creating Temporary Tables

A *temporary table* is a special type of table that is automatically deleted when it is no longer used. Temporary tables have many of the same characteristics as permanent tables and are typically used as work tables that contain intermediate results.

You designate a table as temporary in SQL Server by prefacing the table name with a single pound sign (#) or two pound signs (##). Temporary tables are created in `tempdb`; if a temporary table is not explicitly dropped, it is dropped when the session that created it ends or the stored procedure it was created in finishes execution.

If a table name is prefaced with a single pound sign (for example, `#table1`), it is a *private* temporary table, available only to the session that created it.

A table name prefixed with a double pound sign (for example, `##table2`) indicates that it is a *global* temporary table, which means it is accessible by all database connections. A global temporary table exists until the session that created it terminates. If the creating session terminates while other sessions are accessing the table, the temporary table is available to those sessions until the last session's query ends, at which time the table is dropped.

A common way of creating a temporary table is to use the `SELECT INTO` method as shown in the following example:

```
SELECT* INTO #Employee2 FROM Employee
```

This method creates a temporary table with a structure like the table that is being selected from. It also copies the data from the original table and inserts it into this new temporary table. All of this is done with this one simple command.

NOTE

Table variables are a good alternative to temporary tables. These variables are also temporary in nature and have some advantages over temporary tables. Table variables are easy to create, are automatically deleted, cause fewer recompilations, and use fewer locking and logging resources. Generally speaking, you should consider using table variables instead of temporary tables when the temporary results are relatively small.

Parallel query plans are not generated with table variables, and this can impede overall performance when you are accessing a table variable that has a large number of rows.

For more information on using temporary tables and table variables, see Chapter 43, “Transact-SQL Programming Guidelines, Tips, and Tricks,” that is found on the bonus CD.

Tables created without the `#` prefix but explicitly created in `tempdb` are also considered temporary, but they are a more permanent form of a temporary table. They are not dropped automatically until SQL Server is restarted and `tempdb` is reinitialized.

Summary

Tables are the key to a relational database system. When you create tables, you need to pay careful attention to choosing the proper data types to ensure efficient storage of data, adding appropriate constraints to maintain data integrity, and scripting the creation and modification of tables to ensure that they can be re-created, if necessary.

Good table design includes the creation of indexes on a table. Tables without indexes are generally inefficient and cause excessive use of resources on your database server. Chapter 25, “Creating and Managing Indexes,” covers indexes and their critical role in effective table design.

CHAPTER 25

Creating and Managing Indexes

Just like the index in this book, an index on a table or view allows you to efficiently find the information you are looking for in a database. SQL Server does not require indexes to be able to retrieve data from tables because it can perform a full table scan to retrieve a result set. However, doing a table scan is analogous to scanning every page in this book to find a word or reference you are looking for.

This chapter introduces the different types of indexes available in SQL Server 2008 to keep your database access efficient. It focuses on creating and managing indexes by using the tools Microsoft SQL Server 2008 provides. For a more in-depth discussion of the internal structures of indexes and designing and managing indexes for optimal performance, see Chapter 34, “Data Structures, Indexes, and Performance.”

What’s New in Creating and Managing Indexes

The creation and management of indexes are among the most important performance activities in SQL Server. You will find that indexes and the tools to manage them in SQL Server 2008 are very similar to those in SQL Server 2005. New to SQL Server 2008 is the capability to compress indexes and tables to reduce the amount of storage needed for these objects. This new data compression feature is discussed in detail in Chapter 34.

Also new to SQL Server 2008 are filtered indexes. Filtered indexes utilize a `WHERE` clause that filters or limits the number of rows included in the index. The smaller filtered index

IN THIS CHAPTER

- ▶ Creating Indexes
- ▶ Managing Indexes
- ▶ Dropping Indexes
- ▶ Online Indexing Operations
- ▶ Indexes on Views

allows queries that are run against rows in the index to run faster. These can also save on the disk space used by the index.

Spatial indexes also are new to SQL Server 2008. These indexes are used against spatial data defined by coordinates of latitude and longitude. The spatial data is essential for efficient global navigation. The Spatial indexes are grid based and help optimize the performance of searches against the Spatial data. Spatial indexes are also discussed in more detail in Chapter 34.

Types of Indexes

SQL Server has two main types of indexes: clustered and nonclustered. They both help the query engine get at data faster, but they have different effects on the storage of the underlying data. The following sections describe these two main types of indexes and provide some insight into when to use each type.

Clustered Indexes

Clustered indexes sort and store the data rows for a table, based on the columns defined in the index. For example, if you were to create a clustered index on the `LastName` and `FirstName` columns in a table, the data rows for that table would be organized or sorted according to these two columns. This has some obvious advantages for data retrieval. Queries that search for data based on the clustered index keys have a sequential path to the underlying data, which helps reduce I/O.

A clustered index is analogous to a filing cabinet where each drawer contains a set of file folders stored in alphabetical order, and each file folder stores the files in alphabetical order. Each file drawer contains a label that indicates which folders it contains (for example, folders A–D). To locate a specific file, you first locate the drawer containing the appropriate file folders, then locate the appropriate file folder within the drawer, and then scan the files in that folder in sequence until you find the one you need.

A clustered index is structured as a balanced tree (B-tree). Figure 25.1 shows a simplified diagram of a clustered index defined on a last name column.

The top, or root, node is a single page where searches via the clustered index are started. The bottom level of the index is the leaf nodes. With a clustered index, the leaf nodes of the index are also the data pages of the table. Any levels of the index between the root and leaf nodes are referred to as *intermediate nodes*. All index key values are stored in the clustered index levels in sorted order. To locate a data row via a clustered index, SQL Server starts at the root node and navigates through the appropriate index pages in the intermediate levels of the index until it reaches the data page that should contain the desired data row(s). It then scans the rows on the data page until it locates the desired value.

There can be only one clustered index per table. This restriction is driven by the fact that the underlying data rows can be sorted and stored in only one way. With very few exceptions, every table in a database should have a clustered index. The selection of columns

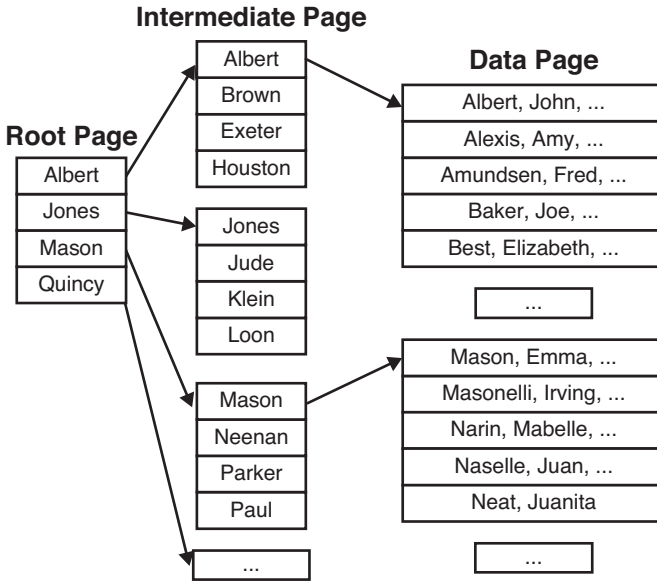

FIGURE 25.1 A simplified diagram of a clustered index.

for a clustered index is very important and should be driven by the way the data is most commonly accessed in the table. You should consider using the following types of columns in a clustered index:

- ▶ Those that are often accessed sequentially
- ▶ Those that contain a large number of distinct values
- ▶ Those that are used in range queries that use operators such as `BETWEEN`, `>`, `>=`, `<`, or `<=` in the `WHERE` clause
- ▶ Those that are frequently used by queries to join or group the result set

When you are using these criteria, it is important to focus on the most critical data access: the queries that are run most often or that must have the best performance. This approach can be challenging but ultimately reduces the number of data pages and related I/O for the queries that matter.

Nonclustered Indexes

A nonclustered index is a separate index structure, independent of the physical sort order of the data rows in the table. You are therefore not restricted to creating only 1 nonclustered index per table; in fact, in SQL Server 2008 you can create up to 999 nonclustered indexes per table. This is an increase from SQL Server 2005, which was limited to 249.

A nonclustered index is analogous to an index in the back of a book. To find the pages on which a specific subject is discussed, you look up the subject in the index and then go to the pages referenced in the index. With nonclustered indexes, you may have to jump around to many different nonsequential pages to find all the references.

A nonclustered index is also structured as a B-tree. Figure 25.2 shows a simplified diagram of a nonclustered index defined on a first name column.

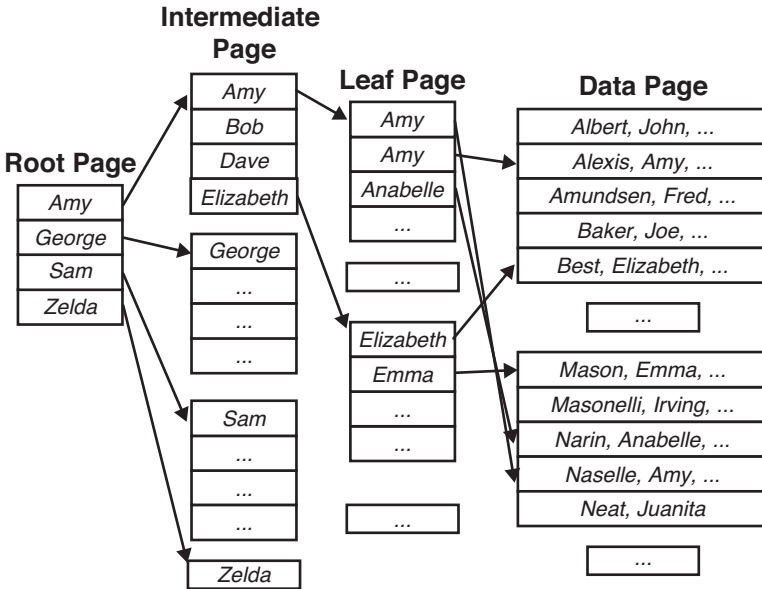

FIGURE 25.2 A simplified diagram of a nonclustered index.

As with a clustered index, in a nonclustered index, all index key values are stored in the nonclustered index levels in sorted order, based on the index key(s). This sort order is typically different from the sort order of the table itself. The main difference between a nonclustered index and clustered index is that the leaf row of a nonclustered index is independent of the data rows in the table. The leaf level of a nonclustered index contains a row for every data row in the table, along with a pointer to locate the data row. This pointer is either the clustered index key for the data row, if the table has a clustered index on it, or the data page ID and row ID of the data row if the table is stored as a heap structure (that is, if the table has no clustered index defined on it).

To locate a data row via a nonclustered index, SQL Server starts at the root node and navigates through the appropriate index pages in the intermediate levels of the index until it reaches the leaf page, which should contain the index key for the desired data row. It then scans the keys on the leaf page until it locates the desired index key value. SQL Server then uses the pointer to the data row stored with the index key to retrieve the corresponding data row.

NOTE

For a more detailed discussion of clustered tables versus heap tables (that is, tables with no clustered indexes) and more detailed descriptions of clustered and nonclustered index key structures and index key rows, as well as how SQL Server internally maintains indexes, see Chapter 34.

The efficiency of the index lookup and the types of lookups should drive the selection of nonclustered indexes. In the book index example, a single page reference is a very simple lookup for the book reader and requires little work. If, however, many pages are referenced in the index, and those pages are spread throughout the book, the lookup is no longer simple, and much more work is required to get all the information.

You should choose your nonclustered indexes with the book index example in mind. You should consider using nonclustered indexes for the following:

- ▶ Queries that do not return large result sets
- ▶ Columns that are frequently used in the `WHERE` clause that return exact matches
- ▶ Columns that have many distinct values (that is, high cardinality)
- ▶ All columns referenced in a critical query (a special nonclustered index called a *covering index* that eliminates the need to go to the underlying data pages)

Having a good understanding of your data access is essential to creating nonclustered indexes. Fortunately, SQL Server comes with tools such as the SQL Server Profiler and Database Engine Tuning Advisor that can help you evaluate your data access paths and determine which columns are the best candidates. SQL Profiler is discussed in more detail in Chapter 6, “SQL Server Profiler.” In addition, Chapter 34 discusses the use of the SQL Server Profiler and Database Engine Tuning Advisor to assist in developing an optimal indexing strategy.

Creating Indexes

The following sections examine the most common means for creating indexes in SQL Server. Microsoft provides several different methods for creating indexes, each of which has advantages. The method used is often a matter of personal preference, but there are situations in which a given method has distinct advantages.

Creating Indexes with T-SQL

Transact-SQL (T-SQL) is the most fundamental means for creating an index. This method was available in all previous versions of SQL Server. It is a very powerful option for creating indexes because the T-SQL statements that create indexes can be stored in a file and

run as part of a database installation or upgrade. In addition, T-SQL scripts that were used in prior SQL Server versions to create indexes can be reused with very little change.

You can create indexes by using the T-SQL `CREATE INDEX` command. Listing 25.1 shows the basic `CREATE INDEX` syntax. Refer to SQL Server 2008 Books Online for the full syntax.

LISTING 25.1 **CREATE INDEX** Syntax

```
CREATE [ UNIQUE ] [ CLUSTERED | NONCLUSTERED ] INDEX index_name
    ON <object> ( column [ ASC | DESC ] [ ,...n ] )
    [ INCLUDE ( column_name [ ,...n ] ) ]
    [ WHERE <filter_predicate> ]
    [ WITH ( <relational_index_option> [ ,...n ] ) ]
```

Table 25.1 lists the `CREATE INDEX` arguments.

TABLE 25.1 Arguments for **CREATE INDEX**

Argument	Explanation
UNIQUE	Indicates that no two rows in the index can have the same index key values. Inserts into a table with a UNIQUE index will fail if a row with the same value already exists in the table.
CLUSTERED NON-CLUSTERED	Defines the index as clustered or nonclustered. NON-CLUSTERED is the default. Only one clustered index is allowed per table.
<i>index_name</i>	Specifies the name of the index to be created.
<i>object</i>	Specifies the name of the table or view to be indexed.
<i>column_name</i>	Specifies the column or columns that are to be indexed.
ASC DESC	Specifies the sort direction for the particular index column. ASC creates an ascending sort order and is the default. The DESC option causes the index to be created in descending order.
INCLUDE (<i>column</i> [,... <i>n</i>])	Allows a column to be added to the leaf level of an index without being part of the index key. This is a new argument.

TABLE 25.1 Arguments for **CREATE INDEX**

Argument	Explanation
WHERE <filter_predicate>	This argument, new to SQL Server 2008, is used to create a filtered index. The <code>filter_predicate</code> contains a WHERE clause that limits the number of rows in the table that are included in the index.
relational_index_option	Specifies the index option to use when creating the index.

Following is a simple example using the basic syntax of the `CREATE INDEX` command:

```
CREATE NONCLUSTERED INDEX [NC_Person_LastName]
ON [Person].[Person]
(
  [LastName] ASC
)
```

This example creates a nonclustered index on the `person.person` table, based on the `LastName` column. The `NONCLUSTERED` and `ASC` keywords are not necessary because they are the defaults. Because the `UNIQUE` keyword is not specified, duplicates are allowed in the index (that is, multiple rows in the table can have the same `LastName`).

Unique indexes are more involved because they serve two roles: they provide fast access to the data via the index's columns, but they also serve as a constraint by allowing only one row to exist on a table for the combination of column values in the index. They can be clustered or nonclustered. Unique indexes are also defined on a table whenever you define a unique or primary key constraint on a table. The following example shows the creation of a nonclustered unique index:

```
CREATE UNIQUE NONCLUSTERED INDEX [AK_CreditCard_CardNumber]

ON [Sales].[CreditCard]
(
  [CardNumber] ASC
)
```

This example creates a nonclustered index named `AK_CreditCard_CardNumber` on the `Sales.CreditCard` table. This index is based on a single column in the table. When it is created, this index prevents credit card rows with the same credit card number from being inserted into the `CreditCard` table.

The relational index options listed in Table 25.2 allow you to define more sophisticated indexes or specify how an index is to be created.

TABLE 25.2 Relational Index Options for **CREATE INDEX**

Argument	Explanation
PAD_INDEX = {ON OFF}	Determines whether free space is allocated to the non-leaf-level pages of an index. The percentage of free space is determined by FILLFACTOR.
FILLFACTOR = <i>fillfactor</i>	Determines the amount of free space left in the leaf level of each index page. The <i>fillfactor</i> values represent a percentage, from 0 to 100. The default value is 0. If <i>fillfactor</i> is 0 or 100, the index leaf-level pages are filled to capacity, leaving only enough space for at least one more row to be inserted.
SORT_IN_TEMPDB = {ON OFF}	Specifies whether intermediate sort results that are used to create the index are stored in tempdb. Using them can speed up the creation of the index (if tempdb is on a separate disk), but it requires more disk space.
IGNORE_DUP_KEY = {ON OFF}	Determines whether multirow inserts will fail when duplicate rows in the insert violate a unique index. When this option is set to ON, duplicate key values are ignored, and the rest of the multirow insert succeeds. When it is OFF (the default), the entire multirow insert fails if a duplicate is encountered.
STATISTICS_NO_RECOMPUTE = {ON OFF}	Determines whether distribution statistics used by the Query Optimizer are recomputed. When ON, the statistics are not automatically recomputed.
DROP_EXISTING = {ON OFF}	Determines whether an index with the same name is dropped prior to re-creation. This can provide some performance benefits over dropping the existing index first and then creating. Clustered indexes see the most benefit.
ONLINE = {ON OFF}	Determines whether the index is built such that the underlying table is still available for queries and data modification during the index creation. This new feature is discussed in more detail in the “Online Indexing Operations” section, later in this chapter.

TABLE 25.2 Relational Index Options for **CREATE INDEX**

Argument	Explanation
ALLOW_ROW_LOCKS = {ON OFF}	Determines whether row locks are allowed when accessing the index. The default for this new feature is ON.
ALLOW_PAGE_LOCKS = {ON OFF}	Determines whether page locks are allowed when accessing the index. The default for this new feature is ON.
MAXDOP = <i>number of processors</i>	Determines the number of processors that can be used during index operations. The default for this new feature is 0, which causes an index operation to use the actual number of processors or fewer, depending on the workload on the system. This can be a useful option for index operations on large tables that may impact performance during the operation. For example, if you have four processors, you can specify MAXDOP = 2 to limit the index operation to use only two of the four processors.
DATA_COMPRESSION = { NONE ROW PAGE } [ON PARTITIONS ({ <partition_number_expression> <range> } [, ...n])	Determines whether data compression is used on the specified index. The compression can be done on the row or page level and specific index partitions can be compressed if the index uses partitioning.

The following example creates a more complex index that utilizes several of the index options described in Table 25.2:

```
CREATE NONCLUSTERED INDEX [
IX_Person_LastName_FirstName_MiddleName] ON [Person].[Person]
(
    [LastName] ASC,
    [FirstName] ASC,
    [MiddleName] ASC
)WITH (SORT_IN_TEMPDB = OFF, IGNORE_DUP_KEY = OFF, DROP_EXISTING = OFF, FILLFACTOR=80)
```

This example creates a nonclustered composite index on the person’s last name (LastName), first name (FirstName), and middle name (MiddleName). It utilizes some of the commonly used options and demonstrates how multiple options can be used in a single CREATE statement.

TIP

SQL Server Management Studio (SSMS) has several methods for generating the T-SQL code that creates indexes. You therefore rarely need to type index CREATE statements from scratch. Instead, you can use the friendly GUI screens that enable you to specify the common index options, and then you can generate the T-SQL script that can be executed to create the index.

Additional syntax options (not listed here) relate to backward compatibility and the creation of indexes on XML columns. Refer to Chapter 47, “Using XML in SQL Server 2008,” and the SQL Server Books Online documentation for further details.

Creating Indexes with SSMS

SQL Server 2008 has many options for creating indexes within SSMS. You can create indexes within SSMS via the Database Engine Tuning Advisor, database diagrams, the Table Designer, and several places within the Object Explorer. The means available from the Object Explorer are the simplest to use and are the focus of this section. The other options are discussed in more detail in related chapters of this book.

Index creation in the Object Explorer is facilitated by the New Index screen. You can launch this screen from SMSS by expanding the database tree in the Object Explorer and navigating to the Indexes node of the table that you want to add the index to. Then you right-click the Indexes node and select New Index. A screen like the one shown in Figure 25.3 is displayed.

The name and options that are populated in Figure 25.3 are based on the person index created in the previous T-SQL section. The `LastName`, `FirstName`, and `MiddleName` columns were selected and added as part of this new index by clicking the Add button, which displays a screen with all the columns in the table that are available for the index. You simply select the column(s) you want to include on the index. This populates the Index Key Columns grid on the default General page.

You can select other options for an index by changing the Select a Page options available on the top-left side of the New Index screen. The Options, Included Columns, Storage, Spatial, and Filter pages each provide a series of options that relate to the corresponding category and are utilized when creating the index.

Of particular interest is the Included Columns page. This page allows you to select columns that you want to include in the leaf-level pages of the index but don't need as part of the index key. For example, you could consider using included columns if you have a critical query that often selects last name, first name, and address from a table but uses only the last name and first name as search arguments in the WHERE clause. This may be a situation in which you would want to consider the use of a covering index that places all the referenced columns from the query into a nonclustered index. In the case of our critical query, the address column can be added to the index as an included column. It is not included in the index key, but it is available in the leaf-level pages of the index so that the additional overhead of going to the data pages to retrieve the address is not needed.

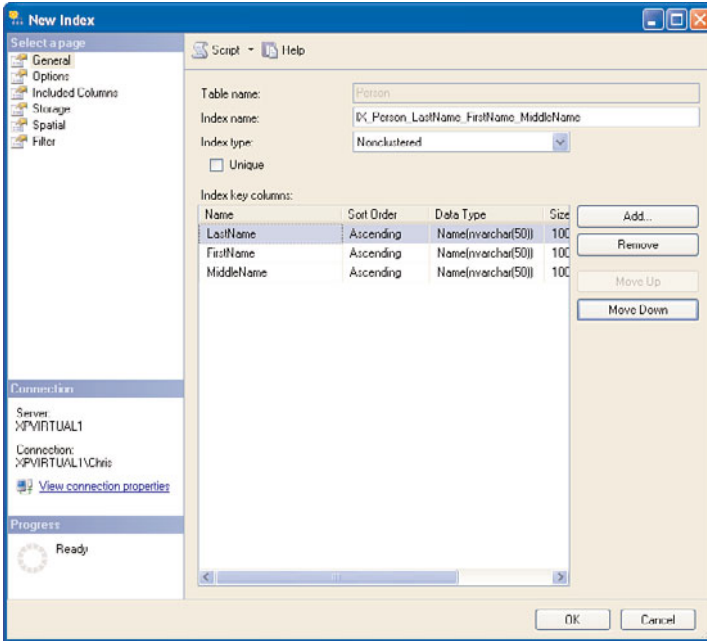

FIGURE 25.3 Using Object Explorer to create indexes.

The Spatial and Filter option pages are new to SQL Server 2008. The Spatial page can be used to create spatial indexes on a column that is defined as a spatial data type; that is either type geometry or geography. If your table contains a column of this data type, you can use the Index Type drop-down to change the index type to Spatial. After this is done, you can add a column that is defined as a spatial data type to the index. Finally, you can select the Spatial option page, as shown in Figure 25.4, that allows you to fully define a spatial index. The meaning of the parameters on this page are beyond the scope of this chapter and are discussed in more detail in Chapter 34.

The Filter option page allows you to define a filtering criterion to limit the rows that are included in the index. The page, shown in Figure 25.5, is relatively simple with a single input area that contains your filtering criterion. This criterion is basically the contents of a WHERE clause that is similar to what you would use in a query window to filter the rows in your result. The filter expression shown in Figure 25.5 was defined for an index on the PersonType column, which is found in the Person.Person table of the AdventureWorks2008 sample database. Many of the rows in this table have a PersonType value equal to 'IN' so a filtered index that does not include rows with this value will dramatically reduce the size of the index and make searches on values other than 'IN' relatively fast.

After selecting all the options you want for your index via the New Index screen, you have several options for actually creating the index. You can script the index, schedule the index creation for a later time, or simply click OK to allow the New Index screen to add the index immediately. As mentioned earlier, it is a good idea to use this New Index

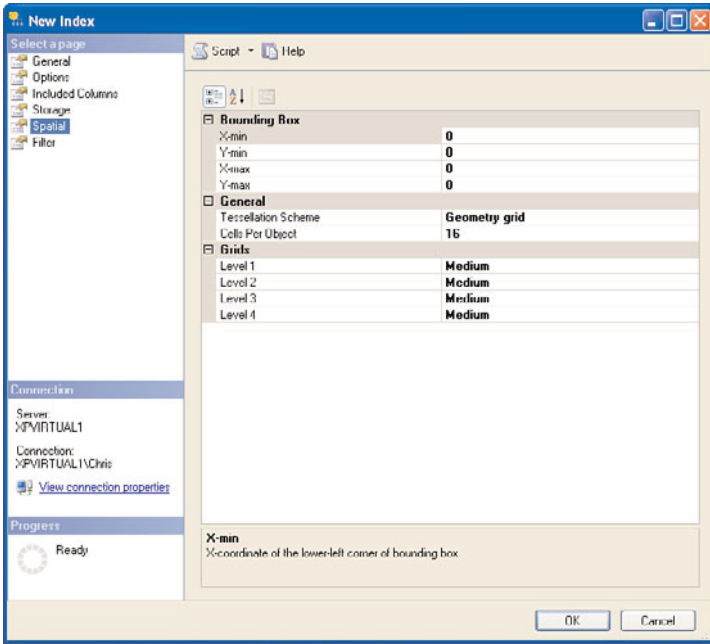

FIGURE 25.4 Spatial Index options page.

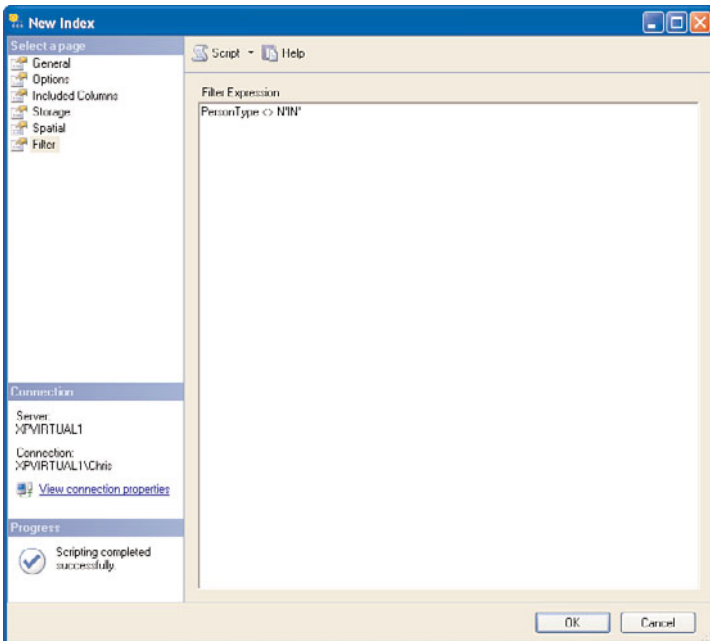

FIGURE 25.5 Filter Index options page.

screen to specify the index options, and then you can click the Script button to generate all the T-SQL statements needed to create the index. You can then save this script to a file to be used for generating a database build script or for maintaining a record of the indexes defined in a database.

Managing Indexes

There are two different aspects to index management. The first aspect is the management of indexes by the SQL Server database engine. Fortunately, the engine does a good job of managing the indexes internally so that limited manual intervention is required. This is predicated on a well-designed database system and the use of SQL Server features, such as automatic updates to distribution statistics.

The other aspect of index management typically comes into play when performance issues arise. Index adjustments and maintenance of these indexes make up the bulk of this effort.

Managing Indexes with T-SQL

One of the T-SQL features available with SQL Server 2008 is the ALTER INDEX statement. This statement simplifies many of the tasks associated with managing indexes. Index operations such as index rebuilds and changes to fill factor that were previously handled with DBCC commands are now available via the ALTER INDEX statement. The basic syntax for ALTER INDEX is as follows:

```
ALTER INDEX {index_name | ALL}
    ON [{database_name}.[schema_name]. | schema_name.}
        {table_or_view_name}
    { REBUILD [WITH(<rebuild_index_option>[,...n])]
    | REORGANIZE [ WITH( LOB_COMPACTION = {ON | OFF})]
    | DISABLE
    | SET (<set_index_option>[,...n]) }
```

Let's look at a few examples that demonstrate the power of the ALTER INDEX statement. The first example simply rebuilds the primary key index on the Production.Product table:

```
ALTER INDEX [PK_Product_ProductID] ON [Production].[Product] REBUILD
```

This offline operation is equivalent to the DBCC DBREINDEX command. The specified index is dropped and re-created, removing all fragmentation from the index pages. This is done dynamically, without the need to drop and re-create constraints that reference any of the affected indexes. If it is run on a clustered index, the data pages of the table are defragmented as well. If you specify the ALL option for the ALTER INDEX command, all indexes as well as the data pages of the table (if the table has a clustered index) are defragmented.

NOTE

If the REBUILD option is run on a heap table (that is, a table with no clustered index), the rebuild operation does not affect the underlying table. Only the specified nonclustered indexes are rebuilt.

For added flexibility, you can also specify index options as part of the REBUILD operation. The options available with the REBUILD command are the same options available when you are creating indexes. The only exception is that the DROP EXISTING option is not available with the REBUILD operation. (Table 25.2, earlier in this chapter, provides detailed descriptions of the options.) The following example rebuilds the clustered index on the Production.Product table and specifies several of the available REBUILD options:

```
ALTER INDEX [PK_Product_ProductID]
ON [
Production].[Product] REBUILD WITH ( PAD_INDEX = OFF,
STATISTICS_NORECOMPUTE = OFF,
ALLOW_ROW_LOCKS = ON,
ALLOW_PAGE_LOCKS = ON, ONLINE = OFF, SORT_IN_TEMPDB = OFF,
DATA_COMPRESSION = NONE )
```

An alternative to the REBUILD operation is the REORGANIZE operation. The REORGANIZE operation is equivalent to the DBCC INDEX DEFRAG command. During the REORGANIZE operation, the leaf-level pages of the index are physically reordered to match the logical order of the index keys. The indexes are not dropped. The REORGANIZE operation is always an online operation and does not require long-term table locks to complete.

TIP

The REORGANIZE operation can generate a large number of transactions during its execution. You need to be sure to carefully evaluate the amount of space available in the transaction log and monitor the free space during this operation. If the transaction log is set to AUTOGROW, you need to make sure you have adequate free space on the drive where your transaction log lives. This is especially true for very large tables. Several options are available for mitigating the growth of the log during these operations, such as setting the recovery model on the database to BULK-LOGGED.

The REORGANIZE operation has just one option: LOB_COMPACTION. When the LOB_COMPACTION option is set to ON, the data for columns with large object (LOB) data types is compacted. This consolidates the data and frees disk space. LOB data types include image, text, ntext, varchar(max), nvarchar(max), varbinary(max), and xml. The following example performs a REORGANIZE operation on the clustered index of the Production.Product table with the LOB_COMPACTION option set to OFF:

```
ALTER INDEX [PK_Product_ProductID] ON [Production].[Product]
```

```
REORGANIZE WITH ( LOB_COMPACTION = ON )
```

Disabling an index is another capability introduced with SQL Server 2005 that can be accomplished with the `ALTER INDEX` statement. When the `DISABLE` option is used on an index, the index is no longer available for retrieving data from a table. If a clustered index is disabled, the entire table is made unavailable. The data remains in the table, but no Data Manipulation Language (DML) operations can be performed on the table until the index is dropped or rebuilt. Unlike dropping an index, when an index is disabled, SQL Server retains the index definition in metadata so it can easily be re-enabled; index statistics are still maintained for nonclustered indexes that have been disabled.

After an index is disabled, you can re-enable it only by re-creating the index. You can accomplish this using the `ALTER INDEX REBUILD` command or `CREATE INDEX WITH DROP_EXISTING` command.

Disabling indexes can be particularly useful for testing purposes. Let's say you have a nonclustered index on a table that you believe is used very little. You can disable the index initially before removing it to evaluate the change. The definition of the index is still contained in the database. If you ultimately determine that the index is still needed, you can rebuild the index to make it available again.

TIP

Another reason for disabling a nonclustered index is to reduce the space requirements when rebuilding the index. If an index to be rebuilt is not disabled, SQL Server requires enough temporary disk space in the database to store both the old and new versions of the index. However, if the index is disabled first, SQL Server can reuse the space required for the disabled index to rebuild it. No additional disk space is necessary except for temporary space required for sorting, which is only about 20% of the index size.

The following example disables a nonclustered index on the `Production.Product` table:

```
ALTER INDEX [AK_Product_Name] ON [Production].[Product] DISABLE
```

One point to keep in mind when an index is disabled is that it is not readily apparent in SSMS that the index has been disabled. The index still appears in the Object Explorer tree under the `Indexes` node, and there are no indicators on the index display to alert you to the fact that it has been disabled. You can, however, use other methods to determine if the index has been disabled. The `sys.indexes` catalog view is one of these methods. Refer to the `is_disabled` column returned with this view. A value of 1 in the `is_disabled` column indicates that it has been disabled, and a value of 0 indicates that it is enabled. The following `SELECT` statement shows an example of how to use the `sys.indexes` catalog view:

```
select is_disabled,* from sys.indexes
where object_name(object_id) = 'Product'
```

You can also easily change options on an index with the `ALTER INDEX` statement. The following example sets several of the available options for a nonclustered index on the authors table:

```
ALTER INDEX [AK_Product_ProductNumber] ON [Production].[Product]
SET (
    ALLOW_PAGE_LOCKS = ON,
    ALLOW_ROW_LOCKS = OFF,
    IGNORE_DUP_KEY = ON,
    STATISTICS_NORECOMPUTE = ON
)
```

Other options exist for managing indexes with T-SQL, but the `ALTER INDEX` statement provides the bulk of what you need. Many of the other T-SQL options that you may have used for managing indexes in SQL Server 2000 and earlier, such as `DBCC DBREINDEX`, are still available in SQL Server 2008 for backward compatibility.

For more information and guidelines on managing indexes for performance, such as why and when to rebuild an index, see Chapter 34.

Managing Indexes with SSMS

Several tools are available in SSMS for managing indexes. You can use tools such as the Database Engine Tuning Advisor, database diagrams, and the Table Designer to view indexes and make modifications. These tools have many features that are geared toward specific tasks, but again, in most cases the Object Explorer provides the simplest means for managing indexes.

Figure 25.6 shows the index options available by right-clicking an index in the Object Explorer. Many of these options are geared toward index management, including the options Rebuild, Reorganize, and Disable.

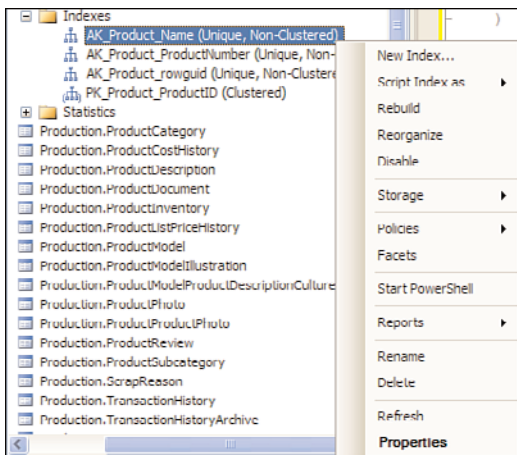

FIGURE 25.6 Using Object Explorer to manage indexes.

Similar options are also available from the Indexes node of the Object Explorer that enable you to rebuild, reorganize, or disable all the indexes for the table.

TIP

You can right-click an index in the Object Explorer and choose Properties to display the index columns and other relevant information. This option was not available with the SQL Server 2000 Object Explorer. You can also run the `SP_HELPINDEX` command on any table in a database to list all the indexes on the table and their related columns. This command must be run in a database engine query window. For example, `sp_helpindex [Production.Product]` returns all the indexes for the Product table in the AdventureWorks database. Make sure to enclose the table name with brackets when including the schema name.

Dropping Indexes

You can drop indexes by using T-SQL or via tools in the SSMS. To drop indexes with T-SQL, you use the `DROP INDEX` command, a simple example of which follows:

```
DROP INDEX [IX_WorkOrder_ScrapReasonID] ON [Production].[WorkOrder]
```

This command drops the index named `IX_WorkOrder_ScrapReasonID` on the `Production.WorkOrder` table.

Using the Object Explorer in SSMS is the simplest alternative for dropping indexes. In the Object Explorer, you simply right-click the index you want to drop and then select Delete. The same execution options available for adding and modifying indexes are also available after you select Delete. This includes the option to script the T-SQL statements like that shown in the preceding `DROP INDEX` example.

NOTE

If you drop a clustered index on a table, SQL Server needs to rebuild all the remaining nonclustered indexes on the table. The reason is that when a clustered index exists on a table, the nonclustered indexes include the clustered index key in the nonclustered index rows as a pointer to the corresponding data rows. When the clustered index is dropped, the clustered index key needs to be replaced with page and row pointers. If a large number of nonclustered indexes exist on the table, the operation to rebuild the nonclustered indexes can be very time consuming and I/O intensive. For more information on the internal structures of clustered and nonclustered indexes, see Chapter 34.

Online Indexing Operations

One of the great features available with SQL Server 2008 is online indexing. This feature, available only with the Enterprise or Developer Edition, allows you to create, rebuild, or drop indexes without having exclusive access to the index or table. This means that users

can have concurrent access to the underlying tables and indexes while the index operation is in progress. This bodes well for high-availability applications and databases that have limited downtime available for offline operations.

Following is an example of the T-SQL syntax for an online index operation:

```
ALTER INDEX [PK_Product_ProductID] ON [Production].[Product]
REBUILD WITH ( ONLINE = ON)
```

The `ONLINE = ON` parameter is the key to making the index operation an online operation.

To accomplish online indexing, SQL Server must maintain the old and new versions of the affected indexes during the operation. The old version (referred to as the *source*) includes any table or indexes that are affected by the index operation. For example, if a clustered index is part of the online operation, the clustered index and all the nonclustered indexes that reference the clustered index are maintained as part of the source. The new version (referred to as the *target*) is the new index or indexes that are being created or rebuilt. In the case of a table without a clustered index, a structure known as a heap is used as the source and target.

During online index operations, the following three phases occur:

- ▶ **Preparation**—Concurrent activity is temporarily suspended while a snapshot of the source index structure is taken and written as an empty structure to the target.
- ▶ **Building**—The source index structures are scanned, sorted, merged, and inserted into the target. User `SELECT` statements are satisfied via the source. Insertions, updates, and deletions to the affected table are written to both the source and target.
- ▶ **Final**—Concurrent activity is temporarily suspended while the source is replaced by the newly created structures (target).

When the final phase is complete, all the query and update plans that were using the old structures are invalidated. Future queries utilize the newly created index structures after this point.

When considering online indexing, you need to account for the following:

- ▶ **Disk space**—Generally, the disk space requirements for online operations are the same as those for offline operations. The exception to this is online index operations on clustered indexes. These operations use a temporary mapping index that requires additional disk space. The temporary mapping index contains one row for each record in the table.
- ▶ **Performance**—Online index operations are generally slower and take more system resources than offline operations. Primarily, the reason is that the old and new index structures are maintained during the index operation. Heavy updates to the tables involved in the index operation can cause an overall decrease in performance and a spike in CPU utilization and I/O as the two index structures are maintained.
- ▶ **Transaction log**—Online index operations are fully logged. You may therefore encounter a heavy burden on your transaction log during online index operations

for large tables. This can cause your transaction log to fill quickly. The transaction log can be backed up, but it cannot be truncated during online index operations. You need to make sure you have enough space for your log to grow; otherwise, the online index operation could fail.

Indexes on Views

SQL Server 2008 supports the creation of indexes on views. Like indexes on tables, indexes on views can dramatically improve the performance of the queries that reference the views. By nature, a view is a virtual table and does not have a separate data structure as does a table, even though it can be referenced like a table. After an index is created on a view, the result set of the view is stored in the database, just as it would be for a table. The indexed view is no longer virtual because it requires maintenance as rows are added to, deleted from, or modified in the tables referenced by the view. Refer to Chapter 27, “Creating and Managing Views in SQL Server,” for a more detailed discussion of views.

The first index created on a view must be a unique clustered index. After that is created, other nonclustered indexes can be built on the view for additional performance gains.

The most difficult part of the index creation process is identifying a view that is valid for index creation. Many requirements must be met for a view to qualify. Refer to the SQL Server Books Online documentation for a complete list of all the restrictions. The following is a partial list of the most common requirements:

- ▶ All the tables in the view must be in the same database as the view and have the same owner as the view.
- ▶ The view must not reference any other views.
- ▶ The view must be created with `SCHEMABINDING`, and any function referenced in the view must also be created with `SCHEMABINDING`.
- ▶ A two-part name with the schema prefix must be used for every table or user-defined function referenced in the view.
- ▶ Many `SET` options, including `ANSI_NULLS`, `ANSI_PADDING`, `ANSI_WARNINGS`, `CONCAT_NULL_YIELDS_NULL`, and `QUOTED_IDENTIFIER` must be set to `ON`.
- ▶ Any functions referenced in the view must be deterministic. (See Chapter 29, “Creating and Managing User-Defined Functions,” for more information on deterministic functions.)
- ▶ Views with aggregate functions must also include `COUNT_BIG(*)`.

The following example shows the creation of a view that can have an index created on it:

```
CREATE VIEW titleview
WITH SCHEMABINDING AS
    select title, au_ord, au_lname, price, ytd_sales, pub_id
    from dbo.authors, dbo.titles, dbo.titleauthor
```

```
where authors.au_id = titleauthor.au_id
AND titles.title_id = titleauthor.title_id
```

The SCHEMABINDING clause and database schema qualifier (dbo) for each table are necessary in the view definition to be able to make the view valid for index creation. The following example creates an index on the titleview view:

```
CREATE UNIQUE CLUSTERED INDEX [AK_vw_Employee] ON [dbo].[vw_Employee]
( [JobTitle] ASC, [LoginID] ASC)
```

After the index is created, you can manage it in much the same way that you manage the indexes on tables. You can use both T-SQL and SSMS to manage these indexes.

For more information and guidelines on creating and using indexed views, see Chapter 27.

Summary

Index creation is an important part of managing a database. Creating useful indexes can vastly improve query performance and should not be overlooked. Fortunately, SQL Server 2008 makes the creation and management of indexes quite easy.

In Chapter 26, “Implementing Data Integrity,” you see how you can use indexes and other methods to enforce data integrity. Subsequent chapters cover the internal working of indexes and give you more insight into their role in performance.

CHAPTER 26

Implementing Data Integrity

The value of your data is determined by its integrity. You may have heard the phrase “garbage in, garbage out.” In the database world, “garbage in” refers to data that has been loaded into a database without validation or without data integrity. This “garbage” data can then be retrieved (“garbage out”), and erroneous decisions can result because of it.

Implementing good data integrity measures is your best defense against the “garbage in, garbage out” scenario. This involves identifying valid values for tables and columns and deciding how to enforce the integrity of those values. This chapter covers the different types of data integrity and the methods for enforcing them.

What’s New in Data Integrity

Much of the functionality related to data integrity has remained the same in SQL Server 2008. Several features that were added in SQL Server 2005, such as cascading integrity constraints, are still supported in SQL Server 2008. The lack of change in this area is generally a blessing. The tools available to enforce data integrity were comprehensive in 2005 and remain so in 2008.

Keep in mind that bound defaults, which were deprecated in SQL Server 2005, are still available in SQL Server 2008. For now, you can still use this statement to create a default that is bound to one or more columns. Microsoft recommends using the `DEFAULT` keyword with `ALTER TABLE` or `CREATE TABLE` instead.

IN THIS CHAPTER

- ▶ What’s New in Data Integrity
- ▶ Types of Data Integrity
- ▶ Enforcing Data Integrity
- ▶ Using Constraints
- ▶ Rules
- ▶ Defaults

Types of Data Integrity

How integrity is enforced depends on the type of integrity being enforced. As described in the following sections, the types of data integrity are domain, entity, and referential integrity.

Domain Integrity

Domain integrity controls the validation of values for a column. You can use domain integrity to enforce the type, format, and possible values of data stored in a column. SQL Server provides several mechanisms to enforce domain integrity:

- ▶ You can control the type of data stored in a column by assigning a data type to the column.
- ▶ You can use CHECK constraints and rules to control the format of the data.
- ▶ You can control the range of values stored in a column by using FOREIGN KEY constraints, CHECK constraints, default definitions, nullability, and rules.

Entity Integrity

Entity integrity requires that all rows in a table be unique. You can enforce entity integrity in SQL Server by using PRIMARY KEY constraints, UNIQUE constraints, and IDENTITY properties.

Referential Integrity

Referential integrity preserves the defined relationships between tables. You can define such a relationship in SQL Server by relating foreign key columns on one table to the primary key or unique key of another table. When it is defined, referential integrity ensures that values inserted in the foreign key columns have corresponding values in the primary table. It also controls changes to the primary key table and ensures that related foreign key rows are not left orphaned.

Enforcing Data Integrity

You can enforce data integrity by using declarative or procedural methods. Implementing declarative data integrity requires little or no coding. Implementing procedural data integrity is more flexible but requires more custom coding.

Implementing Declarative Data Integrity

Declarative integrity is enforced within the database, using constraints, rules, and defaults. This is the preferred method of enforcing integrity because it has low overhead and requires little or no custom programming. It can be centrally managed in the database, and it provides a consistent approach for ensuring the integrity of data.

Implementing Procedural Data Integrity

Procedural integrity can be implemented with stored procedures, triggers, and application code. It requires custom programming that defines and enforces the integrity of the data. The biggest benefits of implementing procedural data integrity are flexibility and control. You can implement the custom code in many different ways to enforce the integrity of your data. The custom code can also be a detriment; the lack of consistency and potential inefficiencies in the way the data integrity is performed can be a real problem.

In general, declarative data integrity should be used as the primary means for control. Procedural data integrity can be used to augment declarative data integrity, if needed.

Using Constraints

Constraints—including PRIMARY KEY, FOREIGN KEY, UNIQUE, CHECK, and DEFAULT—are the primary method used to enforce data integrity. You can implement defaults as constraints or as objects in a database; for more information, see the “Defaults” section, later in this chapter.

The PRIMARY KEY Constraint

The PRIMARY KEY constraint is one of the key methods for ensuring entity integrity. When this constraint is defined on a table, it ensures that every row can be uniquely identified with the primary key value(s). The primary key can have one or more columns as part of its definition. None of the columns in the primary key definition can allow nulls. When multiple columns are used in the definition of the primary key, the combination of the values in all the primary key columns must be unique. Duplication can exist in a single column that is part of a multicolumn primary key.

There can be only one primary key defined for each table. When a primary key is defined on a table, a unique index is automatically created as well. This index contains all the columns in the primary key and ensures that the rows in this index are unique. Generally, every table in a database should have a primary key. The primary key and its associated unique index provide fast access to a database table.

Figure 26.1 shows the Adventureworks2008 database Employee table, which is an example of a table that has a primary key defined. The primary key in this table is EmployeeID, and it is denoted in the dialog shown in Figure 26.1 with a key symbol in the leftmost column.

The existing primary key on the Employee table in the Adventureworks2008 database was generated as a T-SQL script, as shown in the following example:

```
ALTER TABLE [HumanResources].[Employee]
    ADD CONSTRAINT [PK_Employee_BusinessEntityID] PRIMARY KEY CLUSTERED
    (BusinessEntityID ASC)
```

In general, you try to choose a primary key that is relatively short. BusinessEntityID, for example, is a good choice because it is an integer column and takes only 4 bytes of

XPVIRTUAL1.A...rces.Employee			
	Column Name	Data Type	Allow Nulls
🔑	EmployeeID	int	<input type="checkbox"/>
	NationalIDNumber	nvarchar(15)	<input type="checkbox"/>
	ContactID	int	<input type="checkbox"/>
	LoginID	nvarchar(256)	<input type="checkbox"/>
	ManagerID	int	<input checked="" type="checkbox"/>
	Title	nvarchar(50)	<input type="checkbox"/>
	BirthDate	datetime	<input type="checkbox"/>

	ModifiedDate	datetime	<input type="checkbox"/>
▶			<input type="checkbox"/>

FIGURE 26.1 A primary key example.

storage. This is particularly important when the primary key is **CLUSTERED**, as in the case of `PK_Employee_BusinessEntityID`. The key values from the clustered index are used by all nonclustered indexes as lookup keys. If the clustered key is large, this consumes more space and affects performance.

Surrogate keys are often good choices for primary keys. The `BusinessEntityID` column in the `Person.BusinessEntity` table is an example of a surrogate key. Surrogate keys consist of a single column that automatically increments and is inherently unique, as in the case of an identity column. Surrogate keys are good candidates for primary keys because they are implicitly unique and relatively short in length. You should avoid using large, multi-column indexes as primary keys. They can impede performance because fewer index rows can be stored on each index page. The performance implications related to primary key indexes and other indexes are discussed in more detail in Chapter 34, “Data Structures, Indexes, and Performance.”

NOTE

Over the years, there has been much debate over the use of surrogate keys for primary keys. One school of thought is to avoid surrogate keys because insertions always occur at the end of the primary key index and are not distributed. This can lead to “hot spots” in the index because the insert activity is always on the last page of the index. In addition, surrogate keys have no real meaning and are less intuitive than primary keys that have meaning, such as `lastname` and `firstname`.

The other school of thought, in favor of using surrogate keys for primary keys, emphasizes the importance of defining primary keys that are not based on meaningful columns. If meaningful columns are used and the definitions of those columns change, this can have a significant impact on the table that contains the primary key and any tables related to it. Those in favor of using surrogate keys as primary keys also focus on the relatively small key size, which is good for performance and reduces pages splits because the values are always inserted into the index sequentially.

The UNIQUE Constraint

The UNIQUE constraint is functionally similar to PRIMARY KEY. It also uses a unique index to enforce uniqueness, but unlike PRIMARY KEY, it allows nulls in the columns that participate in the UNIQUE constraint. The definition of a UNIQUE constraint with columns that are nulls is generally impractical. The value of NULL is considered a unique value, so you are limited to the number of rows that can be inserted with NULL values. For example, only one row with a NULL value in the constraint column can be inserted if the UNIQUE constraint is based on a single column. UNIQUE constraints with multiple nullable columns can have more than one row with null values in the constraint keys, but the number of rows is limited to the combination of unique values across all the columns.

An alternate unique key on the SalesTaxRate table is a good example of a unique constraint in the AdventureWorks2008 database. The AK_SalesTaxRate_StateProvinceID_TaxType index contain the StateProvinceId and TaxType columns. Each of these columns is defined as NOT NULL. In simple terms this means that TaxTypes must be unique within each state or province. If, however, the StateProvinceId was nullable then you could have one row for a given TaxType that is null then all other rows for that tax type must have the StateProvinceId to make the combination of StateProvinceId and Tax Type unique.

You generally use a UNIQUE constraint when a column other than the primary key must be guaranteed to be unique. For example, consider the Employee table example used in the previous section. The primary key on the identity column EmployeeID ensures that a unique value will be assigned to each employee row, but it does not prevent duplication in any of the other columns. For example, every row in the Employee table could have the same LoginID setting if no other UNIQUE constraints were found on this table. Generally, each employee should have his or her own unique LoginID. You can enforce this policy by adding a UNIQUE constraint on the LoginID column. The following example demonstrates the creation of a UNIQUE constraint on the EmployeeID column:

```
ALTER TABLE [HumanResources].[Employee]
  ADD CONSTRAINT AK_Employee_LoginID
  UNIQUE NONCLUSTERED (LoginID ASC)
```

As with PRIMARY KEY constraints, a unique index is created whenever a UNIQUE constraint is created. If you drop the UNIQUE constraint, you drop the unique index as well.

Conversely, if you drop the unique index, you indirectly drop the `UNIQUE` constraint, too. You can implement a `UNIQUE` constraint as a constraint or an index. To illustrate this, the following example shows the creation of the same `UNIQUE` constraint on `Employee_LoginID` as before, this time using an index:

```
CREATE UNIQUE NONCLUSTERED INDEX [AK_Employee_LoginID]
ON [HumanResources].[Employee]
(LoginID ASC)
```

NOTE

Although `UNIQUE` constraints and unique indexes achieve the same goal, they must be managed based on how they were created. In other words, if you create a `UNIQUE` constraint on a table, you cannot directly drop the associated unique index. If you try to drop the unique index directly, you get a message stating that an explicit `DROP INDEX` is not allowed and that it is being used for unique key constraint enforcement. To drop the `UNIQUE` constraint, you must use the `DROP CONSTRAINT` syntax associated with the `ALTER TABLE` statement. Similarly, if you create a unique index, you cannot drop that index by using a `DROP CONSTRAINT` statement; you must use `DROP INDEX` instead.

You can have more than one unique constraint per table. When creating unique constraints, you have all the standard index-creation options available. These options include how the underlying index is clustered, the fill factor, and a myriad of other index options.

The FOREIGN KEY Referential Integrity Constraint

The basic premise of a relational database is that tables are related. These relationships are maintained and enforced via referential integrity. `FOREIGN KEY` constraints are the declarative means for enforcing referential integrity in SQL Server. You implement `FOREIGN KEY` constraints by relating one or more columns in a table to the columns in a primary key or unique index. The columns in the referencing table can be referred to as *foreign key columns*. The table with the primary key or unique index can be referred to as the *primary table*. Figure 26.2 shows a relationship between the `BusinessEntityAddress` table and `BusinessEntityAddress` table. The foreign key in this example is `AddressTypeID` on the `BusinessEntityAddress` table. `AddressTypeID` on this table is related to the primary key on the `AddressTypeID` table. The foreign key relationship in this diagram is denoted by the line between these two tables.

FIGURE 26.2 A foreign key constraint on the **BusinessEntityAddress** table.

Once defined, a foreign key, by default, enforces the relationship between the tables in the following ways:

- ▶ Values in the foreign key columns must have a corresponding value in the primary table. If the new values in the foreign key columns do not exist in the primary table, the insert or update operation fails.
- ▶ Values in the primary key or unique index that are referenced by the foreign key table cannot be deleted. If an attempt is made to delete a referenced value in the primary table, the delete fails.
- ▶ Values in the primary key or unique index that are referenced by the foreign key table cannot be modified. If an attempt is made to change a referenced value in the primary table, the update fails.

In the case of the **AddressType/BusinessEntityAddress** relationship shown in Figure 26.2, any **AddressTypeID** used in the **BusinessEntityAddress** table must have a corresponding value in the **AddressType** table. Listing 26.1 shows an **INSERT** statement in the **BusinessEntityAddress** table that does not have a valid **AddressTypeID** entry in the **AddressType** table. The statement fails, and the resulting message is shown after the **INSERT** statement. A similar error message is displayed if an attempt is made to delete or update values in the primary key or unique index that does not satisfy the foreign key constraint.

LISTING 26.1 A Foreign Key Conflict with **INSERT**

```
INSERT Person.BusinessEntityAddress
  (BusinessEntityID,AddressID, AddressTypeID, rowguid, ModifiedDate)
VALUES (1,249, 9, NEWID(), GETDATE())
/* RESULTS OF INSERT FOLLOW
Msg 547, Level 16, State 0, Line 1
The INSERT statement conflicted with the FOREIGN KEY
constraint "FK_BusinessEntityAddress_AddressType_AddressTypeID".
The conflict occurred in database "AdventureWorks2008",
table "Person.AddressType", column 'AddressTypeID'.
The statement has been terminated.*/
```

The following example shows the T-SQL needed to create the foreign key relationship between the `AddressType` and `BusinessEntityAddress` tables:

```
ALTER TABLE [Person].[BusinessEntityAddress]
ADD CONSTRAINT [FK_BusinessEntityAddress_AddressType_AddressTypeID]
    FOREIGN KEY([AddressTypeID])
REFERENCES [Person].[AddressType]
    ([AddressTypeID])
```

When you create a `FOREIGN KEY` constraint, the related primary key or unique index must exist first. In the case of the `AddressType/BusinessEntityAddress` relationship, the `AddressType` table and primary key on `AddressTypeID` must exist before you can create the `FK_BusinessEntityAddress_AddressType_AddressTypeID` foreign key. In addition, the data types of the related columns must be the same. The related columns in the two tables can actually have different names, but in practice the columns are usually named the same. Naming the columns the same makes your database much more intuitive.

NOTE

In addition to relating two different tables with a foreign key, you can also relate a table to itself. These self-referencing relationships are often found in organization tables or employee tables. For example, you could have an `Employee` table with a primary key of `EmployeeID`. This table could also have a `ManagerID` column. In this case, `ManagerID` on the `Employee` table has a relationship to the primary key index on `EmployeeID`. The manager is an employee, so it makes sense that they should have a valid `EmployeeID`. A foreign key on the `Employee` table will enforce this relationship and ensure that any `ManagerID` points to a different row in the table with a valid `EmployeeID`.

Cascading Referential Integrity

Cascading referential integrity has been around for some time and was introduced with SQL Server 2000. This type of integrity allows for updates and deletions on the primary table to be cascaded to the referencing foreign key tables. By default, a `FOREIGN KEY` constraint prevents updates and deletions to any primary key or unique index values referenced by a foreign key. With cascading referential integrity, you can bypass this restriction and are able to define the type of action you want to occur when the updates and deletions happen.

You define the cascading actions on the `FOREIGN KEY` constraint, using the `ON DELETE` and `ON UPDATE` clauses. The `ON DELETE` clause defines the cascading action for deletions to the primary table, and the `ON UPDATE` clause defines the actions for updates. These clauses are used with the `CREATE TABLE` or `ALTER TABLE` statements and are part of the `REFERENCES` clause of these statements.

You can specify the same cascading actions for updates and deletions:

- ▶ **NO ACTION**—This action, the default, causes deletions and updates to the primary table to fail if the rows are referenced by a foreign key.

- ▶ **CASCADE**—This option causes updates and deletions to cascade to any foreign key records that refer to the affected rows in the primary table. If the **CASCADE** option is used with the **ON DELETE** clause, any records in the foreign key table that refer to the deleted rows in the primary table are also deleted. When **CASCADE** is used with the **ON UPDATE** clause, any updates to the primary table records are also made in the related rows of the foreign key table.
- ▶ **SET NULL**—This option was new in SQL Server 2005. It is similar to the **CASCADE** option except that the affected rows in the foreign key table are set to **NULL** when deletions or updates are performed on the related primary table. The value of **NULL** is assigned to every column that is defined as part of the foreign key and requires that each column in the foreign key allow null values.
- ▶ **SET DEFAULT**—This option also was new in SQL Server 2005. It is similar to the **CASCADE** option except that the affected rows in the foreign key table are set to the default values defined on the columns when deletions or updates are performed on the related primary table. If you want to set this option, each column in the foreign key must have a default definition assigned to it, or it must be defined as nullable. If no default definition is assigned to the column, **NULL** is used as the default value. It is imperative that the primary table have related records for the default or null entries that can result from the cascading action. For example, if you have a two-column foreign key, and each column has a default of 1, a corresponding record with the key values of 1 and 1 needs to exist in the primary table, or the cascade action fails. The integrity of the relationship must be maintained.

To illustrate the power of cascading actions, consider the `AddressType/BusinessEntityAddress` relationship used in previous examples. Let's say you want to remove the associated `BusinessEntityAddress` records when an `AddressType` record is deleted. The addition of the **ON DELETE CASCADE** clause at the bottom of the following foreign key definition achieves this result:

```
ALTER TABLE [Person].[BusinessEntityAddress]
ADD CONSTRAINT [FK_BusinessEntityAddress_AddressType_AddressTypeID]
    FOREIGN KEY([AddressTypeID])
REFERENCES [Person].[AddressType]
([AddressTypeID])
ON DELETE CASCADE
```

Keep in mind that other factors affect the successful execution of a cascading deletion. If other foreign keys exist on the table, and they do not have **ON DELETE CASCADE** specified, the cascading actions do not succeed if a foreign key violation occurs on these tables. In addition, you need to consider the existence of triggers that may prevent deletions from occurring. Also, you need to consider that a series of cascading actions can be initiated by a single **DELETE** statement. This happens when you have many related tables, each of which has cascading actions defined. This approach works fine as long as there are no circular references that cause one of the tables in the cascading tree to be affected by a table lower in the tree.

If you want to specify the cascading action for updates, you can add an additional `ON UPDATE` clause, along with the `ON DELETE` clause. For example, you can change the foreign key in the previous example so that `BusinessEntityAddress` records are set to `NULL` when an update is made to the related key on the primary table. This can be accomplished with the following foreign key definition:

```
ALTER TABLE [Person].[BusinessEntityAddress]
ADD CONSTRAINT [FK_BusinessEntityAddress_AddressType_AddressTypeID]
    FOREIGN KEY([AddressTypeID])
REFERENCES [Person].[AddressType]
    ([AddressTypeID])
ON DELETE CASCADE
ON UPDATE SET NULL
```

You can see that cascading referential integrity is a powerful tool. However, it must be used with caution. Consider the fact that foreign keys without cascading actions may prevent erroneous actions. For example, if a `DELETE` statement is mistakenly executed against the entire `AddressType` table, the deletion would fail before the records could be deleted because foreign key tables are referencing the `AddressType` table. This failure would be a good thing. If, however, the `ON DELETE CASCADE` clause were used in the foreign key definitions, the erroneous deletion would succeed, and all the foreign key records would be deleted as well.

The CHECK Constraint

You can use the `CHECK` constraint to enforce domain integrity and to provide a means for restricting the values that can be entered in a column. A `CHECK` constraint is implemented as a Boolean expression, and it must not be `FALSE` if the insertion or update is to proceed. The Boolean expression can reference other columns in the same table, but it cannot reference other tables. Foreign keys and triggers can be used to reference columns in other tables, if needed. The expression can also include functions that do not return results. A `CHECK` constraint that is defined on a specific column can reference only the values in the column.

`CHECK` constraints are good for ensuring the format of data inserted in a column and for defining a list of acceptable values. Columns with phone numbers or Social Security numbers are good candidates for `CHECK` constraints that enforce formatting restrictions. Columns that have the data types `money` or `integer` can use `CHECK` constraints to ensure that the values are always greater than or equal to zero. A column that has a small fixed number of valid values is also a good candidate for a `CHECK` constraint. A fixed number of values can be defined in the `CHECK` constraint, and no additional table lookup or coding is necessary to ensure that the valid values are inserted. The following example shows a `CHECK` constraint on the `Employee` table that checks the values for the `Gender` column:

```
ALTER TABLE [HumanResources].[Employee] WITH CHECK
ADD CONSTRAINT [CK_Employee_Gender]
CHECK ((upper([Gender])='F' OR upper([Gender])='M'))
```

The CHECK constraint in this example ensures that only F or M is inserted in this column. These types of CHECK constraints are relatively fast and are preferred over FOREIGN KEY constraints when the values are fixed.

NOTE

Be careful with CHECK constraint expressions that can evaluate to NULL. CHECK constraints allow insertions and updates to the table to proceed when the CHECK constraint expression does not evaluate to FALSE. A NULL value is considered to be unknown and does not evaluate to FALSE, so the insertion or update succeeds. For example, if you have a nullable column that has a constraint specifying that the value must be greater than or equal to zero, this constraint does not prevent a NULL value from being inserted into the column.

Keep in mind that the creation of a CHECK constraint on a table that already has data in it may fail. This is due to a validation performed when the constraint is created. If existing data violates the constraint, the constraint is not created. The only exception is to create the constraint by using the NOCHECK option. When this option is used, the existing data is not checked, but any future updates or insertions are. The following example shows the creation of a CHECK constraint on the Employee table:

```
ALTER TABLE [HumanResources].[Employee] WITH NOCHECK
ADD CONSTRAINT [CK_Employee_Gender_F]
CHECK ((upper([Gender])='F'))
```

The constraint is on the Gender column that already has a check constraint on it, which ensures that the data values are only F or M. The new constraint on the Gender column specifies that the value must be F. The existing data has values of F and M, but the NOCHECK option allows you to add the constraint anyway.

Any new rows added to the Employee table after the new CK_Employee_Gender_F CHECK constraint has been added are then checked. With multiple CHECK constraints defined on a column, the constraints are evaluated in the order in which they were added to the table. In the preceding example, the CK_Employee_Gender constraint is evaluated first, and then the new CK_Employee_Gender_F constraint is evaluated. If a Gender value of F is entered, both constraints evaluate to TRUE, and the change is accepted. If a value of M is inserted in the Gender column, the CK_Employee_Gender constraint succeeds, but the CK_Employee_Gender_F constraint fails, and the change is rejected.

Creating Constraints

You can define constraints on a single column or on multiple columns. Single-column constraints are referred to as *column-level* constraints. You can define this type of constraint when you create the column on the table. Constraints that reference multiple columns must be defined on the table and are considered *table-level* constraints. Table-level constraints must be defined after all the referenced columns in the table are created.

Using T-SQL to Create Constraints

You can create constraints with T-SQL by using the `CREATE TABLE` or `ALTER TABLE` statement. When you create a column-level constraint by using the `CREATE TABLE` statement, the `CONSTRAINT` keyword and constraint definition are included immediately after the column definition. Table-level constraints defined with the `CREATE TABLE` statement are specified after the column list in the table definition.

The `Customer` table in the `Adventureworks2008` database is a good example of a table that has several different types of constraints. Listing 26.2 shows the `CREATE TABLE` command, along with the constraint definitions for a table named `Customer2` that is modeled after the `Customer` table. All the constraints in this example have been included in the `CREATE TABLE` statement. The constraints on this table include `PRIMARY KEY`, `FOREIGN KEY`, and `CHECK` constraints. You can find all the constraints in the `CREATE TABLE` statement by looking for the `CONSTRAINT` keyword.

LISTING 26.2 Creating Constraints by Using a **CREATE TABLE** Statement

```
CREATE TABLE [Sales].[Customer2](
  [CustomerID] [int] IDENTITY(1,1) NOT FOR REPLICATION NOT NULL,
  [TerritoryID] [int] NULL,
  [AccountNumber] AS
    (isnull('AW'+[dbo].[ufnLeadingZeros]([CustomerID]),'')),
  [CustomerType] [nvarchar](1) NOT NULL
    CONSTRAINT CK_Customer_CustomerType2 CHECK
      ((upper([CustomerType])='I' OR upper([CustomerType])='S')),
  [rowguid] [uniqueidentifier] ROWGUIDCOL NOT NULL
    CONSTRAINT [DF_Customer_rowguid2] DEFAULT (newid()),
  [ModifiedDate] [datetime] NOT NULL
    CONSTRAINT [DF_Customer_ModifiedDate2] DEFAULT (getdate()),
  CONSTRAINT [PK_Customer_CustomerID2] PRIMARY KEY CLUSTERED
    ([CustomerID] ASC),
  CONSTRAINT FK_Customer_SalesTerritory_TerritoryID2 FOREIGN KEY
    ([TerritoryID])
    REFERENCES [Sales].[SalesTerritory] ([TerritoryID])
)
GO
```

Generally, it is easier to manage constraints by using the `ALTER TABLE` statement than by integrating them into the `CREATE TABLE` statement. One of the biggest reasons is that the scripting capability in SQL Server Management Studio (SSMS) generates `ALTER TABLE` statements for many of the constraints. You can easily script a table and its constraints by using SSMS, and you will find that SSMS uses the `ALTER TABLE` statement extensively. Listing 26.3 includes a statement to remove the `Customer2` table and a subsequent set of statements that re-creates the `Customer2` table and utilizes the `ALTER TABLE` statement to create several of the constraints. The statements to re-create the `Customer2` table were

generated using the Object Explorer in SSMS. Some of the constraints are created within the initial CREATE TABLE statement, and some are created with the ALTER TABLE statement.

LISTING 26.3 Creating Constraints by Using ALTER TABLE

```

IF EXISTS (SELECT * FROM dbo.sysobjects WHERE id
    = OBJECT_ID(N'[Sales].[Customer2]') AND OBJECTPROPERTY(id, N'IsUserTable') = 1)
    DROP TABLE [Sales].[Customer2]
go

CREATE TABLE [Sales].[Customer2](
    [CustomerID] [int] IDENTITY(1,1) NOT FOR REPLICATION NOT NULL,
    [TerritoryID] [int] NULL,
    [AccountNumber] AS (isnull('AW'+[dbo].[ufnLeadingZeros]([CustomerID]),'')),
    [CustomerType] [nchar](1) COLLATE SQL_Latin1_General_CP1_CI_AS NOT NULL,
    [rowguid] [uniqueidentifier] ROWGUIDCOL NOT NULL
        CONSTRAINT [DF_Customer_rowguid2] DEFAULT (newid()),
    [ModifiedDate] [datetime] NOT NULL
        CONSTRAINT [DF_Customer_ModifiedDate2] DEFAULT (getdate()),
    CONSTRAINT [PK_Customer_CustomerID2] PRIMARY KEY CLUSTERED
    (
        [CustomerID] ASC
    ) ON [PRIMARY]
) ON [PRIMARY]

GO

ALTER TABLE [Sales].[Customer2] WITH CHECK
    ADD CONSTRAINT [FK_Customer_SalesTerritory_TerritoryID2]
        FOREIGN KEY( [TerritoryID])
        REFERENCES [Sales].[SalesTerritory] ( [TerritoryID])
GO

ALTER TABLE [Sales].[Customer2] WITH CHECK
    ADD CONSTRAINT [CK_Customer_CustomerType2]
        CHECK ((upper([CustomerType])='I' OR upper([CustomerType])='S'))

```

Using SSMS to Create Constraints

Most of the examples used so far in this chapter use T-SQL to demonstrate constraints. SSMS simplifies the administration of constraints by providing a user-friendly interface that allows you to view and manage constraints. The visual tools available for managing constraints in SSMS include the Object Explorer, Database Diagram Editor, and Table Designer.

Figure 26.3 shows the Object Explorer with the Constraints node expanded for the Employee table and the New Constraint option selected. The Constraints node contains the CHECK and DEFAULT constraints for the table. Notice in the Object Explorer that some

of the constraints (PRIMARY KEY, UNIQUE, and FOREIGN KEY) are actually contained under the Keys node.

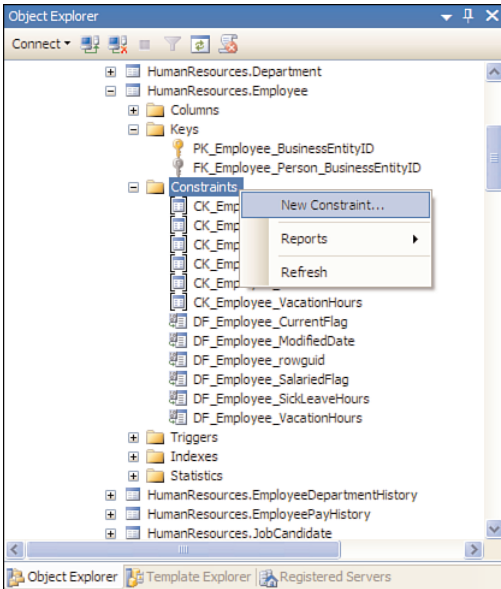

FIGURE 26.3 Constraints in Object Explorer.

When you select the New Constraint option from the Object Explorer, the Check Constraints dialog, shown in Figure 26.4, appears. This dialog gives you the option to define a new CHECK constraint on the table selected. You simply fill in a valid expression for the constraint, give it a unique name, and select the options you want.

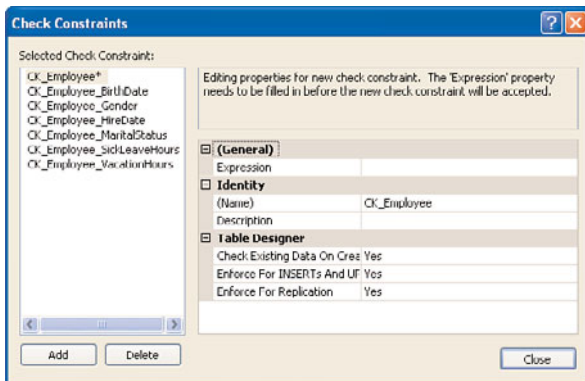

FIGURE 26.4 A new **CHECK** constraint in Object Explorer.

Similarly, you can right-click the Keys node and select New Foreign Key to add a new FOREIGN KEY constraint. Figure 26.5 shows the Foreign Key Relationships dialog displayed after you select New Foreign Key. You click the ellipsis to the right of Tables and Columns Specification, and you can select the primary key table you want the foreign key to relate to. Finally, you select the desired options, and you are ready to add your new FOREIGN KEY constraint.

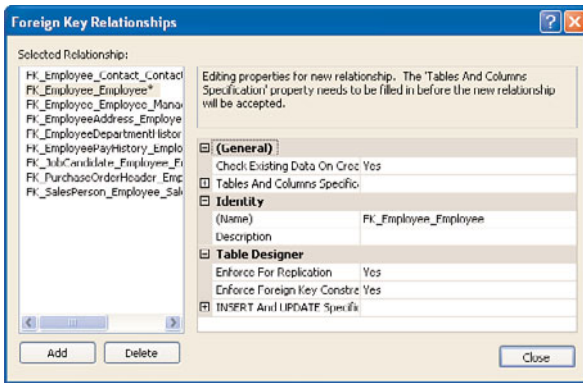

FIGURE 26.5 A new **FOREIGN KEY** constraint in Object Explorer.

TIP

When you use the Object Explorer to add or modify constraints, two windows are important to this process. The first window is the Constraint window, which allows you to input the constraint information. The Table Designer window that displays the column properties for the table is the other window that is important to the change process. It is launched in the background, and you can view it on the tabbed display of SSMS. When you make changes using the Constraint window, those changes are not applied via SSMS until the Table Designer window is closed. This may cause some confusion because even though you close your Constraint window with your changes, those changes may not be reflected in the database. You must close the Table Designer window to be able to actually make the changes to the table. When you close the Table Designer window, a prompt appears, asking whether you want to save the changes to the table. If you click Yes, your constraint changes are applied to the database. If you click No, none of the constraint changes you have made are applied. You can also use the Table Designer menu to script out the related changes and apply them manually via a database engine query window.

The Database Diagram Editor is another great visual tool for adding constraints. This tool is particularly useful for viewing and adding foreign key relationships to tables. Consider, for example, the database diagram shown in Figure 26.6. This diagram shows the AddressType and BusinessEntityAddress tables and the relationships that exist between

them. To add a new relationship, you right-click the table you want to add the foreign key to and select the Relationships option. After you fill in the appropriate information for the relationship, you can generate a change script by using the Table Designer menu, or you can simply close the database diagram window and respond to the prompt to save changes. You can also see options to add other constraints, such as CHECK constraints, by right-clicking the table in the database diagram and selecting the desired option.

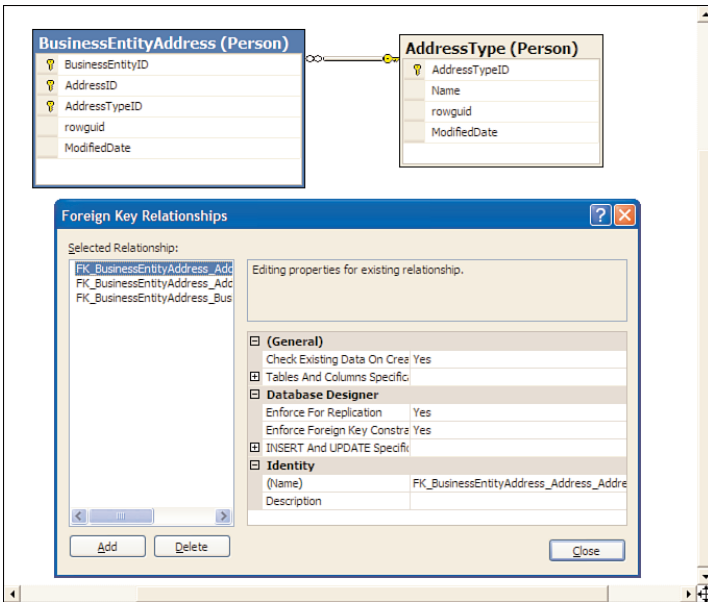

FIGURE 26.6 Adding constraints by using a database diagram.

You can also launch windows for adding constraints from the Table Designer menu. To enable the Table Designer menu, you right-click the table in Object Explorer that you want to add constraints to and select the Design option. The table and column properties are displayed, and the Table Designer menu is enabled. The Table Designer menu includes options to manage relationships, indexes/keys, and CHECK constraints.

TIP

It is a good idea to generate a script to implement changes made using SSMS visual tools. You can review the script for accuracy, run it at a later time, and save it in a file to keep track of the changes. You can also apply the saved script to other environments, if needed.

Managing Constraints

Managing constraints consists of gathering information about constraints, disabling and re-enabling constraints, and dropping constraints. These actions are discussed in the following sections.

Gathering Constraint Information

You can obtain information about constraints by using the visual tools, system stored procedures, and `information_schema` views. The visual tools (including the Object Explorer, Table Designer, and database diagrams) were introduced in the previous section. These tools offer a simple, user-friendly means for obtaining information related to constraints. These tools allow you to view a table's constraints and display the relative information.

The `sp_help` and `sp_helpconstraint` system stored procedures are another good source of information about constraints. Like the visual tools, these procedures allow you to gather constraint information about a specific table. The `sp_helpconstraint` procedure provides the most concise information related to constraints. Figure 26.7 shows the `sp_helpconstraint` output for the `Sales.Customer` table. You need to make sure to enclose the table name in brackets, as shown here, when the schema name is included. The output from `sp_helpconstraint` includes all the constraints for the table, and it supplies a list of tables that have foreign key references to the table.

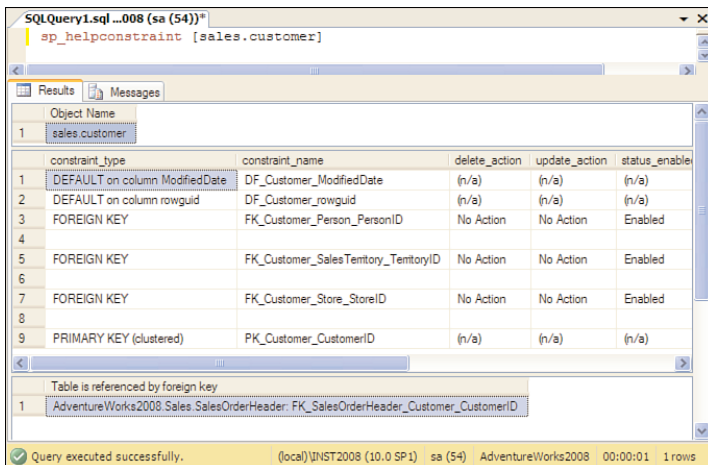

FIGURE 26.7 Executing `sp_helpconstraint` on the `Customer` table.

Catalog views offer a flexible alternative for returning information about constraints. SQL Server Books Online recommends using the `sys.key_constraints`, `sys.check_constraints`, and `sys.default_constraints` catalog views. These catalog views allow you to obtain constraint information for more than one table at a time. They are very flexible and allow you to customize the type of data you want to return simply by adjusting the selection criterion.

Listing 26.4 shows a sample `SELECT` statement for each of the catalog views related to constraints and the resulting output. The `SELECT` statements in this example have a `WHERE` clause in them that limits the results to the `SalesTax` table, but you can remove this clause to retrieve constraints for all the tables.

LISTING 26.4 Using Catalog Views to Display Constraint Information

```
select LEFT(name,30) NAME, type from sys.key_constraints
      where object_name(parent_object_id) = 'SalesTaxRate'
      order by 1

select LEFT(name,30) NAME, type from sys.check_constraints
      where object_name(parent_object_id) = 'SalesTaxRate'
      order by 1

select LEFT(name,30) NAME, type from sys.default_constraints
      where object_name(parent_object_id) = 'SalesTaxRate'
      order by 1

/* Results of the previous SELECT statements
NAME                                     type
-----
PK_SalesTaxRate_SalesTaxRateID PK

(1 row(s) affected)

NAME                                     type
-----
CK_SalesTaxRate_TaxType                C

(1 row(s) affected)

NAME                                     type
-----
DF_SalesTaxRate_ModifiedDate           D
DF_SalesTaxRate_rowguid                 D
DF_SalesTaxRate_TaxRate                 D
```

```
(3 row(s) affected)
*/
```

Dropping Constraints

You can drop constraints by using the visual tools or by using T-SQL. You can right-click a constraint in the Object Explorer and select the Delete option to drop that constraint. The Object Explorer also offers a script option that generates the T-SQL statements used to drop the constraint. The `ALTER TABLE` command is the T-SQL command you use to make the change. For example, to drop the `CK_Employee_Gender` constraint on the `Employee` table, you can use the following command:

```
ALTER TABLE [HumanResources].[Employee]
DROP CONSTRAINT [CK_Employee_Gender]
```

You should use caution when dropping constraints because some constraints affect other tables. For example, if you drop the `PRIMARY KEY` constraint on a table and that table is referenced by foreign keys, the drop statement fails.

Disabling Constraints

You can disable `CHECK` and `FOREIGN KEY` constraints by using the `NOCHECK` clause. This capability allows you to stop the constraints from being checked without removing the constraints from your database. The following `ALTER TABLE` command allows you to disable the `FK_Customer_SalesTerritory_TerritoryID` foreign key constraint on the `Customer` table:

```
ALTER TABLE Sales.Customer
    NOCHECK CONSTRAINT FK_Customer_SalesTerritory_TerritoryID
```

When the constraint is disabled, it no longer performs validation. You should disable constraints with caution because the integrity of your data can be compromised. In the previous example, disabling the `FOREIGN KEY` constraint would allow an invalid `TerritoryID` to be inserted in the `Customer` table.

Why would you disable constraints? One possible reason would be to disable the constraints during large data loads. The execution of constraints can slow the load process. To facilitate the fastest load speed, you can disable constraints and then re-enable them when the data load is complete. To re-enable a constraint, you use the `CHECK` keyword in the `ALTER TABLE` statement. The following example re-enables the `FOREIGN KEY` constraint for the `Customer` table:

```
ALTER TABLE Sales.Customer
    CHECK CONSTRAINT FK_Customer_SalesTerritory_TerritoryID
```

Keep in mind that enabling a constraint does not necessarily mean the underlying data is being validated against the constraint. In fact, the default behavior when enabling a constraint in SQL Server 2008 is not to check the data against the constraint when a constraint is enabled. The default behavior when a constraint is added is to validate the data. You can force the data in the table to be validated using the `WITH CHECK` option. The following `WITH CHECK` option could be used to force the validation of the underlying data when a constraint is enabled:

```
ALTER TABLE Sales.Customer
    WITH CHECK CHECK CONSTRAINT FK_Customer_SalesTerritory_TerritoryID
```

Rules

You can use rules as another method to enforce domain integrity. Rules are similar to `CHECK` constraints but have some limitations. The biggest advantage when using a rule is that one rule can be bound to multiple columns or user-defined data types. This capability can be useful for columns that contain the same type of data and are found in multiple tables in a database. The syntax for creating a rule is as follows:

```
CREATE RULE [ schema_name . ] rule_name
AS condition_expression
[ ; ]
```

condition_expression can include any statement that can be placed in a `WHERE` clause. It includes one variable that is preceded with the `@` symbol. This variable contains the value of the bound column that is supplied with the `INSERT` or `UPDATE` statement. The name of the variable is not important, but the conditions and formatting within the expression are. Only one variable can be referenced per rule. The following example illustrates the creation of a rule that could be used to enforce the format of data inserted in phone number columns:

```
CREATE RULE phone_rule AS
@phone LIKE '([0-9][0-9][0-9]) [0-9][0-9][0-9]-[0-9][0-9][0-9][0-9]'
```

The variable in the condition expression is `@phone`, and it contains the inserted or updated value for any column that the rule is bound to. The following example binds the `phone_rule` rule to the `PhoneNumber` column in the `person.PersonPhone` table:

```
sp_bindrule phone_rule, 'Person.PersonPhone.PhoneNumber'
```

When a rule is bound to a column, any future insertions or updates to data in the bound column are constrained by the rule. Existing data is not affected at the time the rule is bound to the column. For example, many different phone number formats in the `person.PersonPhone` table do not conform to `phone_rule`, but `phone_rule` can be bound to this table successfully. To illustrate this point, the following `UPDATE` statement can be

run against the `person.PersonPhone` table after the `phone_rule` rule is bound to the `PhoneNumber` column:

```
update person.contact
  set phone = phone
```

The preceding update sets the `PhoneNumber` value to itself, but this causes `phone_rule` to execute. The following error message is displayed after the update is run because the existing data in the `person.contact` table violates the `phone_rule` rule:

```
Msg 513, Level 16, State 0, Line 2
A column insert or update conflicts with a rule imposed
by a previous CREATE RULE statement.
The statement was terminated.
The conflict occurred in database 'Adventureworks2008',
table 'PersonPhone', column 'PhoneNumber'.
The statement has been terminated.
```

Although rules are powerful objects, Microsoft has slated them for removal in a future version of SQL Server. Microsoft recommends using `CHECK` constraints on each column instead of rules. `CHECK` constraints provide more flexibility and a consistent approach, and multiple `CHECK` constraints can be applied to a single column.

Defaults

A default provides a value for a column when a value is not supplied. Defaults can be anything that evaluates to a constant, such as a constant, built-in function, or mathematical expression. Defaults are of two types: declarative and bound. The two types are functionally the same; the difference is in how they are implemented.

Declarative Defaults

A *declarative default* is a constraint defined as part of the table definition. Using declarative defaults is the preferred method for assigning default values to columns. You can use the `CREATE TABLE` or `ALTER TABLE` statement to create a default and assign it to a column. Declarative defaults are assigned to a single column and cannot be reused for other columns in the database. The following example shows the creation of a new column named `CustomerType` in the `SalesCustomer` table followed by the creation of a new default on that column:

```
ALTER TABLE Sales.Customer
  ADD CustomerType CHAR(1)
ALTER TABLE Sales.Customer ADD CONSTRAINT
```

```
DF_Customer_CustomerType DEFAULT 'I' FOR CustomerType
```

It is important to remember that a default constraint stores the default value only when a value is not provided during the insertion of a row into the table. The creation of a default constraint does not affect the existing data in the table. UPDATE statements do not utilize the values specified in the default constraint, either, unless the DEFAULT keyword is explicitly referenced; this issue is discussed later in this chapter, in the section “When a Default Is Applied.” Generally, the only time a default comes into play is when the row is initially inserted. The following example shows an INSERT statement that causes the default value defined in the DF_Customer_CustomerType constraint to be used:

```
INSERT Sales.Customer
(TerritoryID)
SELECT TOP 1 TerritoryID from Sales.SalesTerritory
```

```
select CustomerID, CustomerType from Sales.Customer
where CustomerID = @@identity
```

```
/*Results from previous select statement
```

```
CustomerID CustomerType
```

```
-----
```

```
30119      I
```

```
*/
```

The Sales.Customer table in the Adventureworks2008 database is an interesting table because most of the columns have defaults defined, are identity columns, or are nullable. This table has eight columns, but only one value is supplied in the previous example. The rest of the columns, including the CustomerType column, have default definitions that automatically populate the values upon insertion or default to null.

One common misconception with defaults is that a default value is stored when a NULL value is supplied for a column on insertion. However, NULL is considered a value, so the default value is not used in this situation. This is demonstrated in the following example, where the CustomerType column is altered to accept NULL values and then a NULL value is specified for the CustomerType column in the INSERT statement:

```
ALTER TABLE Sales.Customer
ALTER COLUMN CustomerType nchar(1) null
```

```
INSERT Sales.Customer
(TerritoryID, CustomerType)
SELECT TOP 1 TerritoryID, null
from Sales.SalesTerritory
```

The insertion in this example succeeds, and the Null value is stored in the CustomerType column that has a default defined on it.

To remove a declarative default constraint, you use `ALTER TABLE` with the `DROP CONSTRAINT` clause. The following example removes the `DF_Customer_CustomerType` constraint from the `Sales.Customer` table:

```
ALTER TABLE Sales.Customer DROP CONSTRAINT DF_Customer_CustomerType
```

Bound Defaults

Bound defaults are similar to rules in that you first create a bound default and then bind it to a column or set of columns. Bound defaults are also similar to rules in that they are slated for removal in a future version of SQL Server. This section covers the basics of bound defaults, but you should keep in mind that Microsoft recommends you avoid using them for new development work.

You use the `CREATE DEFAULT` command to establish a default that can be bound to a column at a later time. The `CREATE DEFAULT` syntax is as follows:

```
CREATE DEFAULT [ schema_name . ] default_name
AS constant_expression [ ; ]
```

constant_expression can include any constant, built-in function, or mathematical expression. It cannot include user-defined functions. Character and data values that are part of the expression should be enclosed in single quotation marks. Monetary, integer, and floating-point constants do not require the single quotation marks.

The following example creates a default named `password_df` that can be used to supply a default password for any password-oriented columns:

```
CREATE DEFAULT password_df AS 'defaultpw'
```

After you create a default, you can bind it to a column. The following example binds the `password_df` default to the `passwordSalt` column on the `person.password` table:

```
sp_bindefault password_df, 'person.password.PasswordSalt'
```

As you can see, a bound default appears to require an extra step, but after it is created, it offers an advantage: you can bind it to other columns. This capability provides some consistency across all the columns that the default is bound to and reduces the overall number of database objects.

When a Default Is Applied

Defaults are applied only when no value is specified for a column during an insertion. They can also be applied during insertions and updates when the `DEFAULT` keyword is used. To demonstrate the application of defaults, consider the following examples:

```
CREATE TABLE test_default
(id int IDENTITY NOT NULL,
```

```

tmstmp timestamp NOT NULL,
password char(13) NOT NULL DEFAULT 'defaultpw',
Shortdesc VARCHAR(50) NULL)

```

The table in this example has a unique characteristic: each column has some sort of default value associated with it. One column has a default of NULL because it is nullable. The IDENTITY and TIMESTAMP columns automatically generate values because of their data type, and the password column has an explicit default definition. In this scenario, you can supply the keywords DEFAULT VALUES in the INSERT statement to insert a row of data, as shown in the following example:

```

INSERT test_default DEFAULT VALUES
select * from test_default
/* results from previous select statement
id          tmstmp          password          Shortdesc
-----
1           0x000000000000007D1 defaultpw          NULL
*/

```

You can see from the results of the SELECT statement in this example that a row was inserted in the new table, and this row includes default values for all the columns. If you want to supply values for some of the columns and allow the defaults to be used for other columns, you can simply exclude the columns with defaults from the column listing in the INSERT statement. The following example demonstrates how to do this:

```

INSERT test_default (ShortDesc)
VALUES('test default insertion')
SELECT * FROM test_default
where ShortDesc = 'test default insertion'

/* results from previous select statement
id tmstmp          password          Shortdesc
--
2  0x000000000000007D2 defaultpw          test default insertion
*/

```

The DEFAULT keyword can also be listed explicitly in the VALUE listing of the INSERT statement, as shown in the following example:

```

INSERT test_default (tmstmp, password, ShortDesc)
VALUES(DEFAULT, DEFAULT, DEFAULT)
SELECT * FROM test_default where id = @@identity
/*
(1 row(s) affected)
id tmstmp          password          Shortdesc
--
3  0x000000000000007D5 defaultpw          NULL
*/

```

All the examples so far have dealt with INSERT statements, but there is one scenario in which a default value can be applied with an UPDATE statement. This scenario is similar to the preceding example and requires the use of the DEFAULT keyword. The following example demonstrates the use of the DEFAULT keyword in an UPDATE statement:

```
UPDATE top (1) test_default
  SET PASSWORD = DEFAULT
GO
SELECT top 1 * from test_default
/*
id            tmstamp            password            Shortdesc
-----
1            0x00000000000007DE defaultpw            NULL
*/
```

Keep in mind that default values are *not* used for updates unless the DEFAULT keyword is explicitly referenced in the SET clause of the UPDATE statement.

Restrictions on Defaults

When creating defaults, you need to keep in mind the following restrictions:

- ▶ A default cannot be created on columns that have been defined with `TIMESTAMP`, `IDENTITY`, or `ROWGUIDCOL` properties.
- ▶ Only one default can be assigned to a given column. This restriction applies to both declarative and bound defaults.
- ▶ Only one default can exist per column.
- ▶ The default value must be compatible with the data type of the column.
- ▶ A default that is bound cannot be dropped if the default is currently bound to a column. The default must be unbound from the column first.
- ▶ The expression in a default cannot include the names of any columns or other database objects.

There are also some considerations related to the interaction of rules, defaults, and constraints:

- ▶ If a column has both a rule and default, the default is not inserted if it violates the rules.
- ▶ If a default value violates a `CHECK` constraint, the default is not inserted. Ultimately, all the rules, defaults, and constraints that are active are validated. If the change to the data violates any of them, it is rejected.

Summary

This chapter covers the basic tools you can use to ensure the integrity of the data in a database. The integrity of data is directly related to its value; remember the concept of “garbage in, garbage out.” If you take the time to implement the constraints and other methods discussed in this chapter, you provide a solid foundation for the storage of data and avoid the headaches related to dealing with “garbage” data.

Chapter 27, “Creating and Managing Views in SQL Server,” discusses a means for virtually accessing the data in tables. Virtual tables, or views, allow you to selectively choose the data elements on one or more tables that you want to present as a single window into your data.

CHAPTER 27

Creating and Managing Views in SQL Server

Views offer a window into your data that does not require physical storage. They are essentially virtual tables that are defined by a `SELECT` statement. This chapter describes the benefits and advantages of these powerful database objects.

What's New in Creating and Managing Views

Much of the core functionality associated with standard views has remained unchanged in SQL Server 2008. However, some storage enhancements have been added to SQL Server 2008 that can be used with views. These storage enhancements include disk storage compression in both row and page format. It is available on indexed views and can be used on tables and indexes as well. This data compression is not covered in this chapter but is covered in detail in Chapter 34, “Data Structures, Indexes, and Performance.”

Definition of Views

Views are a logical way of viewing data in the underlying physical tables. They are tied to a `SELECT` statement that retrieves data from one or more tables or views in the same database or a different database. In most cases, there is no physical storage of data associated with the view, and the `SELECT` that is associated with the view is run dynamically whenever the view is referenced.

IN THIS CHAPTER

- ▶ What's New in Creating and Managing Views
- ▶ Definition of Views
- ▶ Using Views
- ▶ Creating Views
- ▶ Managing Views
- ▶ Data Modifications and Views
- ▶ Partitioned Views
- ▶ Indexed Views

The following T-SQL statement can be used to create a simple view in the Adventureworks2008 database:

```
CREATE VIEW [dbo].[vw_CustomerAddress]
AS
SELECT      Sales.Customer.CustomerID, Sales.Customer.AccountNumber,
           Person.Address.AddressLine1,
           Person.Address.StateProvinceID, Person.Address.City,
           Person.Address.PostalCode
FROM Sales.Customer
   INNER JOIN Person.Person
      ON Sales.Customer.PersonID = Person.Person.BusinessEntityID
   INNER JOIN Person.BusinessEntityAddress
      ON Person.Person.BusinessEntityID = Person.BusinessEntityAddress.BusinessEntityID
   INNER JOIN Person.Address
      ON Person.BusinessEntityAddress.AddressID =
Person.Address.AddressID
```

The vw_CustomerAddress view in this example selects from four different tables in the Adventureworks2008 database: Sales.Customer, Person.Person, Person.BusinessEntityAddress, and Person.Address. After the view is created, it can be used in the FROM clause of another SELECT statement. The following data retrieval example uses the newly created view:

```
select c.AccountNumber, s.OrderDate, c.city , c.StateProvinceId
   from vw_CustomerAddress c
      INNER JOIN Sales.SalesOrderHeader s
         ON c.CustomerID = s.CustomerID
 WHERE StateProvinceId = 14
      AND s.OrderDate = '9/21/01'
 ORDER BY c.city
```

AccountNumber	OrderDate	city	StateProvinceId
AW00020060	2001-09-21 00:00:00.000	Runcorn	14
AW00011333	2001-09-21 00:00:00.000	Newcastle upon Tyne	14

You can see from the sample SELECT that the view is treated much like a table that is referenced in a SELECT statement. The view can be joined to other tables, individual columns from the view can be selected, and those columns can be included in the ORDER BY clause. All the retrieval is done dynamically when the view is referenced, and the underlying tables that are part of the view definition are implicitly accessed, without the need to know the underlying structure of the view.

Using Views

Views are useful in many scenarios. Some of the most common scenarios include the following:

- ▶ Simplifying data manipulation
- ▶ Focusing on specific data
- ▶ Abstracting data
- ▶ Controlling access to data

Simplifying Data Manipulation

Views can be used to simplify data access. Common queries that utilize complex joins, UNION queries, and more involved SQL can be defined as views. This minimizes the amount of complex code that must be written or rewritten and provides a simple way of organizing your common data access.

SQL Server 2008 comes with a set of system views that demonstrate the views' capability to mask complex queries and simplify data manipulation. These system views include catalog views, information schema views, and compatibility views. In many cases, the definition of these views is hidden, but some of them can be analyzed using the `sp_helptext` system procedure. For example, `sys.triggers`, a catalog view defined in SQL Server 2008, has the following definition associated with it:

```
CREATE VIEW sys.triggers AS
SELECT o.name,
       object_id = o.id,
       parent_class = o.pclass,
       parent_class_desc = pc.name,
       parent_id = o.pid,
       type = o.type,
       type_desc = n.name,
       create_date = o.created,
       modify_date = o.modified,
       is_ms_shipped = sysconv(bit, o.status & 1),           -- OBJALL_MSSHIPPED
       is_disabled = sysconv(bit, o.status & 256),          -- OBJTRG_DISABLED
       is_not_for_replication = sysconv(bit, o.status & 512), -- OBJTRG_NOTFORREPL
       is_instead_of_trigger = sysconv(bit, o.status & 1024) -- OBJTRG_INSTEADOF
FROM sys.syssschobjs o
LEFT JOIN sys.syspalnames n ON n.class = 'OBTY' AND n.value = o.type
LEFT JOIN sys.syspalvalues pc ON pc.class = 'UNCL' AND pc.value = o.pclass
WHERE o.type IN ('TA', 'TR') AND o.pclass <> 100
       AND has_access('TR', o.id, o.pid, o.nsclass) = 1
```

To select the relevant data from the `sys.triggers` view, you need only reference the columns in the view that are of interest, and the complexity of the view is hidden. The

following query demonstrates the simplicity of a SELECT statement against the `sys.triggers` view:

```
select name, type, create_date
  from sys.triggers
 where name like 'i%'
```

You can see from the `sys.triggers` example why the folks at Microsoft are big proponents of views. Complex queries such as the `sys.triggers` view can be written and tested once, and subsequent data retrieval can be accomplished by selecting from the view.

Focusing on Specific Data

Views allow users or developers to focus on the specific data elements they need to work with. Tables that contain hundreds of columns or columns that have limited value for the end user can be filtered with a view such that only the relevant data elements are returned.

The `HumanResources.vEmployee` view in the `Adventureworks2008` database is a good example of a view that focuses on specific data and simplifies data access. The view definition follows:

```
ALTER VIEW [vEmployee]
AS
SELECT
    e.[BusinessEntityID]
    ,p.[Title]
    ,p.[FirstName]
    ,p.[MiddleName]
    ,p.[LastName]
    ,p.[Suffix]
    ,e.[JobTitle]
    ,pp.[PhoneNumber]
    ,pnt.[Name] AS [PhoneNumberType]
    ,ea.[EmailAddress]
    ,p.[EmailPromotion]
    ,a.[AddressLine1]
    ,a.[AddressLine2]
    ,a.[City]
    ,sp.[Name] AS [StateProvinceName]
    ,a.[PostalCode]
    ,cr.[Name] AS [CountryRegionName]
    ,p.[AdditionalContactInfo]
FROM [HumanResources].[Employee] e
    INNER JOIN [Person].[Person] p
        ON p.[BusinessEntityID] = e.[BusinessEntityID]
    INNER JOIN [Person].[BusinessEntityAddress] bea
```

```

ON bea.[BusinessEntityID] = e.[BusinessEntityID]
INNER JOIN [Person].[Address] a
ON a.[AddressID] = bea.[AddressID]
INNER JOIN [Person].[StateProvince] sp
ON sp.[StateProvinceID] = a.[StateProvinceID]
INNER JOIN [Person].[CountryRegion] cr
ON cr.[CountryRegionCode] = sp.[CountryRegionCode]
LEFT OUTER JOIN [Person].[PersonPhone] pp
ON pp.BusinessEntityID = p.[BusinessEntityID]
LEFT OUTER JOIN [Person].[PhoneNumberType] pnt
ON pp.[PhoneNumberTypeID] = pnt.[PhoneNumberTypeID]
LEFT OUTER JOIN [Person].[EmailAddress] ea ON p.[BusinessEntityID] =
ea.[BusinessEntityID]

```

The `HumanResources.vEmployee` view filters out much of the data that is sensitive or superfluous when gathering the basic information about an employee.

Abstracting Data

Data abstraction, in its simplest form, isolates the client code from changes to the underlying structure. A view can be used to implement data abstraction within your database schema. If, for example, you have client code that will retrieve data from a database table that is likely to change, you can implement a view that retrieves data from the underlying table. The client code will then reference the view and never access the underlying table directly. If the underlying tables change or the source of the data for the view changes, these changes can be isolated from the referencing client code.

To demonstrate this scenario, let's look at the following `SELECT` statement, which retrieves data directly from the `Sales.SalesOrderHeader` table:

```

select TerritoryID, sum(TotalDue)
  from Sales.SalesOrderHeader
  group by TerritoryID
 order by TerritoryID

```

The client code could certainly utilize this kind of query to retrieve the territory data. You may find, however, that the data retrieval would be better placed within a view if the summarized territory data were slated to be rolled up into an aggregate table at a later time. In this scenario, a view like the following could be created initially:

```

CREATE VIEW vw_TerritoryOrders AS
select TerritoryID, sum(TotalDue) 'TotalSales'
  from Sales.SalesOrderHeader
  group by TerritoryID

```

The client code that needs the territory data would then reference the `vw_TerritoryOrders` view. If the source of the territory data changes and it is rolled up in an aggregate table, the view can be changed to reflect the new source for the data, but the

client code remains unchanged. The following example alters the `vw_TerritoryOrders` view such that the source of the data is changed:

```
ALTER VIEW vw_TerritoryOrders AS
select TerritoryID, SalesYTD 'TotalSales'
from Sales.SalesTerritory
```

Changing a single view in these types of scenarios can be much easier than changing the client code that has direct references to the table. This type of abstraction also applies to partitioned views, which are discussed later in this chapter.

Controlling Access to Data

Views can be used as a security mechanism to limit a user's access to specific data. This type of view security can be used to limit the columns that a user has access to or the rows that the user has access to. A view that limits the accessible columns can be referred to as *vertical security*, or *column-level security*. A view that restricts the rows that are returned is referred to as *horizontal security*, or *row-level security*.

With vertical security, a view is created that contains only the data elements or columns that you want to make visible. Columns that are sensitive in nature (for example, payroll data) can be excluded from a view so that they are not seen when the user selects from the view.

After the view is created, security can be granted on the view. If the owner of the objects referenced in the view is the same as the owner of the view itself, the user who is granted permission to the view does not need to have permission granted to the underlying objects. Listing 27.1 gives an example of this scenario.

LISTING 27.1 Security with Views

```
USE adventureworks2008
go
CREATE LOGIN OwnerLogin WITH PASSWORD = 'pw'
CREATE USER OwnerLogin FOR LOGIN OwnerLogin
EXEC sp_addrolemember N'db_owner', N'OwnerLogin'

CREATE LOGIN NonOwnerLogin WITH PASSWORD = 'pw'
CREATE USER NonOwnerLogin FOR LOGIN NonOwnerLogin

—Connect as the OwnerLogin at this point
Go

CREATE VIEW OwnerView as
select LoginID, JobTitle, BirthDate, Gender, HireDate, SalariedFlag
from HumanResources.Employee go

GRANT SELECT ON [dbo].[OwnerView] TO [NonOwnerLogin]
```

```

—Connect as the NonOwnerLogin at this point

—The following select succeeds because the owner of the
—view that was granted permission is the same as the underlying
—table in the view
select * from OwnerView

—The following SELECT against the underlying table fails
—because the NonOwnerLogin does not have permission to
—select from the table. He can only select through the view
select * from HumanResources.Employee

```

Listing 27.1 outlines a scenario where one login creates a view that selects specific columns from the `HumanResources.Employee` table. The `Employee` table is part of the `HumanResources` schema, and it is owned by `DBO`. The view that is created is also owned by `DBO` because the login (`OwnerLogin`) that created the view is a member of the `db_owner` role. Ultimately, `NonOwnerLogin` is granted permission to the view. When the `NonOwnerLogin` user connects to the database, that user can select rows from the view and will see only the columns in the `Employee` table that have been selected in the view. If that user tries to select rows directly from the underlying `HumanResources.Employee` table, a permission-related error fires. Ownership chaining is the key to making this scenario work.

With ownership chaining, SQL Server automatically authorizes a user to access the underlying tables, views, or functions referenced in the view. This happens only if the view has the same owner as the underlying objects and the user has been granted permission to the view. If, however, you have various owners of the underlying objects that a view references, permissions must be checked at each level. If access is denied at any level, access to the view is denied. Ownership chaining was available in prior versions and is still available in SQL Server 2008 for backward compatibility.

Horizontal security can also be implemented with a view. With horizontal security, a `WHERE` clause is included in the view's `SELECT` statement to restrict the rows that are returned. The following example demonstrates a simple view that utilizes horizontal security:

```

CREATE VIEW EmpViewHorizontal
as
select EmployeeID, BirthDate, Gender, HireDate, SalariedFlag
from HumanResources.Employee
where HireDate > '3/1/03'

```

—Sample `SELECT` results from the view:

LoginID	BirthDate	Gender	HireDate	SalariedFlag
adventure-works\syed0	1965-02-11	M	2003-04-15	1
adventure-works\lynn0	1961-04-18	F	2003-07-01	1

```
adventure-works\rachel0 1965-08-09 F          2003-07-01 1
```

Only the rows in the `Employee` table with a `HireDate` value greater than March 1, 2003, are returned when you select everything from the view. Separate views can be created based on geography, demographics, or any other data element that requires a different set of security.

Keep in mind that additional conditions can be applied when selecting from a view. You can utilize another `WHERE` clause in the `SELECT` statement that uses a view. This is demonstrated in the following example:

```
select * from EmpViewHorizontal
where HireDate >= '7/1/03'
and BirthDate > '1/1/65'
```

```
LoginID                BirthDate  Gender  HireDate  SalariedFlag
adventure-works\rachel0 1965-08-09 F          2003-07-01 1
```

As you can see, a view with horizontal security restricts your initial result set but does not prevent you from applying additional conditions to obtain the desired result.

Creating Views

You can create several different types of views in SQL Server 2008, including standard views, indexed views, and partitioned views. Standard views are like those that have been discussed thus far in this chapter; they let you achieve most of the benefits associated with views. An indexed view has a unique clustered index defined on it that causes the view to be materialized. In other words, the creation of the index causes physical storage of the data related to the view's index. Partitioned views join horizontally partitioned data from a set of distinct tables. They can be locally partitioned, meaning that the tables are on the same server; or they can be distributed, meaning that some of the tables exist on other servers. Partitioned views and indexed views are discussed in detail later in this chapter.

All types of views share a common set of restrictions:

- ▶ Every column (including derived columns) must have a name.
- ▶ The `SELECT` statement used in the view cannot include the `COMPUTE BY` clause or the `INTO` keyword.
- ▶ The `SELECT` statement used in the view cannot include the `ORDER BY` clause.
- ▶ The `SELECT` statement used in the view cannot contain temporary tables.
- ▶ You cannot associate `AFTER` triggers with views, but you can associate `INSTEAD OF` triggers.
- ▶ You cannot associate rules or default definitions with a view.
- ▶ You cannot define a full-text index on a view.

A view can have a maximum of 1,024 columns. You can select all the columns for a view by using a `SELECT *` statement, but you need to use some caution when doing so. In particular, you must keep in mind that the view will not display columns that have been added to the view's underlying tables after the view has been created. The fact that the new columns are not displayed can be a good thing but is sometimes overlooked. You can prevent changes to the underlying objects (for example, tables) by creating the view with `SCHEMABINDING`. `SCHEMABINDING` is discussed in the next section.

If you want the changes to the underlying objects to be reflected in the views, you can use the `sp_refreshview` stored procedure. This stored procedure updates the metadata for the specified non-schema-bound view.

TIP

SQL Server Books Online lists a handy script that can be used to update any view that has a dependency on an object. The script is shown in the `sp_refreshview` examples. The script, listed here, is coded such that it will generate output that can be run to generate the `sp_refreshview` statements for the `Person.Person` table in the `Adventureworks2008` database:

```
SELECT DISTINCT 'EXEC sp_refreshview ''' + name + ''''
FROM sys.objects so INNER JOIN sys.sql_dependencies sd
ON so.object_id = sd.object_id
WHERE type = 'V'
AND sd.referenced_major_id = object_id('Person.Person')
```

To generate the executions for another object, you simply change the name of the object (that is, `Person.Person`) found at the end of the script to the name of the object you want to investigate.

With these guidelines in mind, you are now ready to create your view. Views can be created in SQL Server 2008 using T-SQL or SQL Server Management Studio (SSMS).

Creating Views Using T-SQL

The `CREATE VIEW` statement is used to create views with T-SQL. The syntax for the `CREATE VIEW` statement follows:

```
CREATE VIEW [ schema_name . ] view_name [ ( column [ ,...n ] ) ]
[ WITH <view_attribute> [ ,...n ] ]
AS select_statement [ ; ]
[ WITH CHECK OPTION ]
```

```
<view_attribute> ::=
{
    [ ENCRYPTION ]
    [ SCHEMABINDING ]
    [ VIEW_METADATA ] }
```

This statement and the related options are essentially the same in SQL Server 2008 as they were in SQL Server 2005 and SQL Server 2000. We first look at a simple example for creating a view with T-SQL and then delve into several other examples that utilize the view attributes. Listing 27.2 shows a sample T-SQL statement for creating a simple view.

LISTING 27.2 Creating a Simple View with T-SQL

```
CREATE VIEW Sales.vw_OrderSummary as
select datepart(yy, orderdate) as 'OrderYear',
       datepart(mm, orderdate) as 'OrderMonth',
       sum(TotalDue) as 'OrderTotal'
from Sales.SalesOrderHeader
group by datepart(yy, orderdate), datepart(mm, orderdate)
```

There are several important aspects to notice in the example in Listing 27.2. First, all the columns in the SELECT statement are derived columns and do not simply reference a column in a table. You do not need to have a derived column in your view, but if you do, the derived column(s) must have a name or an alias assigned to it to be able to create the view. The column name allows you to reference the derived column when selecting from the view. If the derived columns in the SELECT statement are not named, the CREATE VIEW statement will fail.

Another notable characteristic of the simple view example is that an aggregate is used in the SELECT statement. Aggregates are allowed in views and are common implementations of views. Views with aggregates can be used instead of summary tables that denormalize data and use additional disk space. Keep in mind that the results of any view (including those with aggregates) are not returned in any particular order. Views cannot be created with the ORDER BY clause, but the ORDER BY clause can be utilized in a SELECT statement that references the view. The following example shows the first five rows of the vw_OrderSummary view created in Listing 27.2:

```
select top 5 * from Sales.vw_OrderSummary
```

OrderYear	OrderMonth	OrderTotal
2003	5	4449886.2315
2001	11	3690018.6652

2003	8	6775857.0745
2002	7	3781879.0708
2003	11	5961182.6761

You can see from the results of the `SELECT` that the summarized order information is not returned in any particular order. If you want to sort the results, you can treat the view like a table in a `SELECT` statement and use the `ORDER BY` clause to produce the desired results. The following example shows a `SELECT` statement from the `vw_OrderSummary` view and the ordered results:

```
select top 5 *
  from Sales.vw_OrderSummary
 where OrderYear >= 2004
 order by OrderYear, OrderMonth
```

OrderYear	OrderMonth	OrderTotal
2004	1	3691013.2227
2004	2	5207182.5122
2004	3	5272786.8106
2004	4	4722890.7352
2004	5	6518825.2262

TIP

In many cases, it is best to create views that include the primary key columns from the underlying tables. This allows the views to be joined to other tables. Consider, for example, a view created on the `Employee` table in the `Adventureworks2008` database. If you want to join that view to another table (such as `EmployeeAddress`), you need the primary key of the table (that is, `Employee.EmployeeID`) in the view.

Views can also be created with the following special view attributes: `ENCRYPTION`, `SCHEMABINDING`, and `VIEW_METADATA`. Each of these attributes and some other specialized views are discussed in the following sections.

ENCRYPTION

The `ENCRYPTION` attribute causes the view definition to be stored as encrypted text in `sys.syscomments`. This feature is also available for stored procedures and other database code that you may want to protect. One issue to consider when you create a view using the `ENCRYPTION` option is that this option prevents the view from being published as part of SQL Server replication.

The following example shows the creation of one of the prior views with the ENCRYPTION attribute:

```
IF EXISTS (SELECT * FROM sys.views WHERE
object_id = OBJECT_ID(N'[Sales].[vw_OrderSummary]'))
DROP VIEW [Sales].[vw_OrderSummary]
GO

CREATE VIEW Sales.vw_OrderSummary
WITH ENCRYPTION AS
select datepart(yy, orderdate) as 'OrderYear',
       datepart(mm, orderdate) as 'OrderMonth',
       sum(TotalDue) as 'OrderTotal'
from Sales.SalesOrderHeader
group by datepart(yy, orderdate), datepart(mm, orderdate)
go
```

The following SELECT statement from sys.syscomments retrieves the text related to the encrypted view and shows that the view definition is not visible in the Text column:

```
SELECT id, OBJECT_NAME(ID) 'ViewName', text
FROM SYS.sysCOMMENTS
WHERE OBJECT_NAME(ID) LIKE '%vw_OrderSummary%'
```

id	ViewName	text
919674324	vw_OrderSummary	NULL

SCHEMABINDING

The SCHEMABINDING attribute binds a view to the schema of the underlying table(s) referenced in the view's SELECT statement. This binding action prevents any changes to the underlying tables that would affect the view definition. For example, if you have a view that includes the Employee.Title column, this column cannot be altered or dropped in the Employee table. If schema changes are attempted on the underlying tables, an error message is returned, and the change is not allowed. The only way to make the change is to drop the view or alter the view to remove the SCHEMABINDING attribute.

TIP

Views created with SCHEMABINDING have been used in the past to simply prevent changes to the underlying schema. Any table for which you wanted to prevent schema changes was included in a view, and this essentially locked the definition of the table. This approach is no longer needed because you can accomplish the same thing using DDL triggers, which can react to schema changes and prevent them if desired.

VIEW_METADATA

When the `VIEW_METADATA` option is specified, SQL Server returns information about the view, as opposed to the base tables. This happens when browse-mode metadata is requested for a query that references the view via a database API. Browse-mode metadata is additional information returned by SQL Server to client-side DBLIB, ODBC, and OLE DB APIs, which allows them to implement client-side updatable cursors.

WITH CHECK OPTION

`WITH CHECK OPTION` forces all data modifications made through a view to adhere to the conditions in the view. The example shown in Listing 27.3 shows a view created using `WITH CHECK OPTION`.

LISTING 27.3 View using a WITH CHECK OPTION

```
CREATE VIEW HumanResources.vw_MaleEmployees
AS
SELECT LoginID, Gender
FROM HumanResources.Employee
WHERE Gender = 'M'
WITH CHECK OPTION
```

The following `UPDATE` statement fails when executed against the view created in Listing 27.3 because the `Gender` change would cause it to no longer be seen by the view:

```
UPDATE HumanResources.vw_MaleEmployees
SET Gender = 'F'
WHERE LoginId = 'adventure-works\taylor0'
```

Updates and other modifications made through a view are discussed further in the “Data Modifications and Views” section, later in this chapter.

Creating Views Using the View Designer

SQL Server 2008 provides a graphical tool, called the View Designer, you can use to create views. This tool can be an invaluable aid when you are creating or modifying a view. The View Designer is equipped with four panes that provide the information relative to the view. Figure 27.1 shows the View Designer display for the `Person`.

`vStateProvinceCountryRegion` view installed in the `Adventureworks2008` database. To view an existing view in the View Designer, right-click on the view listed in the Object Explorer and select `Design`. To create a new view via the View Designer, right-click the `Views` node in the Object Explorer and select `New View`. An empty View Designer is displayed.

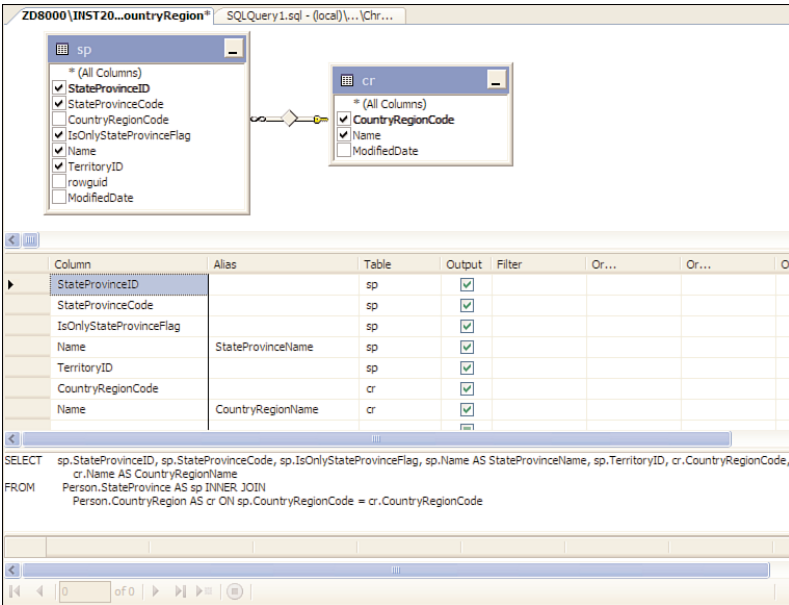

FIGURE 27.1 The View Designer window.

The View Designer has these four panes:

- ▶ **Diagram pane**—Gives a graphical view of the tables that are part of the view. This includes the columns in the tables and relationships between the tables contained in the view.
- ▶ **Criteria pane**—Displays all the columns selected in the view and allows for sorting, filtering, and other related column-oriented criteria.
- ▶ **SQL pane**—Renders the T-SQL associated with the view.
- ▶ **Results pane**—Shows the results of that view's SELECT statement.

The panes in the View Designer are dependent on each other. If you add a WHERE clause in the SQL pane, the corresponding Filter value is added in the Criteria pane. Similarly, if you right-click in the Diagram pane and add a table to the view, the Criteria and SQL panes are updated to reflect this change.

TIP

One of the most amazing features of the View Designer is the capability to render a SQL statement into its graphical form. You can copy T-SQL into the SQL pane, and the View Designer reverse-engineers the tables into the Diagram pane, giving you a graphical display of the query. Some complex SQL statements cannot be rendered, but many of them can. Give it a try; you will be impressed.

You can control the View Designer via the Query Designer menu option as well. Adding a new table, verifying the T-SQL, and changing the panes displayed are just some of the options available on this menu.

NOTE

The View Designer does not allow you to set every attribute of a view. It is a great starting point for creating a view, but you need to set some attributes using T-SQL after creating the view. For example, you cannot specify `WITH CHECK OPTION` in the View Designer, but you can set it by altering the view after it has been created.

There is also no option to script a view from the View Designer. You must close the View Designer first, and then you are asked whether you want to save the view. If you click Yes, a prompt allows you to specify a name.

The Properties window displays information about the view and also allows you to enter additional view properties. If this window is not visible, you can select the Properties window from the View menu or simply press F4. The properties you can set on the view include (but are not limited to) a description, the schema that owns the view, and whether to bind the view to the schema. Figure 27.2 shows the Properties window for the `Person.vStateProvinceCountryRegion` view that we looked at earlier.

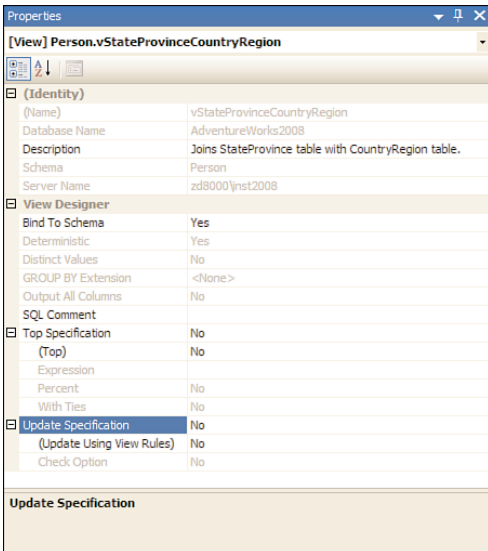

FIGURE 27.2 The view's Properties window.

After defining a view using the panes in the View Designer and setting its properties, you can choose to save the view. You are prompted to give it a name. After you save the view, it appears in the Object Explorer tree.

Managing Views

After creating your view, you can manage the view via T-SQL or the View Designer. The T-SQL commands for managing views are the `ALTER VIEW` and `DROP VIEW` statements. The `ALTER VIEW` statement is used to modify the properties or definition of the view, and the `DROP VIEW` statement is used to remove the view from the database.

Altering Views with T-SQL

The `ALTER VIEW` syntax follows:

```
ALTER VIEW [ schema_name . ] view_name [ ( column [ ,...n ] ) ]
[ WITH <view_attribute> [ ,...n ] ]
AS select_statement [ ; ]
[ WITH CHECK OPTION ]
```

<*view_attribute*> ::=

```
{
    [ ENCRYPTION ]
    [ SCHEMABINDING ]
    [ VIEW_METADATA ]
}
```

The `ALTER VIEW` statement utilizes the same set of options and parameters as the `CREATE VIEW` statement. You should consider using the `ALTER VIEW` statement when making changes to your view instead of dropping and re-creating the view. Altered views retain their associated permissions and do not affect dependent stored procedures or triggers.

An example of the `ALTER VIEW` statement follows:

```
ALTER VIEW [dbo].[vw_employee]
with SCHEMABINDING
AS
SELECT TITLE, GENDER
    FROM HumanResources.Employee
WITH CHECK OPTION
```

The entire definition of the view, including any attributes or options, must be listed in the `ALTER VIEW` statement. This behavior is similar to that of the `ALTER PROCEDURE` statement and some of the other `ALTER` statements. You can generate the `ALTER VIEW` statement from the Object Explorer by right-clicking the view and selecting `Script View As` and then choosing `Alter To`. This allows you to script the `ALTER` statement to a new query editor window, a file, or the Clipboard.

Dropping Views with T-SQL

You can drop views from a database by using the `DROP VIEW` statement. The syntax for `DROP VIEW` follows:

```
DROP VIEW [ schema_name . ] view_name [ ...,n ] [ ; ]
```

You can drop more than one view by using one `DROP VIEW` statement and listing all the targeted views, separated by commas. You should consider running the `sp_depends` stored procedure against the targeted views before dropping them. This procedure lists the objects dependent on the view you are dropping.

TIP

You can also drop more than one view via SSMS. Simply select the Views node in Object Explorer and then activate the Object Explorer Details window. The Object Explorer Details window displays all the views and allows you to select multiple views that are displayed. After selecting the views you want to delete, you can right-click a selection and choose Delete to remove all the views selected.

Managing Views with SSMS

You can use the Object Explorer in SQL Server Management Studio to alter or drop views as well. To do so, you right-click a view in the Object Explorer and choose Design to launch the View Designer. The View Designer allows you to modify a view in an easy-to-use graphical interface. Refer to the “Creating Views Using the View Designer” section, earlier in this chapter, for a detailed review of the View Designer.

To drop a view, you right-click the view in the Object Explorer and choose Delete. You can drop the view by clicking OK on the Delete Object screen, or you can script the drop statement for later execution.

Data Modifications and Views

Data modifications are allowed through a view under certain circumstances. Views that meet these criteria are sometimes called *updatable views*. Updatable views can be referenced in an `INSERT`, `UPDATE`, or `DELETE` statement, and these statements ultimately affect the underlying table(s) in the view.

The following example contains a SQL statement to create an updatable view, followed by an `UPDATE` statement that performs a data modification using the view:

```
CREATE VIEW vw_CreditCard
AS
SELECT CreditCardID, CardType, CardNumber, ExpMonth, ExpYear
```

```
FROM Sales.CreditCard
```

```
UPDATE vw_CreditCard
SET ExpYear = ExpYear + 1
WHERE ExpYear < 2006
```

In general, updatable views are similar to the previous example. The following specific conditions allow a view to be updatable:

- ▶ Any data modification via a view must reference columns from a single base table. This does not restrict a view to only one table, but the columns referenced in the data modification can be for only one of the tables defined in the view.
- ▶ The columns affected by the data modification must directly reference the underlying tables. They cannot be derived through an aggregate function (for example, AVG, COUNT, SUM) and cannot contain computations from an expression that utilizes columns from another table.
- ▶ The TOP clause cannot be part of the SELECT statement that defines the view when the WITH CHECK OPTION clause is used.
- ▶ The columns affected by the data modification cannot be affected by GROUP BY, HAVING, or DISTINCT clauses in the view definition.

You can overcome these restrictions by using INSTEAD OF triggers to perform the data modifications. You can create INSTEAD OF triggers on a view, and the logic within the trigger performs the actual database updates. INSTEAD OF triggers are discussed in detail in Chapter 30, “Creating and Managing Triggers.”

Partitioned views are another means for performing data modifications via a view. Partitioned views can be updatable and are not subject to all the restrictions listed for conventional views. However, some additional restrictions apply to partitioned views. These additional restrictions and other details about partitioned views are discussed in the next section.

Partitioned Views

Partitioned views are used to access data that has been horizontally split, or partitioned, across multiple tables. These tables can be in the same or different databases—or even spread across multiple servers. Partitioning of tables is done to spread the I/O and processing load of large tables across multiple disks or servers.

You combine the tables in a partitioned view by using a UNION ALL statement that causes the data from the separate tables to appear as if they were one table. These separate tables are referred to as *member tables* or *base tables*. The member tables in a SELECT statement of the view must all be structured in the same way, and the view must adhere to the following restrictions:

- ▶ All the columns from the member tables should be included in the view definition.

- ▶ Columns with the same ordinal position in the SELECT list should have the same data type.
- ▶ The same column cannot be used multiple times in the SELECT list.
- ▶ A partitioning column that segments the data must be identified and needs to have the same ordinal position across all the member table SELECT statements.
- ▶ The partitioning column cannot be a computed column, an identity, a default, or a time stamp.
- ▶ The data values in the partitioning column cannot overlap in the underlying tables.
- ▶ The partitioning column must be part of the primary key of the member table.
- ▶ The member tables in the partitioned view need a CHECK constraint on the partitioning column.
- ▶ A table can appear only once as part of the UNION ALL statement.
- ▶ The member tables cannot have indexes created on computed columns in the table.
- ▶ The number of columns in the member table primary key constraints should be the same.
- ▶ All member tables should have the same ANSI PADDING setting when created.

The list of restrictions for creating partitioned views is extensive, but the creation of a partitioned view is relatively straightforward and intuitive. Consider, for example, the `Sales.SalesOrderHeader` table in the `Adventureworks2008` database. This table is relatively small, but it is the type of table that could have a large number of rows and experience heavy utilization. To balance the workload against this table, you could use a partitioned view that utilizes base tables that each contain a separate year's data. Listing 27.4 shows the `CREATE TABLE` statements to create the base tables for each year. The yearly tables are intended to hold summarized daily numbers, and each contains only a subset of the columns in the `Sales.SalesOrderHeader` table.

LISTING 27.4 Creating the Base Tables for a Partitioned View

```
CREATE TABLE Sales.Sales_2001
(
    OrderDay datetime NOT NULL
        CHECK (OrderDay BETWEEN '20010101' AND '20011231'),
    SubTotal money NOT NULL ,
    TaxAmt money not null,
    Freight money not null,
    CONSTRAINT PK_Sales_2001_OrderDay PRIMARY KEY CLUSTERED (OrderDay ASC)
)

CREATE TABLE Sales.Sales_2002
(
```

```

    OrderDay datetime NOT NULL,
        CHECK (OrderDay BETWEEN '20020101' AND '20021231'),
    SubTotal money NOT NULL ,
    TaxAmt money not null,
    Freight money not null,
CONSTRAINT PK_Sales_2002_OrderDay PRIMARY KEY CLUSTERED (OrderDay ASC)
)

CREATE TABLE Sales.Sales_2003
(
    OrderDay datetime NOT NULL
        CHECK (OrderDay BETWEEN '20030101' AND '20031231'),
    SubTotal money NOT NULL ,
    TaxAmt money not null,
    Freight money not null,
CONSTRAINT PK_Sales_2003_OrderDay PRIMARY KEY CLUSTERED (OrderDay ASC)
)

CREATE TABLE Sales.Sales_2004
(
    OrderDay datetime NOT NULL
        CHECK (OrderDay BETWEEN '20040101' AND '20041231'),
    SubTotal money NOT NULL ,
    TaxAmt money not null,
    Freight money not null,
CONSTRAINT PK_Sales_2004_OrderDay PRIMARY KEY CLUSTERED (OrderDay ASC)
)

```

Notice that each table has a primary key on OrderDay, the partitioning column. Also notice that a CHECK constraint is defined for each table; it ensures that only orders for the given year can be stored in the table.

To demonstrate the power of a partitioned view, it is best to populate the base tables that will be used by the view. Listing 27.5 contains a series of INSERT statements that select from the Sales.SalesOrderHeader table and populate the base tables. The SELECT statements summarize several key columns by day and contain a WHERE clause that limits the result to orders for the respective years.

LISTING 27.5 Populating the Base Tables for a Partitioned View

```

INSERT Sales.Sales_2001
SELECT CONVERT(VARCHAR(8),OrderDate,112),
        SUM(SubTotal), SUM(TaxAmt), SUM(Freight)
FROM Sales.SalesOrderHeader
WHERE OrderDate between '20010101' AND '20011231'
GROUP BY CONVERT(VARCHAR(8),OrderDate,112)

```

```

INSERT Sales.Sales_2002
  SELECT CONVERT(VARCHAR(8),OrderDate,112),
         SUM(SubTotal), SUM(TaxAmt), SUM(Freight)
  FROM Sales.SalesOrderHeader
  WHERE OrderDate between '20020102' AND '20021231'
  GROUP BY CONVERT(VARCHAR(8),OrderDate,112)

```

```

INSERT Sales.Sales_2003
  SELECT CONVERT(VARCHAR(8),OrderDate,112),
         SUM(SubTotal), SUM(TaxAmt), SUM(Freight)
  FROM Sales.SalesOrderHeader
  WHERE OrderDate between '20030101' AND '20031231'
  GROUP BY CONVERT(VARCHAR(8),OrderDate,112)

```

```

INSERT Sales.Sales_2004
  SELECT CONVERT(VARCHAR(8),OrderDate,112),
         SUM(SubTotal), SUM(TaxAmt), SUM(Freight)
  FROM Sales.SalesOrderHeader
  WHERE OrderDate between '20040102' AND '20041231'
  GROUP BY CONVERT(VARCHAR(8),OrderDate,112)

```

Now that you have the populated base table, you can create a partitioned view and ensure that the view is selecting only from the base tables that it needs.

Two types of partitioned views are discussed in this chapter: local and distributed. A local partitioned view utilizes base tables found on the same server. A distributed partitioned view contains at least one base table that resides on a different (remote) server. The focus in the section is on local partitioned views; distributed partitioned views are discussed later in this chapter. The T-SQL for creating a local partitioned view named `Sales.vw_Sales_Daily` is shown in Listing 27.6.

LISTING 27.6 Creating a Local Partitioned View

```

Create View Sales.vw_Sales_Daily
as
  SELECT * FROM Sales.Sales_2001
  UNION ALL
  SELECT * FROM Sales.Sales_2002
  UNION ALL
  SELECT * FROM Sales.Sales_2003
  UNION ALL
  SELECT * FROM Sales.Sales_2004

```

The best way to validate that a partitioned view is working properly is to run a conditional SELECT against the view and display the execution plan. If the partitioned view is functioning properly, it should be accessing only the base tables it needs to satisfy the SELECT and should not access all the tables in the view unless it needs to. The following example shows a sample SELECT against the new partitioned view:

```
SELECT * FROM Sales.vw_Sales_Daily
WHERE OrderDay > '20040701'
      and SubTotal > 2000
```

If you execute this statement and review the actual execution plan, you see that an index seek is performed against the Sales.Sales_2004 table. This is the correct result, given that the SELECT statement is targeting order data from 2004.

NOTE

SQL Server Books Online states that the recommended method for partitioning data on a local server in SQL Server 2008 is through the use of partitioned tables and indexes. Partitioned tables and indexes are discussed in Chapter 24, “Creating and Managing Tables.”

Modifying Data Through a Partitioned View

You can modify data via a partitioned view if the SQL statement performing the modification meets certain conditions, as described here:

- ▶ All columns in the partitioned view must be specified in the INSERT statement. Columns that include a DEFAULT constraint or allow nulls are also subject to this requirement.
- ▶ The DEFAULT keyword cannot be used on inserts to partitioned views or on updates to partitioned views.
- ▶ UPDATE statements cannot modify PRIMARY KEY columns if the member tables have text, ntext, or image columns.
- ▶ Inserts and updates to a partitioned view are not allowed if the view contains a time stamp.
- ▶ Identity columns in a partitioned view cannot be modified by an INSERT or UPDATE statement.
- ▶ INSERT, UPDATE, and DELETE statements are not allowed against a partitioned view if there is a self-join with the same view or with any of the member tables in the statement.

NOTE

Data can be modified through partitioned views only in the Enterprise and Developer Editions of SQL Server 2008.

In addition to the conditions shown in this list, you must also satisfy any restrictions that apply to the member tables. Check constraints, foreign key constraints, and any other table-level restrictions must be accounted for in the modification statement. The user executing the modification against the partitioned view must have the appropriate INSERT, UPDATE, or DELETE permissions on the member tables for the update to succeed.

Distributed Partitioned Views

Microsoft provides distributed partitioned views (DPVs) as a primary means to scale out a database server. Scalability allows an application or a database to utilize additional resources, which allows it to perform more work. There are two kinds of scalability: scaleup and scaleout. A scaleup solution focuses on a single server scaled to provide more processing power than its predecessor. An example of scaleup would be migrating from a server with a single dual-core processor to a machine with 4-quad-core processor. Scaleout solutions include the addition of servers to augment the overall processing power.

DPVs are similar to local partitioned views, but they utilize one or more tables located on a remote server. The placement of partitioned data on remote servers allows the processing power of more than one server to be utilized. The partitioning is intended to be transparent to the application and allow for additional partitions and servers as the application's needs scale.

The following list outlines the basic requirements for creating a DPV:

- ▶ A linked server definition is added to each member server that will contain the partitioned data. The linked server contains the connection information required to run distributed queries on another member server.
- ▶ The `lazy_schema_validation` option is set to `true` on each of the member servers, using `sp_serveroption`. This option is set for performance reasons and allows the query processor to skip schema checking of remote tables if the query can be satisfied on a single member server.
- ▶ A DPV is created on each member server. This DPV references the local tables in addition to the tables found on the other member servers.

Listing 27.7 shows SQL commands that can be used to satisfy the requirements in the preceding list. The DPV created in the last portion of the script is similar to the local partitioned view created in the previous section. The key difference in this DPV example is the inclusion of a distributed query that retrieves records for `Sales.Sales_2002` from a remote server. The remote server in this example is named `DbSvrXP`.

LISTING 27.7 Creating a Distributed Partitioned View

```
Exec sp_addlinkedserver @server='dbsvrxp',
    @srvproduct='',
    @provider='MSDASQL',
    @provstr='DRIVER={SQL Server}';
SERVER=dbsvrxp;UID=linklogin;PWD=pw;Initial Catalog=Adventureworks2008'
```

```

--Set the server option for improved DPV performance
exec sp_serveroption dbservrpx, 'lazy schema validation', true

```

```

Create View Sales.vw_Sales_Daily
as
    SELECT * FROM Sales.Sales_2001
    UNION ALL
    SELECT * FROM dbservrpx.Adventureworks2008.Sales.Sales_2002
    UNION ALL
    SELECT * FROM Sales.Sales_2003
    UNION ALL
    SELECT * FROM Sales.Sales_2004

```

The DPV created in Listing 27.7 contains only one remote table. The example could be further expanded to have each table in the UNION clause on a different remote server. Keep in mind that the DPV CREATE statement needs to be adjusted when run on the remote server(s). The tables that are local on one server are now remote on the other server, and those that are remote can now be local.

If the DPVs are properly defined, SQL Server 2008 attempts to optimize their performance by minimizing the amount of data transferred between member servers. The query processor retrieves the CHECK constraint definitions from each member table. This allows the query processor to map the specified search arguments to the appropriate table(s). The query execution plan then accesses only the necessary tables and retrieves only the remote rows needed to complete the SQL statement.

Data can be modified through a DPV as well. Updatable DPVs, which were introduced in SQL Server 2000, are still available in SQL Server 2008. Data modifications are performed against a view, allowing true transparency. The view is accessed as if it were a base table, and the user or application is unaware of the actual location of the data. If it is configured properly, SQL Server determines via the WHERE clause specified in the update query which partition defined in the view must be updated rather than updating all tables in the join.

NOTE

Data can be modified through distributed partitioned views only in the Enterprise and Developer Editions of SQL Server 2008.

Indexed Views

You establish indexed views by creating a unique clustered index on the view itself, independent of the member tables that it references. The creation of this unique index transforms a view from an object that is virtual in nature to one that has physical storage associated with it. Like all other indexes, the index on a view takes up physical storage,

requires maintenance, and, most importantly, can provide performance benefits that justify its creation.

Creating Indexed Views

Indexed views were first available for creation in SQL Server 2000 and continue to be a viable means for improving query performance in SQL Server 2008. An index can be created on a view in all versions of SQL Server 2008, but there are limitations on some of the versions. The Developer and Enterprise Editions of SQL Server 2008 are the only editions that support the use of indexed views for queries that don't specifically reference the views. Other editions of SQL Server must reference the view by name in the SQL statements and must also use the `NOEXPAND` keyword in the query. The details of `NOEXPAND` are discussed in the section "To Expand or Not to Expand," later in this chapter.

Regardless of the edition of SQL Server you are running, some basic requirements must be satisfied for you to create an indexed view. These requirements, which follow, are detailed in SQL Server 2008 Books Online:

- ▶ The `ANSI_NULLS` and `QUOTED_IDENTIFIER` options must be set to `ON` when the `CREATE VIEW` statement is executed.
- ▶ The `ANSI_NULLS` option must be set to `ON` for the execution of all `CREATE TABLE` statements that create tables referenced by the view.
- ▶ The view must not reference any other views, only base tables.
- ▶ All base tables referenced by the view must be in the same database as the view and have the same owner as the view.
- ▶ The view must be created with the `SCHEMABINDING` option. Schema binding binds the view to the schema of the underlying base tables.
- ▶ User-defined functions referenced in the view must be created with the `SCHEMABINDING` option.
- ▶ Tables and user-defined functions must be referenced via two-part names in the view. One-part, three-part, and four-part names are not allowed.
- ▶ All functions referenced by expressions in the view must be deterministic.
- ▶ If the view definition uses an aggregate function, the `SELECT` list must also include `COUNT_BIG (*)`.
- ▶ The `DATA ACCESS` property of a user-defined function must be `NO SQL`, and the `EXTERNAL ACCESS` property must be `NO`.
- ▶ CLR functions can appear only in the `SELECT` list of the view and can reference only fields that are not part of the clustered index key. They cannot appear in the `WHERE` clause of the view or the `ON` clause of a `JOIN` operation in the view.
- ▶ CLR functions and methods of CLR user-defined types used in the view definition must have the properties set as `DETERMINISTIC = TRUE`, `PRECISE = TRUE`, `DATA ACCESS = NO SQL`, and `EXTERNAL ACCESS = NO`.

- ▶ If `GROUP BY` is specified, the view `SELECT` list must contain a `COUNT_BIG(*)` expression, and the view definition cannot specify `HAVING`, `CUBE`, or `ROLLUP`.
- ▶ The view cannot contain any of the T-SQL elements shown in the following list:

* or <code>tablename.*</code>	An expression on a column found in the <code>GROUP BY</code> clause	A derived table
A common table expression (CTE)	A rowset function	The <code>UNION</code> , <code>EXCEPT</code> , or <code>INTERSECT</code> operators
Subqueries	Outer joins or self-joins	The <code>TOP</code> clause
The <code>ORDER BY</code> clause	The <code>DISTINCT</code> keyword	<code>COUNT</code> (<code>COUNT_BIG</code> is allowed)
<code>AVG</code> , <code>MAX</code> , <code>MIN</code> , <code>STDEV</code> , <code>STDEVP</code> , <code>VAR</code> , or <code>VARP</code>	A <code>SUM</code> function that references a nullable expression	A CLR user-defined aggregate function
The full text predicate	<code>COMPUTE</code> or <code>COMPUTE BY CONTAINS</code> or <code>FREETEXT</code>	<code>CROSS APPLY</code> or <code>OUTER APPLY</code> operators
Table hints	Join hints	

You can see from this list that the number of requirements is extensive. It can therefore be difficult to determine whether all the requirements have been met for a particular view. To simplify this determination, you can query the `IsIndexable` property, using the `OBJECTPROPERTY` function. The following example demonstrates the use of the `IsIndexable` property against the `sys.views` catalog view:

```
SELECT name AS ViewName
       ,SCHEMA_NAME(schema_id) AS SchemaName
       ,OBJECTPROPERTYEX(object_id,'IsIndexed') AS IsIndexed
       ,OBJECTPROPERTYEX(object_id,'IsIndexable') AS IsIndexable
       ,create_date
       ,modify_date
FROM sys.views;
```

The `IsIndexable` property returns a 1 (or `TRUE`) if an index can be created on the view and a 0 if it is not indexable. Most of the views in the `Adventureworks2008` database are not indexable, but the database does contain a couple of examples of views that have been indexed. The following example shows the `CREATE` statement for an index on the `vProductAndDescription` view. The `SET` options required when creating the index are included in the example as well:

```
SET ARITHABORT ON — for 80 compatibility or earlier
GO
SET CONCAT_NULL_YIELDS_NULL ON
GO
```

```

SET QUOTED_IDENTIFIER ON
GO
SET ANSI_NULLS ON
GO
SET ANSI_PADDING ON
GO
SET ANSI_WARNINGS ON
GO
SET NUMERIC_ROUNDABORT OFF
GO

CREATE UNIQUE CLUSTERED INDEX [IX_vProductAndDescription]
  ON [Production].[vProductAndDescription]
(
    [CultureID] ASC,
    [ProductID] ASC
)

```

The following example shows the `Production.vProductAndDescription` view that the index was created on:

```

CREATE VIEW [Production].[vProductAndDescription]
WITH SCHEMABINDING
AS
View (indexed or standard) to display products
—and product descriptions by language.
SELECT
    p.[ProductID]
    ,p.[Name]
    ,pm.[Name] AS [ProductModel]
    ,pmx.[CultureID]
    ,pd.[Description]
FROM [Production].[Product] p
    INNER JOIN [Production].[ProductModel] pm
    ON p.[ProductModelID] = pm.[ProductModelID]
    INNER JOIN [Production].[ProductModelProductDescriptionCulture] pmx
    ON pm.[ProductModelID] = pmx.[ProductModelID]
    INNER JOIN [Production].[ProductDescription] pd
    ON pmx.[ProductDescriptionID] = pd.[ProductDescriptionID];

```

Indexed Views and Performance

Adding indexes to tables is a generally accepted means for improving database performance. Indexes provide a keyed lookup to rows of data that can improve database access and avoid the performance nightmare of a table scan where the entire contents of a table

are searched. The same basic principles apply to indexes on views, but indexed views are best utilized to increase performance in the following scenarios:

- ▶ Aggregations such as `SUM` or `AVG` can be precomputed and stored in the index to minimize the potentially expensive computations during query execution.
- ▶ Large table joins can be persisted to eliminate the need to write a join when retrieving the data.
- ▶ A combination of aggregations and large table joins can be stored.

The performance improvements from the aforementioned scenarios can be significant and can justify the use of an index. The Query Optimizer can use the precomputed results stored in the view's index and avoid the cost of aggregating or joining the underlying tables. Keep in mind that the Query Optimizer may still use the indexes found on the member tables of the view instead of the index on the view. The Query Optimizer uses the following conditions in determining whether the index on the view can be utilized:

- ▶ The tables in the query `FROM` clause must be a superset of the tables in the indexed view's `FROM` clause. In other words, the query must contain all the tables in the view. The query can contain additional tables not contained in the view.
- ▶ The join conditions in the query must be a superset of the view's join conditions.
- ▶ The aggregate columns in the query must be derivable from a subset of the aggregate columns in the view.
- ▶ All expressions in the query `SELECT` list must be derivable from the view `SELECT` list or from the tables not included in the view definition.
- ▶ All columns in the query search condition predicates that belong to tables in the view definition must appear in the `GROUP BY` list, the `SELECT` list if there is no `GROUP BY`, or the same or equivalent predicate in the view definition.

NOTE

Predicting the Query Optimizer's use of an indexed view can be complicated and depends on the complexity of the view that is indexed and the complexity of the query that may utilize the view. A detailed discussion of these scenarios is beyond the scope of this chapter, but the Microsoft TechNet article "Improving Performance with SQL Server 2005 Indexed Views" provides that detail. This article includes more than 20 examples that illustrate the use of indexed views and the conditions the Query Optimizer uses in selecting an indexed view. As you can see from the title, this article was written for SQL Server 2005, but the content is still relative for SQL Server 2008.

The flip side of performance with indexes (including those on views) is that there is a cost in maintaining an index. This cost can adversely affect the performance of data modifications against objects that have these indexes. Generally speaking, indexes should *not* be placed on views that have underlying data sets that are frequently updated. Caution must

be exercised when placing indexes on views that support online transaction processing (OLTP) applications. A balance must be struck between improving the performance of database modification and improving the performance of database inquiry. Indexed views improve database inquiry. Databases used for data warehousing and decision support are usually the best candidates for indexed views.

The impact of data modifications on indexed views is exacerbated by the fact that the complete result set of a view is stored in the database. When the clustered index is created on a view, you specify the clustered index key(s) in the `CREATE UNIQUE CLUSTERED INDEX` statement, but more than the columns in the key are stored in the database. As in a clustered index on a base table, the B-tree structure of the clustered index contains only the key columns, but the data rows contain all the columns in the view's result set.

The increased space utilized by the index view is demonstrated in the following examples. This first example creates a view and an associated index view similar to the Adventureworks2008 `Production.vProductAndDescription` view used in a prior example:

```
result set
CREATE VIEW [Production].[vProductAndDescription_2]
WITH SCHEMABINDING
AS
View (indexed or standard) to display products and
— product descriptions by language.
SELECT
    p.[ProductID]
    ,pmx.[CultureID]
FROM [Production].[Product] p
    INNER JOIN [Production].[ProductModel] pm
    ON p.[ProductModelID] = pm.[ProductModelID]
    INNER JOIN [Production].[ProductModelProductDescriptionCulture] pmx
    ON pm.[ProductModelID] = pmx.[ProductModelID]
    INNER JOIN [Production].[ProductDescription] pd
    ON pmx.[ProductDescriptionID] = pd.[ProductDescriptionID];
go
CREATE UNIQUE CLUSTERED INDEX [IX_vProductAndDescription_2]
ON [Production].[vProductAndDescription_2]
(
    [CultureID] ASC,
    [ProductID] ASC
)
```

The difference with this new view is that the result set returns only the two columns in the clustered index; there are no additional columns in the result set.

When the new view and associated index are created, you can compare the amount of physical storage occupied by each. The following example shows the `sp_spaceused` commands for each view and the associated results:

```
exec sp_spaceused 'Production.vProductAndDescription'
```

```

/* results
name                rows        reserved    data        index_size  unused
-----
vProductAndDescription  1764      592 KB     560 KB     16 KB       16 KB
*/
exec sp_spaceused 'Production.vProductAndDescription_2'
/* results
name                rows        reserved    data        index_size  unused
-----
vProductAndDescription_2  1764      64 KB      48 KB      16 KB       0 KB
*/

```

Take note of the reserved space and data results for each view. The view that was created with only two result columns takes much less space than the view that has an index with five result columns. You need to consider the overhead of storing these additional result columns along with the index when creating the view and related index. Changes made to any of the columns in the base tables that are part of the view results must also be maintained for the index view as well.

Nonclustered indexes can be created on a view, and they can also provide added query performance benefits when used properly. Typically, columns that are not part of the clustered index on a view are added to the nonclustered index. Like nonclustered indexes on tables, the nonclustered indexes on the view provide additional options for the Query Optimizer when it is choosing the best query path. Common search arguments and foreign key columns that may be joined in the view are common targets for nonclustered indexes.

To Expand or Not to Expand

The expansion of a view to its base tables is a key consideration when evaluating the use of indexes on views. The SQL Server Query Optimizer can expand a view to its base tables or decide to utilize indexes that are found on the view itself. The selection of an index on a view is directly related to the edition of SQL Server 2008 you are running and the expansion options selected for a related query.

As mentioned earlier, the Enterprise and Developer Editions are the only editions that allow the Query Optimizer to use an indexed view to solve queries that structurally match the view, even if they don't refer to the view by name. For other editions of SQL Server 2008, the view must be referenced in the query, and the `NOEXPAND` hint must be used as well for the Query Optimizer to consider the index on the view. The following example demonstrates the use of the `NOEXPAND` hint:

```

SELECT *
FROM Production.vProductAndDescription (NOEXPAND)
WHERE cultureid = 'he'

```

When this example is run against the Adventureworks2008 database, the execution plan indicates that a clustered index seek will be performed, using the index on the view. If the NOEXPAND hint is removed from the query, the execution plan will ignore the index on the view and return the results from the base table(s). The only exception to this is when the Enterprise or Developer Edition is used. These editions can always consider indexed views but may or may not choose to use them.

SQL Server also has options to force the Query Optimizer to use the expanded base tables and ignore indexed views. The (EXPAND VIEWS) query hint ensures that SQL Server will process a query by accessing data directly from the base tables. This option might seem counterproductive, but it can be useful in situations in which contention exists on an indexed view. It is also handy for testing indexed views and determining overall performance with and without the use of indexed views.

The following example, which utilizes the same view as the previous example, demonstrates the use of the (EXPAND VIEWS) query hint:

```
SELECT *
FROM Production.vProductAndDescription
WHERE cultureid = 'he'
OPTION (EXPAND VIEWS)
```

The query plan in this example shows the use of the base tables, and the index on the view is ignored. For more information on query optimization and indexes, see Chapter 34.

Summary

Views provide a broad spectrum of functionality, ranging from simple organization to improved overall query performance. They can simplify life for developers and users by filtering the complexity of a database. They can help organize data access and provide a security mechanism that helps keep a database safe. Finally, they can provide performance improvements via the use of partitioned views and indexed views that help keep your database fast.

Some of the same benefits, including performance and security benefits, can also be achieved through the use of stored procedures. Chapter 28, “Creating and Managing Stored Procedures,” delves into these useful and powerful database objects.

This page intentionally left blank

CHAPTER 28

Creating and Managing Stored Procedures

A *stored procedure* is one or more SQL commands stored in a database as an executable object. Stored procedures can be called interactively, from within client application code, from within other stored procedures, and from within triggers. Parameters can be passed to and returned from stored procedures to increase their usefulness and flexibility. A stored procedure can also return a number of result sets and a status code.

What's New in Creating and Managing Stored Procedures

Unlike SQL Server 2005 with its addition of .NET CLR stored procedures, SQL Server 2008 doesn't introduce any significant changes to the creation and functionality of stored procedures. However, one of the most welcome enhancements is the return of the Transact-SQL (T-SQL) debugger to SQL Server Management Studio (SSMS). System administrators can now debug stored procedures without having to install Visual Studio (VS). An introduction to debugging stored procedures is provided later in this chapter in the section "Debugging Stored Procedures Using SQL Server Management Studio."

One small enhancement to the functionality of stored procedures in SQL Server 2008 is the capability to use table-valued parameters. Table-valued parameters allow you to pass table variables as input parameters to stored procedures so that the contents may be accessed from within the stored procedure. In previous versions of SQL Server, it was not possible to access the contents of table variables outside

- ▶ Startup Procedures

the scope in which they were declared. The “Using Table-Valued Parameters” section in this chapter provides a description and examples on how to make use of this new feature.

One other enhancement in SQL Server 2008 is that there is no longer a maximum size for your stored procedure source code.

Advantages of Stored Procedures

Using stored procedures provides many advantages over executing large and complex SQL batches from client applications. Following are some of them:

- ▶ **Modular programming**—Subroutines and functions are often used in ordinary 3GL and 4GL languages (such as C, C++, and Microsoft Visual Basic) to break code into smaller, more manageable pieces. The same advantages are achieved when using stored procedures, with the difference that the stored procedure is stored in SQL Server and can be called by any client application.
- ▶ **Restricted, function-based access to tables**—A user can have permission to execute a stored procedure without having permissions to operate directly on the underlying tables.
- ▶ **Reduced network traffic**—Stored procedures can consist of many individual SQL statements but can be executed with a single statement. This allows you to reduce the number and size of calls from the client to the server.
- ▶ **Faster execution**—Stored procedures’ query plans are kept in memory after the first execution. The code doesn’t have to be reparsed and reoptimized on subsequent executions.
- ▶ **Enforced consistency**—If users modify data only through stored procedures, problems that often result from ad hoc modifications (such as omitting a crucial WHERE clause) are eliminated.
- ▶ **Reduced operator and programmer errors**—Because less information is being passed, complex tasks can be executed more easily, with less likelihood of SQL errors.
- ▶ **Automating complex or sensitive transactions**—If all modifications of certain tables take place in stored procedures, you can guarantee the data integrity on those tables.

Some of the disadvantages of using stored procedures (depending on the environment) are as follows:

- ▶ **Increase in server processing requirements**—Using stored procedures can increase the amount of processing that takes place on the server. In a large user environment with considerable activity in the server, it may be more desirable to offload some of the processing to the client workstation.
- ▶ **Less cross-DBMS portability**—Although the ANSI-99 SQL standard provides a standard for stored procedures in database management systems (DBMSs), the format and structure are different from those of SQL Server stored procedures. These

procedures would all have to be rewritten to be compatible with another DBMS environment.

Should you use stored procedures? The answer is (as it often is), it depends.

If you are working in a two-tier environment, using stored procedures is often advantageous. The trend is shifting to three- (or more) tier environments. In such environments, business logic is often handled in some middle tier (possibly ActiveX objects managed by Microsoft Transaction Server). If you operate in that type of environment, you might want to restrict the stored procedures to performing basic data-related tasks, such as retrievals, insertions, updates, and deletions.

NOTE

You can use stored procedures to make a database sort of a “black box” as far as the developers and the application code are concerned. If all database access is managed through stored procedures, the applications are shielded from possible changes to the underlying database structures.

For example, one organization found the need to split one table across multiple databases. By simply modifying the existing stored procedures to handle the multiple tables and by using distributed partitioned views, the company was able to make this change without requiring any changes to the front-end application code.

Creating Stored Procedures

To create a stored procedure, you need to give the procedure a unique name within the schema and then write the sequence of SQL statements to be executed within the procedure. Following is the basic syntax for creating stored procedures:

```
CREATE { PROC | PROCEDURE } [schema_name.]procedure_name [ ; number ]
    [ { @parameter [ schema_name.]data_type }
      [ VARYING ] [ = default ] [ OUT | OUTPUT ] [READONLY]
    ] [ ,...n ]
[ WITH { [ ENCRYPTION ]
        , [ RECOMPILE ]
        , [ EXECUTE_AS_Clause ]
        [ ,...n ]
      }
[ FOR REPLICATION ]
AS
[BEGIN]
    SQL_Statements
[ RETURN scalar_expression ]
[END]
```

It is good programming practice to always end a procedure with the RETURN statement and to specify a return status other than 0 when an error condition occurs. Listing 28.1 shows

a simple stored procedure that returns book titles and the names of the authors who wrote them.

LISTING 28.1 A Sample Stored Procedure

```

use bigpubs2008
go
IF EXISTS ( SELECT * FROM sys.procedures
            WHERE schema_id = schema_id('dbo')
            AND name = N'title_authors')
    DROP PROCEDURE dbo.title_authors
GO
CREATE PROCEDURE title_authors
AS
BEGIN
    SELECT a.au_lname, a.au_fname, t.title
        FROM titles t INNER JOIN
            titleauthor ta ON t.title_id = ta.title_id RIGHT OUTER JOIN
            authors a ON ta.au_id = a.au_id
    RETURN 0
END

```

NOTE

Unless stated otherwise, all examples in this chapter run in the context of the bigpubs2008 database.

Creating Procedures in SSMS

To create a stored procedure in SSMS, open the object tree for the database in which you want to create the procedure, open the Programmability folder, right-click the Stored Procedures folder, and from the context menu, choose New Stored Procedure. SSMS opens a new query window, populated with code that is based on a default template for stored procedures. Listing 28.2 shows an example of the default template code for a stored procedure that would be opened into a new query window.

LISTING 28.2 An Example of a New Stored Procedure Creation Script Generated by SSMS

```

-- =====
-- Template generated from Template Explorer using:
-- Create Procedure (New Menu).SQL
--
-- Use the Specify Values for Template Parameters
-- command (Ctrl-Shift-M) to fill in the parameter
-- values below.

```

```

--
-- This block of comments will not be included in
-- the definition of the procedure.
.. =====
SET ANSI_NULLS ON
GO
SET QUOTED_IDENTIFIER ON
GO
.. =====
-- Author:          <Author,,Name>
-- Create date: <Create Date,,>
-- Description:     <Description,,>
.. =====
CREATE PROCEDURE <Procedure_Name, sysname, ProcedureName>
    - Add the parameters for the stored procedure here
    <@Param1, sysname, @p1> <Datatype_For_Param1, , int> =
<Default_Value_For_Param1, , 0>,
    <@Param2, sysname, @p2> <Datatype_For_Param2, , int> =
<Default_Value_For_Param2, , 0>
AS
BEGIN
    - SET NOCOUNT ON added to prevent extra result sets from
    - interfering with SELECT statements.
    SET NOCOUNT ON;

    -- Insert statements for procedure here
    SELECT <@Param1, sysname, @p1>, <@Param2, sysname, @p2>
END
GO

```

You can modify the template code as necessary to set the procedure name and to specify the parameters, return value, and procedure body. When you are finished, you can execute the contents of the query window to create the procedure. After you have created the procedure successfully, it is recommended that you save the source code to a file by choosing the Save or Save As option from the File menu. This way, you can re-create the stored procedure from the file if it is accidentally dropped from the database.

TIP

When you create a new stored procedure in SSMS, the procedure does not show up in the Stored Procedures folder in the Object Browser unless you right-click the Stored Procedures folder and choose the Refresh option.

One thing you might notice about the stored procedure template is that it contains template parameters for parameter names, procedure name, author name, create date, and so on. These template parameters are in the format `<parameter, type, value>`:

- ▶ *parameter_name* is the name of the template parameter in the script.
- ▶ *data_type* is the optional data type of the template parameter.
- ▶ *value* is the default value to be used to replace every occurrence of the template parameter in the script

You can auto substitute values for template parameters by selecting Query, Specify Values for Template Parameters or by pressing Ctrl+Shift+M. This brings up the dialog shown in Figure 28.1.

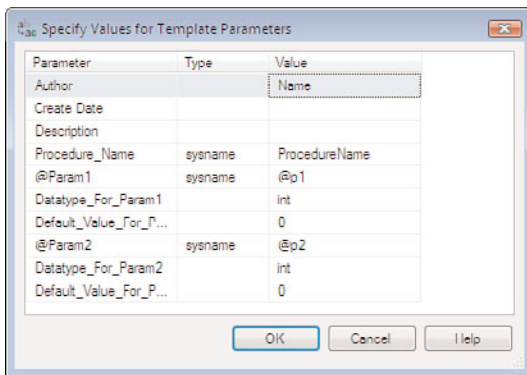

FIGURE 28.1 Using the Specify Values for Template Parameters dialog in SSMS.

You enter the values for the template parameters in the Value column and then click OK. SSMS then substitutes any values you specified wherever the template parameter is used within the template.

An alternative way to create a stored procedure from a template is to use the Template Explorer in SSMS. You can open the Template Explorer by selecting View, Template Explorer in SSMS or by pressing Ctrl+Alt+T. The Template Explorer window appears in SSMS, as shown in Figure 28.2.

You can double-click the name of the stored procedure template you want to use or right-click the desired template and then select Open. SSMS opens a new query window, populated with the template code.

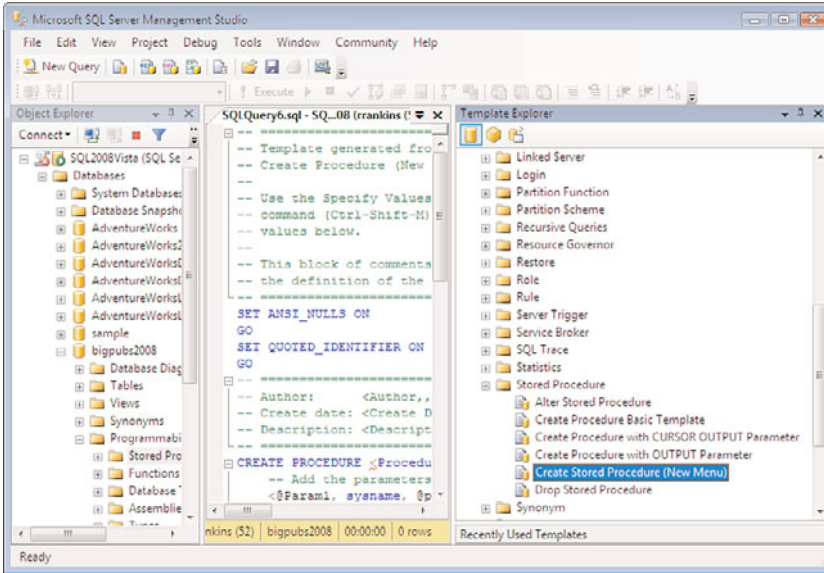

FIGURE 28.2 Using the Template Explorer for creating stored procedures in SSMS.

NOTE

It is also possible to edit the provided stored procedure templates available in the Template Explorer by right-clicking them and selecting the Edit option. You can then customize the templates to include code fragments, comments, or structure that is more to your preference and save the changes to the template file. However, it is generally recommended that you not modify the provided templates and instead create your own custom templates.

Creating Custom Stored Procedure Templates

To create a custom stored procedure template, right-click the Stored Procedure folder in the Template Explorer and select New. SSMS then creates an entry in the Template Explorer, and you can specify the name for the template.

To begin adding code to the template, right-click the template and select Edit. This opens a query window in which you can start entering the new template code. Probably the best way to get started is to copy the template code from one of the templates provided with SQL Server 2008 and then modify it as you desire. You then select File, Save to save the template code to the file.

Listing 28.3 shows an example of a new stored procedure template.

LISTING 28.3 An Example of Custom Stored Procedure Template

```

-- =====
-- Create basic stored procedure template
-- =====

-- Drop stored procedure if it already exists
IF EXISTS (
  SELECT *
  FROM sys.procedures
  WHERE schema_id = schema_id('dbo')
  AND name = N'<Proc_Name, sysname, myproc>'
)
DROP PROCEDURE <Schema_Name, sysname, dbo>.<Proc_Name, sysname, myproc>
GO
-- =====
-- Author:          <Author,,Name>
-- Create date:    <Create Date,,>
-- Description:    <Description,,>
-- =====
CREATE PROCEDURE <Schema_Name, sysname, dbo>.<Proc_Name, sysname, myproc>
  -- Add the parameters for the stored procedure here
  <@param1, sysname, @p1> <param1_type, , int> = <param1_default, , 0>,
  <@param2, sysname, @p2> <param2_type, , int> = <param2_default, , 0>,
  <@param3, sysname, @p3> <param3_type, , int> OUTPUT
AS
BEGIN
  -- SET NOCOUNT ON added to prevent extra result sets from
  -- interfering with SELECT statements.
  SET NOCOUNT ON;

  DECLARE @trancnt int
  SELECT @trancnt = @@TRANCOUNT

  if @trancnt = 0
    BEGIN TRAN <Proc_Name, sysname, myproc>
  else
    SAVE TRAN <Proc_Name, sysname, myproc>

  /* Insert processing code here */

  if (@@error != 0) -- check for error condition
  begin
    -- rollback to savepoint, or begin tran
    rollback tran <Proc_Name, sysname, myproc>
    -- return error code indicating rollback

```

```

        return -101
    end

    /* Insert more processing here if required */

    -- set value of output parameter
    set <@param3,sysname, @p3> = <@param1,sysname, @p1> + <@param2,sysname, @p2>

    if @trancnt = 0      -- this proc issued begin tran
        -- commit tran, decrement @@trancount to 0
        commit tran <Proc_Name, sysname, myproc>
        -- commit not required with save tran

    return 0 /* successful return */

END
GO

-- =====
-- Example to execute the stored procedure
-- =====
DECLARE <@output_variable, sysname, @p3_output> <output_datatype, , int>

EXECUTE <Schema_name, sysname, dbo>.<Proc_name, sysname, myproc>
    <@param1, sysname, @p1> = <param1_value, , 1>,
    <@param2, sysname, @p2> = <param2_value, , 1>,
    <@param3, sysname, @p3> = <@output_variable, sysname, @p3_output> OUTPUT

SELECT <@output_variable, sysname, @p3_output>
GO

```

After you define a custom stored procedure template, you can use it as you would use the built-in templates. You can double-click it or right-click and select Open, and SSMS opens a new query window with a new stored procedure creation script based on the custom template. If you use the default values for the template parameters, after the parameter substitution, the CREATE PROCEDURE script looks like the one in Listing 28.4.

LISTING 28.4 An Example of a **CREATE PROCEDURE** Script Generated from the Custom Stored Procedure Template

```

.. =====
.. Create basic stored procedure template
.. =====

```

```

-- Drop stored procedure if it already exists
IF EXISTS (
  SELECT *
    FROM sys.procedures
   WHERE schema_id = schema_id('dbo')
     AND name = N'myproc'
)
  DROP PROCEDURE dbo.myproc
GO

-- =====
-- Author:          Name
-- Create date:
-- Description:
-- =====
CREATE PROCEDURE dbo.myproc
  -- Add the parameters for the stored procedure here
  @p1 int = 0,
  @p2 int = 0,
  @p3 int OUTPUT
AS
BEGIN
  -- SET NOCOUNT ON added to prevent extra result sets from
  -- interfering with SELECT statements.
  SET NOCOUNT ON;

  DECLARE @trancnt int
  SELECT @trancnt = @@TRANCOUNT

  if @trancnt = 0
    BEGIN TRAN myproc
  else
    SAVE TRAN myproc

  /* Insert processing code here */

  if (@@error != 0) -- check for error condition
  begin
    -- rollback to savepoint, or begin tran
    rollback tran myproc
    -- return error code indicating rollback
    return -101
  end

  /* Insert more processing here if required */

```

```

-- set value of output parameter
set @p3 = @p1 + @p2

if @trancnt = 0      -- this proc issued begin tran
  -- commit tran, decrement @@trancount to 0
  commit tran myproc
-- commit not required with save tran

return 0 /* successful return */

END
GO

-- =====
-- Example to execute the stored procedure
-- =====
DECLARE @p3_output int

EXECUTE dbo.myproc
    @p1 = 1,
    @p2 = 1,
    @p3 = @p3_output OUTPUT

SELECT @p3_output
GO

```

Temporary Stored Procedures

SQL Server enables you to create private and global temporary stored procedures. Temporary stored procedures are analogous to temporary tables in that they can be created with the # and ## prefixes added to the procedure name. The # prefix denotes a local temporary stored procedure; ## denotes a global temporary stored procedure. A local temporary stored procedure can be executed only by the connection that created it, and the procedure is automatically deleted when the connection is closed. A global temporary stored procedure can be accessed by multiple connections and exists until the connection used by the user who created the procedure is closed and any currently executing versions of the procedure by any other connections are completed.

If a stored procedure not prefixed with # or ## is created directly in the tempdb database, the stored procedure exists until SQL Server is shut down. Procedures created directly in tempdb continue to exist even after the creating connection is terminated.

Temporary stored procedures are provided for backward compatibility with earlier versions of SQL Server that did not support the reuse of execution plans for T-SQL statements or batches. Applications connecting to SQL Server 2000 and higher should use the `sp_executesql` system stored procedure to execute dynamic SQL statements instead of creating temporary stored procedures.

TIP

It is strongly recommended that `sp_executesql` be used instead of temporary stored procedures. Excessive use of temporary stored procedures can lead to locking contention on the system tables in `tempdb`, which can adversely affect overall system performance. For more information on using `sp_executesql`, see Chapter 44, "Advanced Stored Procedure Programming and Optimization."

Executing Stored Procedures

To execute a stored procedure, you simply invoke it by using its name (the same way you probably have already executed system stored procedures, such as `sp_help`). If the execution of the stored procedure isn't the first statement in a batch, you need to precede the procedure name with the `EXEC` keyword. Following is the basic syntax for executing stored procedures:

```
[EXEC[UTE]] [@status =] [schema].procedure_name[; number]
  [[@param_name =] expression [output][, ... ]]
[WITH RECOMPILE]
```

NOTE

The reason you need the `EXEC` keyword when invoking a stored procedure in a batch or other stored procedure is quite simple. SQL Server parses the commands sent to it in a batch by searching for keywords. Stored procedure names aren't keywords. If SQL Server finds a procedure name among the SQL statements, chances are that SQL Server will return an error message because it tries to treat it as part of the preceding command. Sometimes the execution is successful, but SQL Server doesn't execute what you want. Consider this example:

```
SELECT * FROM titles
sp_help
```

The `SELECT` statement runs fine, but the procedure is not executed. The reason is that `sp_help` ends up being used as a table alias for the `titles` table in the `SELECT` statement.

However, if you precede the procedure name with `EXEC`, like this, you get the expected behavior:

```
SELECT * FROM titles
```

```
EXEC sp_help
```

Why don't you have to put EXEC in front of the procedure name if the procedure is the first statement in a batch? If SQL Server doesn't recognize the first string in a batch, it simply assumes that it is a name of a stored procedure. For example, execute the following string and notice the error message:

```
Dsfdskgkghk
```

```
go
```

```
Msg 2812, Level 16, State 62, Line 1
```

```
Could not find stored procedure 'Dsfdskgkghk'.
```

As good programming practice, it is best to always precede stored procedures with the EXEC keyword. This way, it will always work as expected, whether or not it's the first statement in a batch.

Executing Procedures in SSMS

To execute a stored procedure in SSMS, open the object tree for the database, open the Programmability folder, and open the Stored Procedures folder. Then right-click the stored procedure, and from the context menu, choose Execute Stored Procedure. SSMS then presents you with the Execute Procedure dialog, as shown in Figure 28.3. In this window, you can enter values for any parameters contained in the stored procedure. If you want to pass a NULL value to a parameter, you need to be sure to place a check mark in the Pass Null Value check box for that parameter.

After you specify values for all the parameters, SSMS opens a new query window with the generated execute statement and automatically executes it. It displays any results in the Results window. If the stored procedure contains output parameters, SSMS generates local variables for the output parameters and uses a SELECT statement to display the values returned to the output parameters. Listing 28.5 shows an example of the execute script and its results for the procedure invoked in Figure 28.3 (this procedure is the one generated from the custom procedure template, as shown in Listing 28.4).

LISTING 28.5 A Procedure Execution Script Generated by SSMS

```
USE [bigpubs2008]
GO

DECLARE    @return_value int,
           @p3 int

EXEC @return_value = [dbo].[myproc]
           @p1 = 100,
           @p2 = 200,
           @p3 = @p3 OUTPUT
```

```
SELECT @p3 as N'@p3'
```

```
SELECT 'Return Value' = @return_value
```

```
GO
```

```
@p3
```

```
-----  
300
```

```
Return Value
```

```
-----  
0
```

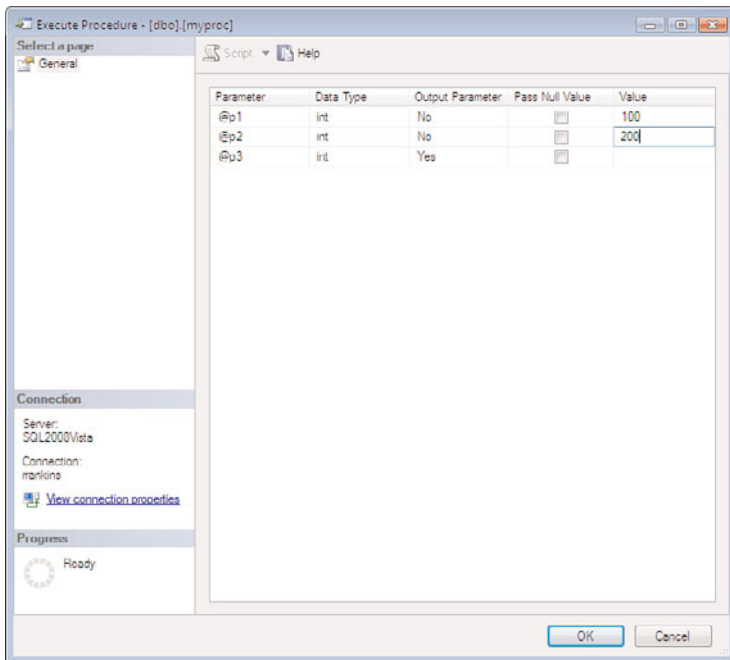

FIGURE 28.3 Using the Execute Procedure dialog in SSMS.

Execution Context and the EXECUTE AS Clause

Normally, stored procedures execute within the security context of the current user. The user must have execute permission on the procedure and if the objects referenced within the stored procedure are not owned by the user who created the stored procedure, the current user must also have the necessary permissions granted on the referenced objects. The current user does not inherit the permissions of the procedure creator. The only

exception to this occurs when the objects referenced by a stored procedure *are* owned by the same user who created the stored procedure. In this case, permissions on the referenced objects in the stored procedure are dependent on the ownership chain that exists between the calling procedure and referenced objects. For example, if the creator of a stored procedure also owns the table that it references, the user executing the stored procedure inherits the rights on the referenced table from the owner within the context of the stored procedure, without having to be granted explicit rights on the table by the table owner.

However, there are limitations to using ownership chaining alone for inheriting access permissions:

- ▶ The rights inherited by ownership chaining apply only to DML statements: SELECT, INSERT, UPDATE, and DELETE.
- ▶ The owners of the calling and called objects must be the same.
- ▶ The rights inherited by ownership chaining do not apply to dynamic queries inside the stored procedure.

In SQL Server 2008, you can implicitly define the execution context of functions (except inline table-valued functions), stored procedures, and triggers by specifying the EXECUTE AS clause. The EXECUTE AS clause allows you to go beyond ownership chaining to specify the security context under which a stored procedure will execute and what access rights the user will have on the referenced objects. The EXECUTE AS clause allows you to specify explicitly the security context under which the stored procedure will execute. In other words, it allows you to specify which user account SQL Server should use to validate permissions on the database objects referenced by the stored procedure. The user executing the stored procedure, in effect, impersonates the user specified in the EXECUTE AS clause within the context of the execution of the stored procedure.

The EXECUTE AS clause can be specified when the stored procedure is created to set the default security context for all users when executing the stored procedure. Alternatively, the EXECUTE AS clause can be specified explicitly within the stored procedure code or within each individual user session. When specified in a user session, the security context switches to that specified until the connection is closed, a REVERT statement is run, or another EXECUTE AS statement is run.

The syntax of the EXECUTE AS clause for stored procedures is as follows:

```
{ EXEC | EXECUTE } AS { CALLER | SELF | OWNER | 'user_name' }
```

You can specify the following security context options when using the EXECUTE AS clause:

- ▶ **CALLER**—This option specifies that the statements inside the stored procedure are executed in the context of the caller of the module (that is, the current user). The user executing the stored procedure must have execute permission on the stored procedure and also permissions on any database objects that are referenced by the stored procedure that are not owned by the procedure creator. **CALLER** is the default behavior for all stored procedures, and it is the same as SQL Server 2000 behavior.

- ▶ **SELF**—This option is equivalent to **EXECUTE AS** *user_name*, where the specified user is the person creating or modifying the stored procedure.
- ▶ **OWNER**—This option specifies that the statements inside the stored procedure execute in the context of the current owner of the stored procedure. If the procedure does not have a specified owner, the owner of the schema in which the procedure was created is used. **OWNER** must map to a single user account and cannot be a role or group.
- ▶ '*user_name*'—This option specifies that the statements inside the stored procedure execute in the context of the **user_name** specified. Permissions for any objects within the stored procedure are verified against this user. The user specified must exist in the current database and cannot be a group, role, certificate, key, or built-in account.

To determine the execution context of a stored procedure, you can query the *execute_as_principal_id* column in either the `sys.sql_modules` or `sys.assembly_modules` catalog view.

Specifying an execution context for a stored procedure can be very useful when you want to define custom permission sets. For example, some actions, such as `TRUNCATE TABLE`, cannot be explicitly granted to other users. However, if you use the `EXECUTE AS` clause to set the execution context of a stored procedure to a user who does have truncate table permissions (for example, a user who has permissions to alter the table), you can then incorporate the `TRUNCATE TABLE` statement within the procedure. Any user to whom you then grant `EXECUTE` permission on the stored procedure is able to run it to execute the `TRUNCATE TABLE` command contained in it.

TIP

When using the `EXECUTE AS` clause to customize the permission set for a stored procedure, it is good security policy to specify a login or user that has the least privileges required to perform the operations defined in the stored procedure. Do not specify an account such as a database owner account unless those permissions are required.

To specify the `EXECUTE AS` clause when you create or modify a stored procedure and specify a user account other than your own, you must have impersonate permissions on the specified user account in addition to having permissions to create or alter the stored procedure. When no execution context is specified or `EXECUTE AS CALLER` is specified, impersonate permissions are not required.

The following example demonstrates how the user context changes when you use the `EXECUTE AS` clause in the creation of a stored procedure:

```
use bigpubs2008
go
sp_addlogin fred, fred2008
go
```

```

sp_grantdbaccess fred
go

create proc test_execute_as
with EXECUTE AS 'fred'
as
select user_name() as 'User context within proc'
go

select user_name() as 'User context before EXEC'
exec test_execute_as

```

```

User context before EXEC
-----
dbo

User context within proc
-----
fred

```

Deferred Name Resolution

In SQL Server 2008, the object names that a stored procedure references do not have to exist at the time the procedure is created. SQL Server 2008 checks for the existence of database objects at the time the stored procedure is executed and returns an error message at runtime if the referenced object doesn't exist. The only exception is when a stored procedure references another stored procedure that doesn't exist. In that case, a warning message is issued, but the stored procedure is still created (see Listing 28.6).

LISTING 28.6 Procedure Name Resolution During Stored Procedure Creation

```

create proc p2
as
exec p3
go

```

The module 'p2' depends on the missing object 'p3'. The module will still be created; however, it cannot run successfully until the object exists.

When a table or view *does* exist at procedure creation time, the column names in the referenced table are validated. If a column name is mistyped or doesn't exist, the procedure is not created (see Listing 28.7).

LISTING 28.7 Column Name Validation in Stored Procedures

```

IF EXISTS ( SELECT * FROM sys.procedures
            WHERE schema_id = schema_id('dbo')
            AND name = N'get_authors_and_titles')
    DROP PROCEDURE dbo.get_authors_and_titles
GO
create proc get_authors_and_titles
as

select a.au_lname, au_fname, title, isbn_number
    from authors a join titleauthor ta on a.au_id = ta.au_id
    join titles t on t.title_id = ta.title_id
return
go

```

```

Server: Msg 207, Level 16, State 1, Procedure get_authors_and_titles, Line 4
Invalid column name 'isbn_number'.

```

One advantage of delayed (or deferred) name resolution is the increased flexibility when creating stored procedures; the order of creating procedures and the tables they reference does not need to be exact. Delayed name resolution is an especially useful feature when a stored procedure references a temporary table that isn't created within that stored procedure. However, at other times, it can be frustrating to have a stored procedure create successfully only to have it fail when it runs due to a missing table, as shown in Listing 28.8.

LISTING 28.8 Runtime Failure of a Stored Procedure with an Invalid Object Reference

```

create proc get_authors_and_titles
as

select a.au_lname, au_fname, title, pub_date
    from authors a join titleauthor ta on a.au_id = ta.au_id
    join books t on t.title_id = ta.title_id

go

EXEC get_authors_and_titles
go

```

```

Server: Msg 208, Level 16, State 1, Procedure get_authors_and_titles, Line 4
Invalid object name 'books'.

```

Another issue to be careful of with deferred name resolution is that you can't rename objects referenced by stored procedures and have the stored procedure continue to work. In versions of SQL Server prior to 7.0, after the stored procedure was created, object references within the stored procedure were made via the object ID rather than the object name. This allowed stored procedures to continue to function properly if a referenced object was renamed. However, now that object names are resolved at execution time, the procedure fails at the statement referencing the renamed object. For the stored procedure to execute successfully, it needs to be altered to specify the new object name.

Identifying Objects Referenced in Stored Procedures

Because changing the name of a table can cause stored procedures to no longer work, you might want to identify which stored procedures reference a specific table so you know which stored procedures will be affected by changes to the table name or columns. You can view the dependencies between database objects by querying the `sys.sql_dependencies` object catalog view. Unfortunately, all you really see if you query the `sys.sql_dependencies` view is a bunch of numbers—just the IDs of the objects and columns that have a dependency relationship, along with some additional status information.

The better way to display a list of stored procedures that reference a specific table or view, or to display a list of objects referenced by a stored procedure, is to use the `sys.dm_sql_referencing_entities` and `sys.dm_sql_referenced_entities` dynamic management functions.

```
sys.dm_sql_referencing_entities ( ' schema_name.table_or_view_name ' , ' OBJECT ' )
sys.dm_sql_referenced_entities ( ' schema_name.proc_name ' , ' OBJECT ' )
```

For example, to display the stored procedures, triggers, functions, and views that reference the `titles` table, you would execute the following:

```
select referencing_schema_name, referencing_entity_name
  From sys.dm_sql_referencing_entities ( 'dbo.titles' , 'OBJECT' )
go
```

In the `bigpubs2008` database, the `titles` table is referenced by the following:

```
referencing_schema_name  referencing_entity_name
-----
dbo                      AverageBookPrice
dbo                      AverageBookPrice2
dbo                      AveragePricebyType
dbo                      AveragePricebyType2
dbo                      reptq1
dbo                      reptq2
dbo                      reptq3
dbo                      title_authors
```

```
dbo                titleview
dbo                valid_book_types
```

To display the objects referenced by the `title_authors` stored procedure, you could execute the following:

```
select distinct
    referenced_entity_name as table_name,
    referenced_minor_name as column_name
From sys.dm_sql_referenced_entities ('dbo.title_authors' , 'OBJECT' )
go
```

In the current database, the specified object references the following:

table_name	column_name
authors	NULL
authors	au_fname
authors	au_id
authors	au_lname
titleauthor	NULL
titleauthor	au_id
titleauthor	title_id
titles	NULL
titles	title
titles	title_id

You can also see dependency information in SSMS by right-clicking an object and choosing View Dependencies. This brings up the Object Dependencies window, as shown in Figure 28.4. You can view either the objects that depend on the selected object or objects on which the selected object depends. You can also expand the dependency tree for the objects listed in the Dependencies pane.

Viewing Stored Procedures

You can view the source code for stored procedures in SQL Server 2008 by querying the definition column of the object catalog view `sys.sql_modules` or by using the system procedure `sp_helptext` (see Listing 28.9).

LISTING 28.9 Viewing Code for a Stored Procedure by Using `sp_helptext`

```
exec sp_helptext title_authors
go
```

Text

```
CREATE PROCEDURE title_authors
```

```

AS
BEGIN
    SELECT a.au_lname, a.au_fname, t.title
    FROM titles t INNER JOIN
        titleauthor ta ON t.title_id = ta.title_id RIGHT OUTER JOIN
        authors a ON ta.au_id = a.au_id
    RETURN
END

```

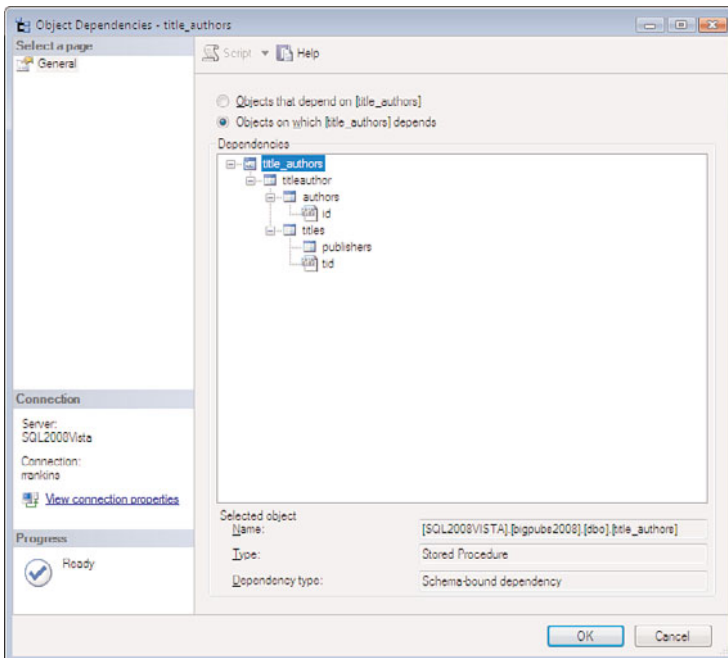

FIGURE 28.4 Viewing object dependencies in SSMS.

By default, all users have permission to execute `sp_helptext` to view the SQL code for the stored procedures in a database. If you want to protect the source code of stored procedures and keep its contents from prying eyes, you can create a procedure by using the `WITH ENCRYPTION` option. When this option is specified, the source code stored in the database is encrypted.

NOTE

If you use encryption when creating stored procedures, be aware that although SQL Server can internally decrypt the source code, no mechanisms exist for the user or for any of the end-user tools to decrypt the stored procedure text for display or editing. With this in mind, make sure that you store a copy of the source code for those procedures in a file in case you need to edit or re-create them. Also, procedures created by using the `WITH ENCRYPTION` option cannot be published as part of SQL Server replication.

You can, however, attach a debugger to the server process and retrieve a decrypted procedure from memory at runtime.

You can also view the text of a stored procedure by using the ANSI `INFORMATION_SCHEMA` view routines. The `routines` view is an ANSI standard view that provides the source code for the stored procedure in the `routine_description` column. The following example uses the `INFORMATION_SCHEMA.routines` view to display the source code for the `title_authors` stored procedure:

```
select routine_definition
from INFORMATION_SCHEMA.routines
where specific_catalog = 'bigpubs2008'
    and specific_schema = 'dbo'
    and routine_type = 'Procedure'
    and routine_name = 'title_authors'
go
```

```
routine_definition
-----
CREATE PROCEDURE title_authors
AS
BEGIN
    SELECT a.au_lname, a.au_fname, t.title
        FROM titles t INNER JOIN
            titleauthor ta ON t.title_id = ta.title_id RIGHT OUTER JOIN
                authors a ON ta.au_id = a.au_id
    RETURN
END
```

However, the `routine_description` column is limited to only the first 4,000 characters of the stored procedure code. A better way to view the code with a query is to use the `sys.sql_modules` object catalog view:

```
select definition
    from sys.sql_modules
    where object_id = object_id('title_authors')
go

CREATE PROCEDURE title_authors
AS
BEGIN
    SELECT a.au_lname, a.au_fname, t.title
        FROM titles t INNER JOIN
            titleauthor ta ON t.title_id = ta.title_id RIGHT OUTER JOIN
                authors a ON ta.au_id = a.au_id
```

```
RETURN
END
```

Finally, one other method of displaying the source code for a stored procedure is to use the new `object_definition()` function. This function takes the object ID as a parameter. If you, like most other people, do not know the object ID of the procedure in question, you can use the `object_id()` function. The following is an example of using the `object_definition()` function:

```
select object_definition(object_id('dbo.title_authors'))
go
```

```
-----
CREATE PROCEDURE title_authors @state char(2) = '%'
AS
BEGIN
    SELECT a.au_lname, a.au_fname, t.title
           FROM titles t INNER JOIN
                titleauthor ta ON t.title_id = ta.title_id RIGHT OUTER JOIN
                authors a ON ta.au_id = a.au_id
RETURN
END
```

TIP

If you are running these queries to display the procedure code in a query window in SSMS, you probably need to modify the query results options to have the procedures display correctly. From the Query menu, select Query Options. Expand the Results item and select Text. Enter a value up to 8192 for the Maximum Number of Characters Displayed in Each Column setting and click OK.

You probably also want to have the results displayed as text rather than in the grid. To make this change, under the Query menu, select the Results To submenu and then select Results to Text. As a shortcut, you can press Ctrl+T to switch to Results to Text. You can press Ctrl+D to switch back to Results to Grid.

Modifying Stored Procedures

You can modify the text of a stored procedure by using the `ALTER PROCEDURE` statement. The syntax for `ALTER PROCEDURE` is similar to the syntax for `CREATE PROCEDURE` (see Listing 28.10). Using `ALTER PROCEDURE` has a couple advantages over dropping and re-creating a procedure to modify it. The main advantage is that you don't have to drop the procedure first to make the change, so it remains available, even if the `ALTER PROCEDURE` command fails due to a syntax or object reference error. The second advantage is that because you

don't have to drop the procedure, you don't have to worry about reassigning permissions to it after modifying it.

LISTING 28.10 Modifying a Stored Procedure by Using **ALTER PROCEDURE**

```
ALTER PROCEDURE title_authors @state char(2) = '%'
AS
BEGIN
    SELECT a.au_lname, a.au_fname, t.title, t.pubdate
    FROM titles t
    INNER JOIN titleauthor ta ON t.title_id = ta.title_id
    RIGHT OUTER JOIN authors a ON ta.au_id = a.au_id
    where state like @state
RETURN
END
```

Viewing and Modifying Stored Procedures with SSMS

You can also use SSMS to create, view, and modify stored procedures.

To edit a stored procedure in SSMS, expand the Programmability folder and then the Stored Procedures folder, right-click the name of the procedure you want to modify, and select Modify (see Figure 28.5).

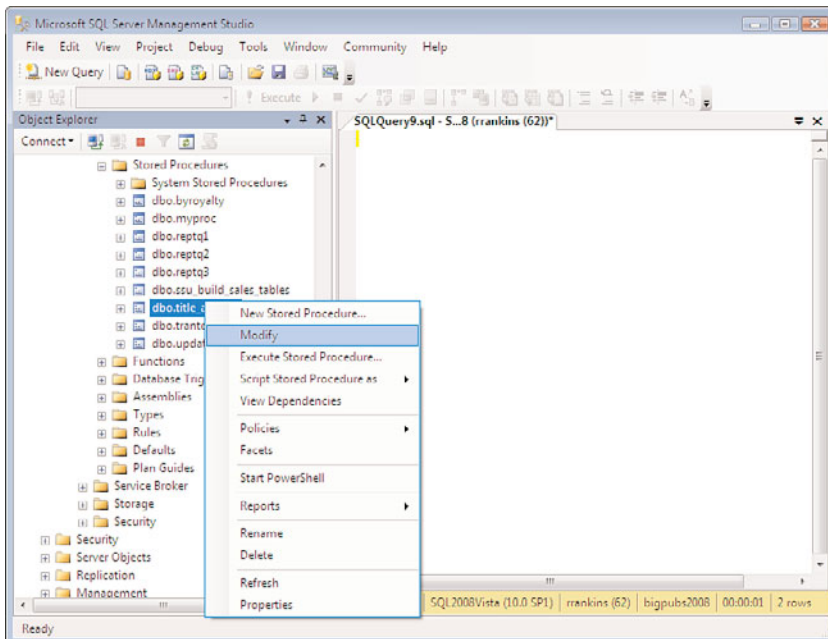

FIGURE 28.5 Modifying stored procedures in SSMS.

SSMS then extracts the ALTER PROCEDURE statement for the selected procedure into a new query window. Here, you can edit the procedure code as needed and then execute the contents of the query window to modify the procedure. In addition, the Object Browser in SSMS provides other options for extracting the stored procedure source code. It can generate code to create, alter, or drop the selected stored procedure. You can script the stored procedure source code to a new window, to a file, or to the Windows Clipboard by right-clicking the stored procedure name in the Object Browser and choosing the appropriate option (see Figure 28.6).

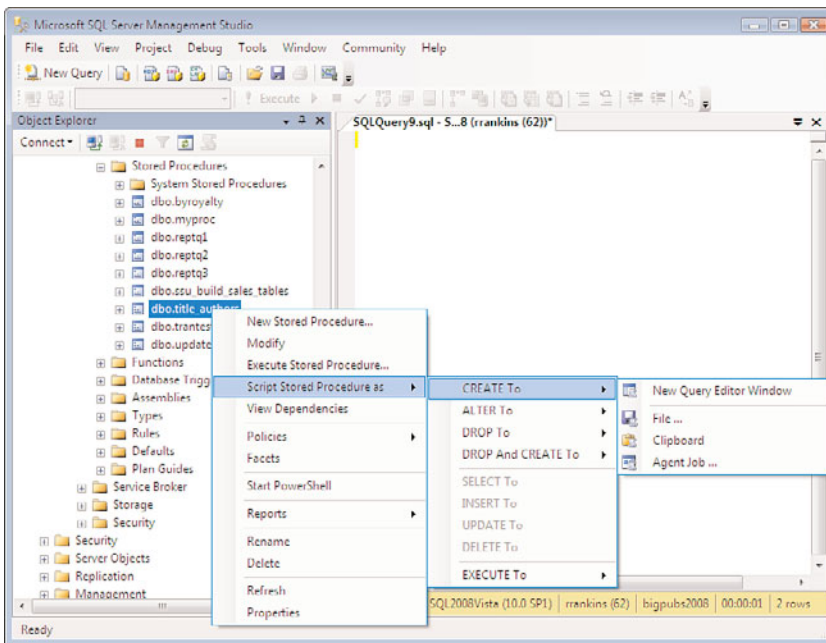

FIGURE 28.6 Extracting stored procedure source code to a new query window.

Using Input Parameters

To increase the flexibility of stored procedures and perform more complex processing, you can pass parameters to procedures. The parameters can be used anywhere that local variables can be used within the procedure code.

The following example is a stored procedure that requires three parameters:

```
CREATE PROC myproc
  @parm1 int, @parm2 int, @parm3 int
AS
```

```
-- Processing goes here
RETURN
```

If you want to help identify the data values for which the parameters are defined, it is recommended that you give your parameters meaningful names. Parameter names, like local variables, can be up to 128 characters in length, including the @ sign, and they must follow SQL Server rules for identifiers. Up to 2,100 parameters can be defined for a stored procedure.

When you execute a procedure, you can pass the parameters by position or by name:

```
--Passing parameters by position
EXEC myproc 1, 2, 3
--Passing parameters by name
EXEC myproc @parm2 = 2, @parm2 = 1, @parm3 =3
--Passing parameters by position and name
EXEC myproc 1, @parm3 =3, @parm2 = 2
```

After you specify one parameter by name, you must pass all subsequent parameters for the procedure in that EXECUTE statement by name as well. You cannot pass any of the subsequent parameters by position. If you want to skip parameters that are not the last parameter(s) in the procedure and have them take default values (as described in the next section), you also need to pass parameters by name or use the DEFAULT keyword in place of the parameter value.

TIP

When you are embedding calls to stored procedures in client applications and script files, it is advisable to pass parameters by name. Reviewing and debugging the code becomes easier that way. One time we spent half a day debugging a set of nested stored procedures to figure out why they weren't working correctly, only to find the problem was due to a missed parameter; all the parameter values were shifted over one place and the wrong values ended up being passed to the wrong parameters. This resulted in the queries not finding any matching values. Had the parameters been passed by name, this issue would not have occurred. This was a lesson learned the hard way!

Input parameter values passed in can be only explicit constant values, local variables, parameters, or, new for SQL Server 2008, table-valued parameters. However, you cannot specify a function or another expression as an input parameter value. You would have to store a return value from the function or expression value in a local variable and pass the local variable as the input parameter. Likewise, you cannot use a function or another expression as a default value for a parameter.

Setting Default Values for Parameters

You can assign a default value to a parameter by specifying a value in the definition of the parameter, as shown in Listing 28.11.

LISTING 28.11 Assigning a Default Value for a Parameter in a Stored Procedure

```
ALTER PROCEDURE title_authors @state char(2) = '%'
AS
SELECT a.au_lname, a.au_fname, t.title
      FROM titles t
      INNER JOIN titleauthor ta ON t.title_id = ta.title_id
      RIGHT OUTER JOIN authors a ON ta.au_id = a.au_id
      WHERE a.state like @state
RETURN
GO
```

You can have SQL Server apply the default value for a parameter during execution by not specifying a value or by specifying the `DEFAULT` keyword in the position of the parameter, as shown in Listing 28.12.

LISTING 28.12 Applying a Default Value for a Parameter When Executing a Stored Procedure

```
EXEC title_authors
EXEC title_authors DEFAULT
EXEC title_authors @state = DEFAULT
```

TIP

If you are involved in creating stored procedures that other people will use, you probably want to make the stored procedures as easy to use as possible.

If you leave out a parameter that is required, SQL Server presents an error message. The `myproc` procedure, shown earlier in this section, requires three parameters: `@parm1`, `@parm2`, and `@parm3`:

```
EXEC myproc
```

```
Server: Msg 201, Level 16, State 4, Procedure myproc, Line 0
Procedure 'myproc' expects parameter '@parm1', which was not
supplied.
```

Note that SQL Server complains only about the first missing parameter. The programmer passes the first parameter, only to find out that more parameters are required. This is a good way to annoy a programmer or an end user.

When you execute a command-line program, you probably expect that you can use `/?` to obtain a list of the parameters the program expects. You can program stored procedures in a similar manner by assigning `NULL` (or some other special value) as a default value to the parameters and checking for that value inside the procedure. The following is an outline of a stored procedure that presents the user with information about the parameters expected if the user doesn't pass parameters:

```
CREATE PROC MyProc2
    @parm1 int = NULL, @parm2 int = 32, @parm3 int = NULL
AS
IF (@parm1 IS NULL or @parm1 NOT BETWEEN 1 and 10) OR
    @parm3 IS NULL
PRINT 'Usage:
EXEC MyProc2
@parm1 int,    (Required: Can be between 1 and 10)
@parm2 = 32,  (Optional: Default value of 32)
@parm3 int,   (Required: Any number within range)'
-- Processing goes here
RETURN
GO

EXEC MyProc2
GO
```

```
Usage:
EXEC MyProc2
@parm1 int,    (Required: Can be between 1 and 10)
@parm2 = 32,  (Optional: Default value of 32)
@parm3 int,   (Required: Any number within range)
```

You can develop your own standards for the way the message is presented to the user, but what is important is that the information is presented at all.

To display the parameters defined for a stored procedure, you can view them in the SSMS Object Explorer (see Figure 28.7) or by executing the `sp_help` stored procedure, as shown in Listing 28.13. (Note that the output has been edited to fit the page.)

LISTING 28.13 Displaying Stored Procedure Parameters by Using **sp_help**

```
exec sp_help title_authors
Name                Owner                Type                Created_datetime
```

```
-----
title_authors      dbo          stored procedure  2008-09-15 21:15:06.540
```

```
Parameter_name Type Length Prec Scale Param_order Collation
-----
@state          char  2      2    NULL          1 SQL_Latin1_General_CP1_CI_AS
```

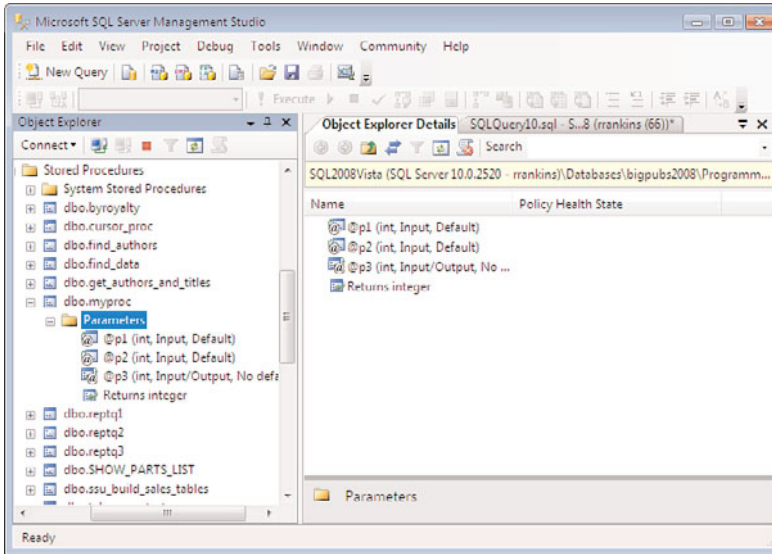

FIGURE 28.7 Displaying stored procedure parameters in SSMS.

You can also display the stored procedure parameters by running a query against the INFORMATION_SCHEMA view parameters:

```
select substring(Parameter_NAME,1, 30) as Parameter_name,
       substring (DATA_TYPE, 1, 20) as Data_Type,
       CHARACTER_MAXIMUM_LENGTH as Length,
       ordinal_position as param_order,
       Collation_name
from INFORMATION_SCHEMA.parameters
where specific_name = 'title_authors'
   and specific_schema = 'dbo'
order by ordinal_position
```

```
go
```

Parameter_name	Data_Type	Length	param_order	Collation_name
@state	char	2	1	SQL_Latin1_General_CP1_CI_AS

You can view parameter information for a stored procedure as well using the `sys.parameters` catalog view:

```
select substring(p.name,1, 30) as Parameter_name,
       substring (t.name, 1, 20) as Data_Type,
       p.max_length as Length,
       parameter_id as param_order,
       default_value
from sys.parameters p
inner join sys.types t
  on p.user_type_id = t.user_type_id
where p.object_id = object_id('title_authors')
order by parameter_id
```

```
go
```

Parameter_name	Data_Type	Length	param_order	default_value
@state	char	2	1	NULL

Passing Object Names as Parameters

In SQL Server 2008, if you pass an object name as a parameter to a stored procedure, SQL Server attempts to treat it as a table-valued parameter unless the object name is used either as an argument in a `WHERE` clause or in a dynamic SQL query. For example, the code in Listing 28.14 generates an error message when you try to create the stored procedure.

LISTING 28.14 Attempting to Create a Stored Procedure by Using a Parameter to Pass in a Table Name

```
CREATE proc find_data @table varchar(128)
as

select * from @table

GO
```

Msg 1087, Level 16, State 1, Procedure find_data, Line 4
Must declare the table variable "@table".

As you can see, when the parameter is used in the `FROM` clause, SQL Server expects it to be defined as a table variable. To use the value in the parameter as a table name, you can build a dynamic SQL query similar to the example shown in Listing 28.15.

LISTING 28.15 Passing a Table as a Parameter to a Stored Procedure for Dynamic SQL Execution

```

CREATE proc find_data @table varchar(128)
as

exec ('select * from ' + @table)
return
go

exec find_data @table = 'publishers'
go

```

pub_id	pub_name	city	state	country
0736	New Moon Books	Boston	MA	USA
0877	Binnet & Hardley	Washington	DC	USA
1389	Algodata Infosystems	Berkeley	CA	USA
1622	Five Lakes Publishing	Chicago	IL	USA
1756	Ramona Publishers	Dallas	TX	USA
...				
9952	Scootney Books	New York	NY	USA
9999	Lucerne Publishing	Paris	NULL	France

Using Wildcards in Parameters

Wildcards can be included in varchar-based input parameters and used in a LIKE clause in a query to perform pattern matching. However, you should not use the char data type for parameters that will contain wildcard characters because SQL Server pads spaces onto the value passed in to the parameter to expand it to the specified size of the char data type. For example, if you declared an @lastname parameter as char(40) and passed in 'S%', SQL Server would search not for a string starting with 'S' but for a string starting with 'S', any characters, and ending with up to 38 spaces. This would likely not match any actual data values.

Also, to increase the flexibility of a stored procedure that searches for character strings, you can default the parameter to '%', as in the following example:

```

IF EXISTS ( SELECT * FROM sys.procedures
            WHERE schema_id = schema_id('dbo')
            AND name = N'find_authors')
    DROP PROCEDURE dbo.find_authors
GO
create proc find_authors @lastname varchar(40) = '%'
as
    select au_id, au_lname, au_fname

```

```

from authors
where au_lname like @lastname
order by au_lname, au_fname

```

This procedure, if passed no parameter, returns data for all authors in the authors table. If passed a string containing wildcard characters, this procedure returns data for all authors matching the search pattern specified. If a string containing no wildcards is passed, the query performs a search for exact matches against the string value.

Unfortunately, wildcard searches can be performed only against character strings. If you want to have similar flexibility searching against a numeric value, such as an integer, you can default the value to NULL and when the parameter is NULL, compare the column with itself, as shown in the following example:

```

IF EXISTS ( SELECT * FROM sys.procedures
            WHERE schema_id = schema_id('dbo')
            AND name = N'find_titles_by_sales')
DROP PROCEDURE dbo.find_titles_by_sales
GO
create proc find_titles_by_sales @ytd_sales int = null
as
    select title_id, title, ytd_sales
    from titles
    where ytd_sales = isnull(@ytd_sales, ytd_sales)

```

However, the problem with this approach is that the procedure returns all rows from the titles table except those in which ytd_sales contains a NULL value. The reason is that NULL is never considered equal to NULL; you cannot compare an unknown value with another unknown value. To return all rows, including those in which ytd_sales is NULL, you need to implement a dual-query solution, as in the following example:

```

IF EXISTS ( SELECT * FROM sys.procedures
            WHERE schema_id = schema_id('dbo')
            AND name = N'find_titles_by_sales')
DROP PROCEDURE dbo.find_titles_by_sales
GO
create proc find_titles_by_sales @ytd_sales int = null
as
if @ytd_sales is null
    select title_id, title, ytd_sales
    from titles
else
    select title_id, title, ytd_sales
    from titles
    where ytd_sales= @ytd_sales

```

Using Table-Valued Parameters

In previous versions of SQL Server, it was not possible to share the contents of table variables between stored procedures. SQL Server 2008 changes that with the introduction of table-valued parameters, which allow you to pass table variables to stored procedures. Table-valued parameters provide more flexibility and, in many cases, better performance than temporary tables as a means to pass result sets between stored procedures.

NOTE

For more information on using temporary tables and the `table` data type in stored procedures, see Chapter 44.

Table-valued parameters provide many of the same performance advantages as table data types. Table-valued parameters also share some of the same restrictions as table variables, such as SQL Server not maintaining statistics on table-valued parameters and table-valued parameters not permitted as the target of a `SELECT INTO` or `INSERT EXEC` statement. In addition, table-valued parameters can be passed only as `READONLY` input parameters to stored procedures. DML operations, such as `UPDATE`, `INSERT`, and `DELETE`, cannot be performed on table-valued parameters within the body of a stored procedure.

To create and use table-valued parameters, you must first create a user-defined table type and define the table structure. You do so using the `CREATE TYPE` command, as in the following example:

```
if exists (select * from sys.systypes t where t.name = 'ytdsales_tabletype'
          and t.uid = USER_ID('dbo'))
    drop type ytdsales_tabletype
go
CREATE TYPE ytdsales_tabletype AS TABLE
(title_id char(6),
 title varchar(50),
 pubdate date,
 ytd_sales int)
go
```

After the table data type is created, you can use it for declaring local table variables and for stored procedure parameters. To use the table-valued parameter in a procedure, you create a procedure to receive and access data through a table-valued parameter:

```
/* Create a procedure to receive data for the table-valued parameter. */
if OBJECT_ID('tab_parm_test') is not null
    drop proc tab_parm_test
go
create proc tab_parm_test
```

```

        @pubdate datetime = null,
        @sales_minimum int = 0,
        @ytd_sales_tab ytdsales_tabletype READONLY
as
set nocount on

if @pubdate is null
    -- if no date is specified, set date to last year
    set @pubdate = dateadd(month, -12, getdate())

select * from @ytd_sales_tab
where pubdate > @pubdate
and ytd_sales >= @sales_minimum
return
go

```

Then, when calling that stored procedure, you declare a local table variable using the table data type defined previously, populate the table variable with data, and then pass the table variable to the stored procedure:

```

/* Declare a variable that references the type. */
declare @ytd_sales_tab ytdsales_tabletype

/* Add data to the table variable. */
insert @ytd_sales_tab
    select title_id, convert(varchar(50), title), pubdate, ytd_sales
    from titles

/* Pass the table variable populated with data to a stored procedure. */
exec tab_parm_test '6/1/2001', 10000, @ytd_sales_tab
go

```

title_id	title	ytd_sales
BU2075	You Can Combat Computer Stress!	18722
MC3021	The Gourmet Microwave	22246
TC4203	Fifty Years in Buckingham Palace Kitchens	15096

Using Output Parameters

If a calling batch passes a variable as a parameter to a stored procedure and that parameter is modified inside the procedure, the modifications are not passed to the calling batch unless you specify the `OUTPUT` keyword for the parameter when executing the stored procedure.

If you want a procedure to be able to pass parameter values out from the procedure, you need to use the keyword `OUTPUT` when creating the procedure. The following example shows a stored procedure that accepts two parameters, one of which is used as an output parameter:

```
IF EXISTS ( SELECT * FROM sys.procedures
            WHERE schema_id = schema_id('dbo')
            AND name = N'ytd_sales')
    DROP PROCEDURE dbo.ytd_sales
GO
CREATE PROC ytd_sales
@title varchar(80), @ytd_sales int OUTPUT
AS
SELECT @ytd_sales = ytd_sales
    FROM titles
    WHERE title = @title
RETURN
```

The calling batch (or stored procedure) needs to declare a variable to store the returned value. The `execute` statement must include the `OUTPUT` keyword as well, or the modifications won't be reflected in the calling batch's variable:

```
DECLARE @sales_up_to_today int
EXEC ytd_sales 'Life Without Fear', @sales_up_to_today OUTPUT
PRINT 'Sales this year until today's date: ' +
    CONVERT(VARCHAR(10), @sales_up_to_today) + '.'
```

Sales this year until today's date: 111.

You can also pass the output parameter by name:

```
DECLARE @sales_up_to_today int
EXEC ytd_sales 'Life Without Fear',
    @ytd_sales = @sales_up_to_today OUTPUT
PRINT 'Sales this year until today's date: ' +
    CONVERT(VARCHAR(10), @sales_up_to_today) + '.'
```

Note that when you pass an output parameter by name, the parameter name (`@ytd_sales`, in this example) is listed on the left side of the expression, and the local variable (`@sales_up_to_today`), which is set equal to the value of the output parameter, is on the right side of the expression. An output parameter can also serve as an input parameter.

Output parameters can also be passed back and captured in a client application by using ADO, ODBC, OLE DB, and so on.

Returning Procedure Status

Most programming languages are able to pass a status code to the caller of a function or subroutine. A value of 0 generally indicates that the execution was successful. SQL Server stored procedures are no exception.

SQL Server automatically generates an integer status value of 0 after successful completion of a stored procedure. If SQL Server detects a system error, a status value between -1 and -99 is returned. You can use the RETURN statement to explicitly pass a status value less than -99 or greater than 0. The calling batch or procedure can set up a local variable to retrieve and check the return status.

In Listing 28.16, the stored procedure returns the year-to-date sales for a given title as a result set. If the title does not exist, to avoid returning an empty result set, the procedure returns the status value -101. In the calling batch or stored procedure, you need to create a variable to hold the return value. The variable name is passed the EXECUTE keyword and the procedure name as shown in Listing 28.16.

LISTING 28.16 Returning a Status Code from a Stored Procedure

```

IF EXISTS ( SELECT * FROM sys.procedures
            WHERE schema_id = schema_id('dbo')
            AND name = N'ytd_sales2')
    DROP PROCEDURE dbo.ytd_sales2
GO
--Create the procedure
CREATE PROC ytd_sales2 @title varchar(80)
AS
IF NOT EXISTS (SELECT * FROM titles WHERE title = @title)
    RETURN -101
SELECT ytd_sales
    FROM titles
    WHERE title = @title
RETURN
GO

-- Execute the procedure
DECLARE @status int
EXEC @status = ytd_sales2 'Life without Fear'
IF @status = -101
    PRINT 'No title with that name found.'
go

ytd_sales
-----
111

```

```
-- Execute the procedure
DECLARE @status int
EXEC @status = ytd_sales2 'Life without Beer'
IF @status = -101
    PRINT 'No title with that name found.'
go
```

No title with that name found.

Return values can also be passed back and captured by client applications developed in ADO, ODBC, OLE DB, and so on.

Debugging Stored Procedures Using SQL Server Management Studio

One of the great tools available in the SQL Server 2000 Query Analyzer, the built-in SQL Debugger, was left out of SQL Server Management Studio (SSMS) in SQL Server 2005. Fortunately, SQL Server 2008 brings the T-SQL debugger back to SSMS.

The Transact-SQL debugger in SQL Server Management Studio enables you to step through Transact-SQL scripts, stored procedures, triggers, and functions as they are running. The Transact-SQL debugger allows you to do the following:

- ▶ Step through the Transact-SQL statements in the Query Editor line by line or set breakpoints to stop at specific lines.
- ▶ Step into or over Transact-SQL stored procedures, functions, or triggers run by the code in the query editor window.
- ▶ Watch the values assigned to variables and observe system objects such as the call stack and threads.

If you want to run the T-SQL Debugger, the query editor window must be connected to SQL Server as a member of the sysadmin server role.

NOTE

Debugging of T-SQL code should be done only on a test or development server, not on a production server. Debugging sessions can often run for long periods of time while you are investigating the operations of your Transact-SQL statements. If the code being debugged involves a multistatement transaction, locks acquired by the session could be held for extended periods while the code is paused in the debugger until the debugging session is ended or the transaction committed or rolled back. This could lead to extensive locking contention or blocking for other applications accessing production data.

You start the debugger in a query editor window by either clicking the Debug button on the Query toolbar or by clicking Start Debugging on the Debug menu, as shown in Figure 28.8.

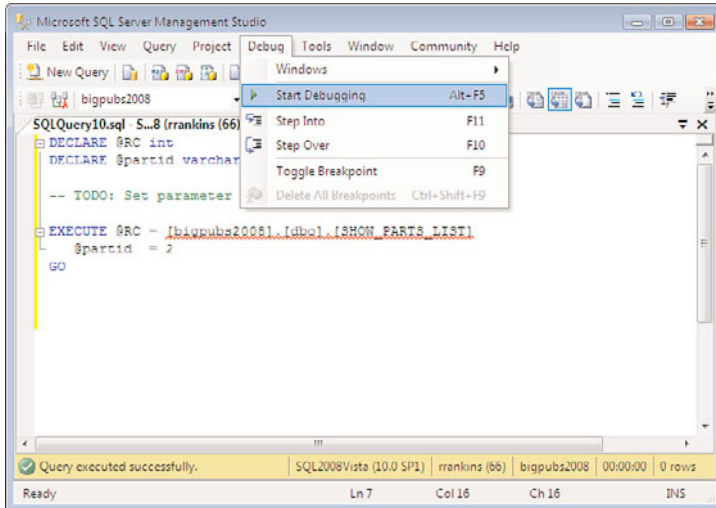

FIGURE 28.8 Invoking the T-SQL debugger in SSMS.

When the query editor window enters debug mode, the debugger initially stops on the first line of code in the stored procedure, as shown in Figure 28.9. You can then set any breakpoints and run to the breakpoints or step through the procedure code one line at a time. You can press F10 to step through the code one line at a time. If the SQL code invokes a stored procedure or function, or a DML statement invokes a trigger, you can press F11 to step into the called routine. If you step into a routine in the T-SQL Debugger, SQL Server Management Studio opens a new query editor window populated with the source code for the routine, places the window into debug mode, and then pauses execution on the first statement in the routine. You can then step through or set breakpoints in the code for that routine.

Located near the bottom of the debugger window are some useful information windows. The first group of windows is the Locals/Watch window, which displays the contents of local variables or any watch expressions you have defined. The Locals window displays the current values in all the local variables within the current scope. You can also modify the values of the variables in the Locals window to test various scenarios or to adjust data values so the code executes differently. To modify the value of a variable, right-click the row and select Edit Value.

In the four Watch windows, you can add variables or expressions whose values you want to watch, such as the global variables @@NESTLEVEL, @@FETCH_STATUS, or @@ROWCOUNT. To add an expression to a Watch window, you can either select Add Watch in the QuickWatch dialog box or enter the name of the expression in the Name column of an

empty row in a Watch window. The Watch windows, like the other tabbed windows in the debugger, can be set as docked or floating windows, allowing you to view multiple windows simultaneously (Figure 28.9 shows an example of the Watch1 window set as a floating window).

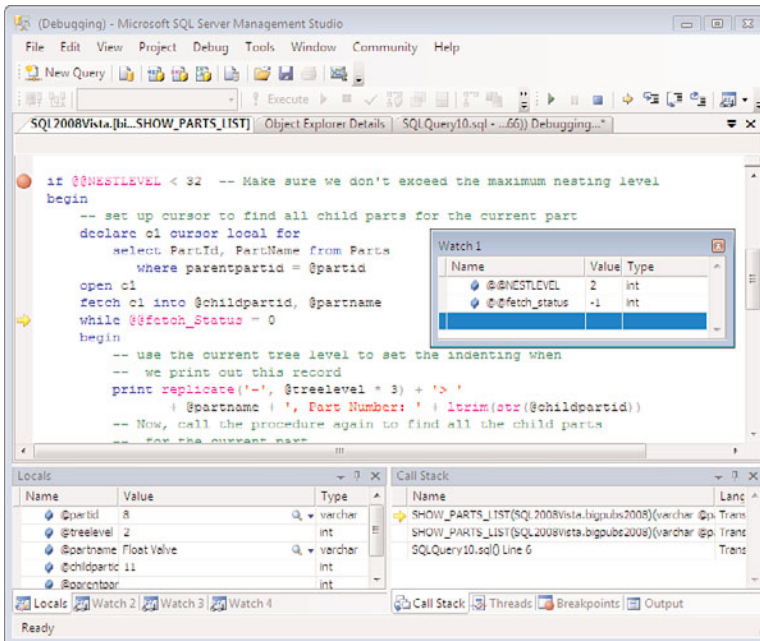

FIGURE 28.9 Debugging a T-SQL stored procedure in SSMS.

The second group of windows is the Call Stack, Breakpoints, Output, and Results and Messages windows. The Call Stack window displays the current execution location and also displays information about how execution passed from the original query editor window to the current execution location through any other functions, procedures, or triggers. The Breakpoints window lets you view information about the breakpoints you have set. From this window, you can also jump to the source code where the breakpoint is set or disable or delete the breakpoint. The Output window displays various messages and program data, including system messages from the debugger. The Results and Messages tabs on the query editor window display the results of previously executed Transact-SQL statements within the debugging session. The query editor window stays in debug mode until either the last statement in the query editor window is executed or you manually stop debugging. You can stop debugging, along with any further statement execution, using any one of the following methods:

- ▶ On the Debug menu, click Stop Debugging.
- ▶ On the Debug toolbar, click the Stop Debugging button.
- ▶ On the Query menu, click Cancel Executing Query.

- ▶ On the Query toolbar, click the Cancel Executing Query button.

If you want to stop debugging but allow the remaining Transact-SQL statements to run to completion, click Detach All on the Debug menu.

Using System Stored Procedures

A system stored procedure is a stored procedure that has some special characteristics. These procedures, created when SQL Server is installed or upgraded, are generally used to administer SQL Server. They shield a DBA from accessing the system catalogs directly. Some system stored procedures are used to present information from the system catalog, and others modify the system catalogs.

NOTE

System stored procedures seem to have fallen out of favor with Microsoft. Most of them have been listed as deprecated features in SQL Server 2008 and been replaced with T-SQL commands, or the information provided by system stored procedures is now available via the catalog views and dynamic management views. Many of the current system stored procedures may be removed in future versions of Microsoft SQL Server, so it is recommended that you avoid using many of the system stored procedures in any of your development work and modify any code currently using system stored procedures to use the alternatives.

Although many of the system stored procedures have been deprecated and are not as critical to administering SQL Server as they once were, it is still a good idea to be familiar with the basic system stored procedures. There are currently around 400 documented system stored procedures in SQL Server 2008, so it would be a tough job to learn the names and syntax for all of them. The total number of system stored procedures is more than 1,400. Some of the undocumented stored procedures are called by other procedures, and others are called from SSMS or other SQL Server tools and utility programs.

The following attributes characterize a system stored procedure:

- ▶ The stored procedure name begins with `sp_`.
- ▶ The stored procedure resides in the Resource database.
- ▶ The procedure is defined in the sys schema.

These attributes make the procedure *global*, which means you can execute the procedure from any database without qualifying the database name. The procedure executes within the current database context.

Although system stored procedures reside in the Resource database, they also run in any database context when fully qualified with a database name, regardless of the current database context. For instance, `sp_helpfile` shows information about the files configured for the current database. In the following example, when not qualified, `sp_helpfile`

returns file information for the master database, and when qualified with `bigpubs2008..`, it returns file information for the `bigpubs2008` database:

```
exec sp_helpfile
go
```

```

name      fileid filename                                filegroup
size      maxsize  growth usage
-----
-----
master    1      C:\MSSQL2008\MSSQL10.SQL2008UNLEASHED\MSSQL\DATA\master.mdf PRIMARY
4096 KB  Unlimited 10%  data only
mastlog   2      C:\MSSQL2008\MSSQL10.SQL2008UNLEASHED\MSSQL\DATA\mastlog.ldf NULL
512 KB   Unlimited 10%  log only

```

```
exec bigpubs2008..sp_helpfile
go
```

```

name      fileid filename                                filegroup size
maxsize  growth usage
-----
-----
bigpubs2008    1      E:\MSSQL2008\DATA\bigpubs2008.mdf    PRIMARY  214912 KB
Unlimited 10%  data only
bigpubs2008_log 2      E:\MSSQL2008\DATA\bigpubs2008_log.LDF NULL    504 KB
Unlimited 10%  log only

```

Table 28.1 describes the categories of system stored procedures.

TABLE 28.1 System Stored Procedure Categories

Category	Description
Catalog stored procedures	Used to implement ODBC data dictionary functions and isolate ODBC applications from changes to underlying system tables.
Cursor stored procedures	Used to implement cursor variable functionality.
Database engine stored procedures	Used for general maintenance of the SQL Server Database Engine.
Database mail stored procedures	Used to perform email operations from within an instance of SQL Server.
Database maintenance plan procedures	Used to set up core database maintenance tasks.
Distributed queries stored procedures	Used to link remote servers and manage distributed queries.

TABLE 28.1 System Stored Procedure Categories

Category	Description
Full-text search stored procedures	Used to implement and query full-text indexes.
Log shipping stored procedures	Used to configure, modify, and monitor log shipping configurations.
Automation stored procedures	Allow OLE automation objects to be used within a T-SQL batch.
Notification services stored procedures	Used to manage SQL Server 2008 Notification Services.
Replication stored procedures	Used to manage replication.
Security stored procedures	Used to manage security, such as login IDs, usernames, and so on.
SQL Server Profiler stored procedures	Used by SQL Server Profiler to monitor performance and activity.
SQL Server Agent stored procedures	Used by SQL Server Agent to manage scheduled and event-driven activities.
Web task stored procedures	Used for creating web pages.
XML stored procedures	Used for XML text management.
General extended stored procedures	Provide an interface from an instance of SQL Server to external programs for various maintenance activities (for example, <code>xp_sqlmaint</code>)

Some of the more useful system stored procedures are listed in Table 28.2.

TABLE 28.2 Useful System Stored Procedures

Procedure Name	Description
<code>sp_who</code> and <code>sp_who2</code>	Return information about current connections to SQL Server.
<code>sp_help</code> [<i>object_name</i>]	Lists the objects in a database or returns information about a specified object.
<code>sp_helpdb</code>	Returns a list of databases or information about a specified database.
<code>sp_configure</code>	Lists or changes configuration settings.

Startup Procedures

A SQL Server administrator can create stored procedures that are marked for execution automatically whenever SQL Server starts. They are often referred to as *startup procedures*. Startup procedures are useful for performing housekeeping-type tasks or starting up a background process when SQL Server starts. Some possible uses for startup procedures include the following:

- ▶ Automatically perform system or maintenance tasks in tempdb, such as creating a global temporary table.
- ▶ Enable custom SQL Server Profiler traces automatically whenever SQL Server is running. (For more information on SQL Server Profiler traces, see Chapter 6.)
- ▶ Automatically start other external processes on the SQL Server machine, using `xp_cmdshell`. (Using `xp_cmdshell` is discussed in the section “Using Extended Stored Procedures,” in Chapter 44.)
- ▶ Prime the data cache with the contents of your critical, frequently used tables.
- ▶ Prime the plan cache by executing procedures or functions you want to have compiled and cached before applications start using them.

To create a startup procedure, you log in as a system administrator and create the procedure in the master database. Then you set the procedure startup option to true by using `sp_procoption`:

```
sp_procoption procedure_name, startup, true
```

If you no longer want the procedure to run at startup, remove the startup option by executing the same procedure and changing the value to `false`.

By default, a startup procedure runs in the context of the system administrator, but it can use `SETUSER` to impersonate another account, if necessary. If you need to reference objects in other databases from within a startup procedure, you need to fully qualify the object with the appropriate database and owner names.

Startup procedures are launched asynchronously; that is, SQL Server doesn't wait for them to complete before continuing with additional startup tasks. This allows a startup procedure to execute in a loop for the duration of the SQL Server process, or it allows several startup procedures to be launched simultaneously. While a startup procedure is running, it runs as a separate worker thread.

TIP

If you need to execute a series of stored procedures in sequence during startup, you can nest the stored procedure calls within a single startup procedure. This approach consumes only a single worker thread.

Any error messages or print statements generated by a startup procedure are written to the SQL Server error log. For example, consider the following whimsical but utterly useless startup procedure:

```
use master
go
create procedure good_morning
as
print 'Good morning, Dave'
return
go
sp_procoption good_morning, startup, true
go
```

When SQL Server is restarted, the following entries would be displayed in the error log:

```
2009-06-12 13:21:00.04 spid5s      Recovery is complete. This is an
    informational message only. No user action is required.
2009-06-12 13:21:00.15 spid5s      Launched startup procedure 'good_morning'.
2009-06-12 13:21:00.15 spid51s     Good morning, Dave
```

Any result sets generated by a startup procedure vanish into the infamous bit bucket. If you need to return result sets from a startup procedure, the procedure should be written to insert the results into a table. The table needs to be a permanent table and not a temporary table because a temporary table would be automatically dropped when the startup procedure finished executing.

The following example is a startup procedure that could preload all tables within the Sales and Purchasing schemas in the AdventureWorks database into data cache memory on SQL Server startup:

```
use master
go
create procedure prime_cache
as
declare @tablename varchar(128),
        @schemaname varchar(128)
```

```

declare c1 cursor for
select s.name, o.name
    from AdventureWorks.sys.objects o
    join AdventureWorks.sys.schemas s
        on o.schema_id = s.schema_id
    where type = 'U'
    and s.name in ('Sales', 'Purchasing')

open c1
fetch c1 into @schemaname, @tablename
while @@fetch_status = 0
begin
    print 'Loading ''' + @schemaname + '.' + @tablename + ''' into data cache'
    exec ('select * from AdventureWorks.' + @schemaname + '.' + @tablename)
    fetch c1 into @schemaname, @tablename
end
close c1
deallocate c1
return
go

sp_procoption prime_cache, startup, true
go

```

The error log output from this startup procedure would be similar to the following:

```

2009-06-15 19:39:18.970 spid7s      Launched startup procedure 'prime_cache'.
2009-06-15 19:39:20.550 spid30s      Loading 'Sales.Store' into data cache
2009-06-15 19:39:20.870 spid30s      Loading 'Sales.StoreContact' into data cache
2009-06-15 19:39:20.870 spid30s      Loading 'Purchasing.ProductVendor' into data
cache
2009-06-15 19:39:20.950 spid30s      Loading 'Purchasing.Vendor' into data cache
2009-06-15 19:39:21.010 spid30s      Loading 'Purchasing.PurchaseOrderDetail' into
data cache
2009-06-15 19:39:21.140 spid30s      Loading 'Purchasing.VendorAddress' into data
cache
2009-06-15 19:39:21.150 spid30s      Loading 'Purchasing.VendorContact' into data
cache
2009-06-15 19:39:21.160 spid30s      Loading 'Purchasing.PurchaseOrderHeader' into
data cache
2009-06-15 19:39:21.220 spid30s      Loading 'Sales.ContactCreditCard' into data
cache
2009-06-15 19:39:21.310 spid30s      Loading 'Sales.CountryRegionCurrency' into
data cache
2009-06-15 19:39:21.420 spid30s      Loading 'Sales.CreditCard' into data cache
2009-06-15 19:39:21.540 spid30s      Loading 'Sales.Currency' into data cache

```

```

2009-06-15 19:39:21.570 spid30s Loading 'Sales.SalesOrderDetail' into data
cache
2009-06-15 19:39:22.040 spid30s Loading 'Sales.CurrencyRate' into data cache
2009-06-15 19:39:22.120 spid30s Loading 'Sales.Customer' into data cache
2009-06-15 19:39:22.420 spid30s Loading 'Sales.SalesOrderHeader' into data cache
2009-06-15 19:39:23.170 spid30s Loading 'Sales.CustomerAddress' into data
cache
2009-06-15 19:39:23.290 spid30s Loading 'Sales.SalesOrderHeaderSalesReason'
into data cache
2009-06-15 19:39:23.340 spid30s Loading 'Sales.SalesPerson' into data cache
2009-06-15 19:39:23.360 spid30s Loading 'Sales.SalesPersonQuotaHistory' into
data cache
2009-06-15 19:39:23.380 spid30s Loading 'Sales.SalesReason' into data cache
2009-06-15 19:39:23.380 spid30s Loading 'Sales.Individual' into data cache

```

If you want to disable the automatic execution of all startup procedures, you can use `sp_configure` to disable the `scan for startup procs` configuration option. Setting this option to `0` disables the running of startup procedures on subsequent SQL Server restarts.

If SQL Server is not currently running and you want to skip running the startup procedures, you can specify Trace Flag 4022 as a startup parameter. You can set the trace flag for a SQL Server instance by using the SQL Server Configuration Manager. In SQL Server Configuration Manager, perform the following steps:

1. Click on SQL Server 2008 Services.
2. In the right pane, right-click the SQL Server instance you want to set the trace flag for and select Properties.
3. Go to the Advanced tab and select the Startup Parameters box.
4. Click the expand arrow to the right of the input field to expand the entire field.
5. Place your cursor at the end of the value and type a semicolon (;).
6. Type **-T4022** (see Figure 28.10).
7. Click OK.

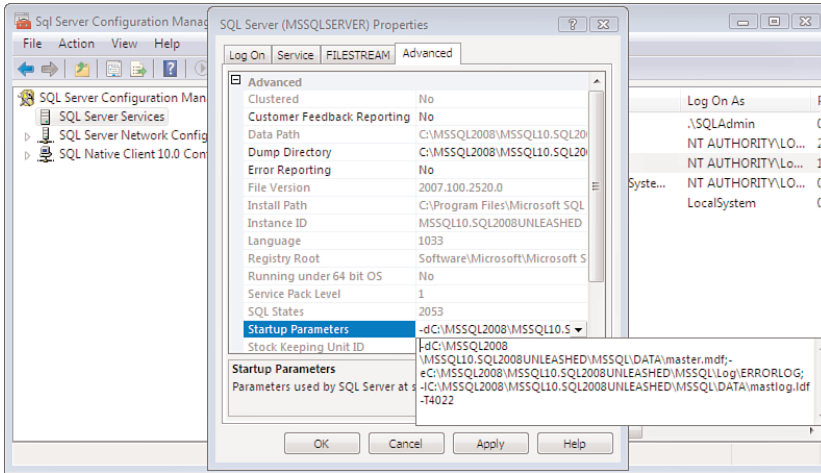

FIGURE 28.10 Setting Trace Flag 4022 to prevent startup procedures from executing.

Also, if you start SQL Server with minimal configuration (by using the `-f` flag), the startup stored procedures are not executed.

Summary

Stored procedures are among the premier features of Microsoft SQL Server. They provide a number of benefits over using ad hoc SQL, including faster performance; restricted, function-based access to tables; protection of application code from database changes; and the ability to simplify complex tasks into a simple stored procedure call.

In the next chapter, you learn how to expand the capabilities of your T-SQL code by creating and using user-defined functions developed in T-SQL.

CHAPTER 29

Creating and Managing User-Defined Functions

SQL Server provides a number of predefined functions that are built in to the T-SQL language. The supplied functions help extend the capabilities of T-SQL, providing the ability to perform string manipulation, mathematic calculations, data type conversions, and so on within T-SQL code. Although SQL Server provides a reasonably extensive set of functions, you might sometimes wish you had available a function that is not provided. You could create a stored procedure to perform custom processing, but you can't use the result of a stored procedure in a WHERE clause or as a column in a SELECT list. For this type of situation, SQL Server 2008 provides user-defined functions.

A user-defined function can return a single scalar value, like the majority of the built-in functions, or it can return a result set as a table result, similarly to a table variable.

This chapter takes a look at how to create and manage user-defined functions as well as when it may be better to rewrite stored procedures as functions.

What's New in SQL Server 2008

Not much has really changed with user-defined functions in SQL Server 2008 from SQL Server 2005. No real new functionality or features have been added beyond the ability to specify up to 2,100 parameters instead of 1,024. User-defined functions can still be created in T-SQL or using the .NET common language runtime (CLR). Being able to define functions in the CLR significantly extends what you can do in user-defined functions by opening up the power and capabilities of the .NET Framework languages. This

IN THIS CHAPTER

- ▶ What's New in SQL Server 2008
- ▶ Why Use User-Defined Functions?
- ▶ Types of User-Defined Functions
- ▶ Creating and Managing User-Defined Functions
- ▶ Rewriting Stored Procedures as Functions
- ▶ Creating and Using CLR Functions

means you can develop functions in SQL Server that are either impossible or very difficult to achieve using T-SQL alone. Later in this chapter, in the section “Creating and Using CLR Functions,” you learn about CLR functions and some general guidelines on when to use CLR functions versus T-SQL functions.

NOTE

This chapter focuses primarily on creating T-SQL functions. For more information and examples related to creating and coding examples of CLR functions, see Chapter 46, “SQLCLR: Developing SQL Server Objects..”

Why Use User-Defined Functions?

The main benefit of user-defined functions is that they mean you are not limited to just the functions SQL Server provides. You can develop your own functions to meet your specific needs or to simplify complex SQL code. For example, the `getdate()` function returns the current system date and time. It always includes both a date component and time component, with accuracy down to the milliseconds. What if you wanted to return a `datetime` value with just the date and have the time always set to midnight? To do this, you would have to pass the result from `getdate()` through some other functions to zero out the time component. The following is one possible solution:

```
select convert(datetime, convert(date, getdate()))
```

Each time you wanted just the date, with the time always set to midnight, you would have to perform this same conversion operation on the result of the `getdate()` function. As an alternative, you could create a user-defined function that performs the operations on `getdate()` automatically and always returns the current date, with a time value of midnight, as in this example:

```
USE bigpubs2008
go

CREATE FUNCTION getonlydate ( )
RETURNS datetime
AS
BEGIN    RETURN (select convert(datetime, convert(date, getdate())))
END
GO
```

You could then use the user-defined function in your SQL code in place of the more complex conversion operation on the `getdate()` function each time. Like the built-in system functions, user-defined functions can be used in `SELECT` lists, `SET` clauses of `UPDATE` statements, `VALUES` clauses of `INSERT` statements, as default values, and so on. For

example, the following query uses the user-defined function `getonlydate()` to return the current date, with a time of midnight:

```
select dbo.getonlydate()
```

The following examples show how you could use the `getonlydate()` user-defined function in other statements:

```
USE bigpubs2008
go
CREATE TABLE Orders (
    OrderID int IDENTITY (1, 1) NOT NULL Primary Key,
    CustomerID nchar (5) COLLATE SQL_Latin1_General_CP1_CI_AS NULL ,
    EmployeeID int NULL ,
    OrderDate datetime NULL default dbo.getonlydate(),
    RequiredDate datetime NULL ,
    ShippedDate datetime NULL
)
go

insert Orders (CustomerID, EmployeeID, RequiredDate)
    values ('BERGS', 3, dbo.getonlydate() + 7)
go

update Orders
    set ShippedDate = dbo.getonlydate()
    where OrderID = 1
go

select OrderDate,
       RequiredDate,
       ShippedDate
    from Orders
    where OrderDate = dbo.getonlydate()
go
```

OrderDate	RequiredDate	ShippedDate
-----	-----	-----
2008-06-03 00:00:00.000	2008-06-10 00:00:00.000	2008-06-03 00:00:00.000

If you use the `getonlydate()` function consistently when you want to store only dates with a time value of midnight, searching against `datetime` columns is easier because you don't have to concern yourself with the time component. For example, if you use `getdate()` instead of `getonlydate()`, you have to account for the time component in your queries against `OrderDate` to ensure that you find all records for a particular day:

```

SELECT OrderDate,
       RequiredDate,
       ShippedDate
  from Orders
 where OrderDate >= convert(varchar(10), getdate(), 110)
       and OrderDate < convert(varchar(10), getdate() + 1, 110)

```

From this example, you can see how much using the `getonlydate()` user-defined function can simplify your queries.

TIP

Another way to avoid the issues related to storing a time component in your date-valued columns in SQL Server 2008 is to use the new `DATE` data type instead of `DATETIME`. This new data type is discussed in more detail in Chapter 42, “What’s New for Transact-SQL in SQL Server 2008.”

In addition to functions that return scalar values, you can also define functions that return table results. You can use functions that return table results anywhere in queries that a table or view can be used, including joins, subqueries, and so on. The following examples show how to use a user-defined table-valued function that returns a list of valid book types:

```

use bigpubs2008
go
create function valid_book_types()
returns TABLE
as
return (SELECT distinct type from titles)
go

select * from dbo.valid_book_types()
go
insert titles
select * from newtitles
where type in (select * from dbo.valid_book_types())

```

Essentially, this example reduces a query to a simple function that you can now use anywhere a table can be referenced.

With a few restrictions—which are covered later in this chapter, in the “Creating and Managing User-Defined Functions” section—you can write all types of functions in SQL Server to perform various calculations or routines. For example, you could create a T-SQL function that returns a valid list of code values, a function to determine the number of days items are backordered, a function to return the average price of all books, and so on. Plus, with the capability to create CLR-based functions, you can create significantly more

powerful functions than what can be accomplished using T-SQL alone. Examples of CLR-based functions include a more robust `soundex()` function, a function to return the factorial of a number, and an address comparison function. The possibilities are nearly endless. As you have can see, user-defined functions significantly increase the capabilities and flexibility of T-SQL.

Types of User-Defined Functions

SQL Server supports three types of user-defined functions:

- ▶ Scalar functions
- ▶ Inline table-valued functions
- ▶ Multistatement table-valued functions

The next few sections take an in-depth look at the differences between the function types and how and where you can use them.

Scalar Functions

A scalar function is like the standard built-in functions provided with SQL Server. It returns a single scalar value that can be used anywhere a constant expression can be used in a query. (You saw an example of this in the earlier description of the `getonlydate()` function.)

A scalar function typically takes one or more arguments and returns a value of a specified data type. Every T-SQL function must return a result using the `RETURN` statement. The value to be returned can be contained in a local variable defined within the function, or the value can be computed in the `RETURN` statement. The following two functions are variations of a function that returns the average price for a specified type of book from the `titles` table:

```
use bigpubs2008
go
CREATE FUNCTION AverageBookPrice(@booktype varchar(12) = '%')
RETURNS money
AS
BEGIN
    DECLARE @avg money
    SELECT @avg = avg(price)
    FROM titles
    WHERE type like @booktype

    RETURN @avg
END
go
```

```

CREATE FUNCTION AverageBookPrice2(@booktype varchar(12) = '%')
RETURNS money
AS
BEGIN
    RETURN ( SELECT avg(price)
            FROM titles
            WHERE type like @booktype)
END

```

As mentioned earlier in this chapter, a scalar function can be used anywhere a constant expression can be used. For example, SQL Server doesn't allow aggregate functions in a WHERE clause unless they are contained in a subquery. The AvgBookPrice() function lets you compare against the average price without having to use a subquery:

```

select title_id, type, price from titles
where price > dbo.AverageBookPrice('popular_comp')
go

```

```

title_id type          price
-----
PC1035   popular_comp 17.1675
PS2091   psychology   17.0884

```

When invoking a user-defined scalar function, you must include the schema name. If you omit the schema name, you get the following error, even if the function is created in your default schema or exists only in the dbo schema in the database:

```

select AverageBookPrice('popular_comp')
go

```

```

Server: Msg 195, Level 15, State 10, Line 1
'AverageBookPrice' is not a recognized function name.

```

You can return the value from a user-defined scalar function into a local variable in two ways. You can assign the result to a local variable by using the SET statement or an assignment select, or you can use the EXEC statement. The following commands are functionally equivalent:

```

declare @avg1 money,
        @avg2 money,
        @avg3 money
select @avg1 = dbo.AverageBookPrice('popular_comp')
set @avg2 = dbo.AverageBookPrice('popular_comp')
exec @avg3 = dbo.AverageBookPrice 'popular_comp'
select @avg1 as avg1, @avg2 as avg2, @avg3 as avg3
go

```

Warning: Null value is eliminated by an aggregate or other SET operation.

avg1	avg2	avg3
-----	-----	-----
16.0643	16.0643	16.0643

Notice, however, that when you use a function in an EXEC statement, you invoke it similarly to the way you invoke a stored procedure, and you do not use parentheses around the function parameters. Also, when you invoke a function in the EXEC statement, the function generates the following warning message: “Warning: Null value is eliminated by an aggregate or other SET operation.” This warning isn’t generated when the function is invoked in the SET or SELECT statement. To avoid confusion, you should stick to using the EXEC statement for stored procedures and invoke scalar functions as you would normally invoke a SQL Server built-in function.

Table-Valued Functions

A table-valued user-defined function returns a rowset instead of a single scalar value. You can invoke a table-valued function in the FROM clause of a SELECT statement, just as you would a table or view. In some situations, a table-valued function can almost be thought of as a view that accepts parameters, so the result set is determined dynamically. A table-valued function specifies the keyword TABLE in its RETURNS clause.

Table-valued functions are of two types: inline and multistatement. The two types of table-valued functions return the same thing, and they are also invoked the same way. The only real difference between them is the way the function is written to return the rowset. The next couple sections look at each of these types of table-valued functions.

Inline Table-Valued Functions

An inline table-valued function specifies only the TABLE keyword in the RETURNS clause, without table definition information. The code inside the function is a single RETURN statement that invokes a SELECT statement. For example, you could create an inline table-valued function that returns a rowset of all book types and the average price for each type, where the average price exceeds the value passed into the function:

```
use bigpubs2008
go
CREATE FUNCTION AveragePricebyType (@price money = 0.0)
RETURNS table
AS

RETURN ( SELECT type, avg(isnull(price, 0)) as avg_price
        FROM titles
        group by type
        having avg(isnull(price, 0)) > @price)
```

You can invoke the function by referencing it in a FROM clause as you would a table or view:

```
select * from AveragePricebyType (15.00)
go
```

```
type          avg_price
-----
business      15.0988
mod_cook      15.4236
```

Notice that when you invoke a table-valued function, you do not have to specify the schema name as you do with a user-defined scalar function.

Multistatement Table-Valued Functions

Multistatement table-valued functions differ from inline functions in two major ways:

- ▶ The RETURNS clause specifies a table variable and its definition.
- ▶ The body of the function contains multiple statements, at least one of which populates the table variable with data values.

You define a table variable in the RETURNS clause by using the TABLE data type. The syntax to define the table variable is similar to the CREATE TABLE syntax. Note that the name of the table variable comes before the TABLE keyword:

```
RETURNS @variable TABLE ( column definition | table_constraint [, ...] )
```

The scope of the table variable is limited to the function in which it is defined. Although the contents of the table variable are returned as the function result, the table variable itself cannot be accessed or referenced outside the function.

Within the function in which a table variable is defined, that table variable can be treated like a regular table. You can perform any SELECT, INSERT, UPDATE, or DELETE statement on the rows in a table variable, except for SELECT INTO. Here's an example:

```
INSERT INTO @table SELECT au_lname, au_fname from authors
```

The following example defines the inline table-valued function AveragePricebyType() as a multistatement table-valued function called AveragePricebyType2():

```
use bigpubs2008
go
CREATE FUNCTION AveragePricebyType2 (@price money = 0.0)
RETURNS @table table (type varchar(12) null, avg_price money null)
AS
begin
    insert @table
        SELECT type, avg(isnull(price,0)) as avg_price
        FROM titles
        group by type
```

```

        having avg(isnull(price, 0)) > @price
    return
end

```

Notice the main differences between this version and the inline version: in the multistatement version, you have to define the structure of the table rowset you are returning and also have to include the `BEGIN` and `END` statements as wrappers around the multiple statements that the function can contain. Other than that, both functions are invoked the same way and return the same rowset:

```

select * from AveragePricebyType2 (15.00)
go

```

```

type          avg_price
-----
business      15.0988
mod_cook      15.4236

```

Why use multistatement table-valued functions instead of inline table-valued functions? Generally, you use multistatement table-valued functions when you need to perform further operations (for example, inserts, updates, or deletes) on the contents of the table variable before returning a result set. You would also use them if you need to perform more complex logic or additional processing on the input parameters of the function before invoking the query to populate the table variable.

Creating and Managing User-Defined Functions

In the preceding sections of this chapter, you saw some examples of creating functions. The following sections discuss in more detail the `CREATE FUNCTION` syntax and the types of operations allowed in functions. These sections also show how to create and manage T-SQL functions by using SQL Server Management Studio (SSMS).

Creating User-Defined Functions

You create T-SQL functions by using T-SQL statements. You can enter the T-SQL code in `sqlcmd`, SSMS, or any other third-party query tool that allows you to enter ad hoc T-SQL code. The following sections first show the basic syntax for creating functions and then show how you can create functions by using the features of SSMS.

Creating T-SQL Functions

User-defined functions can accept 0–2,100 input parameters but can return only a single result: either a single scalar value or table result set.

The T-SQL syntax for the `CREATE FUNCTION` command for scalar functions is as follows:

```

CREATE FUNCTION [ schema_name. ] function_name
    ( [ { @parameter_name [AS] [ schema_name.]scalar_datatype [ = default ] } ]

```

```

    [ ,...n ] ] )
RETURNS scalar_datatype
[ WITH { [ ENCRYPTION ]
        [ , SCHEMABINDING ]
        [ , RETURNS NULL ON NULL INPUT | CALLED ON NULL INPUT ]
        [ , EXECUTE_AS_Clause ]
      } ]
[ AS ]
BEGIN
    SQL_Statements
    RETURN scalar_expression
END

```

The syntax for the CREATE FUNCTION command for inline table-valued functions is as follows:

```

CREATE FUNCTION [ schema_name. ] function_name
    ( [ { @parameter_name [AS] [ schema_name.]scalar_datatype [ = default ] }
      [ ,...n ] ] )
RETURNS TABLE
[ WITH { [ ENCRYPTION ]
        [ , SCHEMABINDING ]
        [ , RETURNS NULL ON NULL INPUT | CALLED ON NULL INPUT ]
        [ , EXECUTE_AS_Clause ]
      } ]
[ AS ]
RETURN [ ( ) select-stmt [ ( ) ]

```

The syntax for the CREATE FUNCTION command for multistatement table-valued functions is as follows:

```

CREATE FUNCTION [ schema_name. ] function_name
    ( [ { @parameter_name [AS] [ schema_name.]scalar_datatype [ = default ] }
      [ ,...n ] ] )
RETURNS @table_variable TABLE ( { column_definition | table_constraint }
                                [ ,...n ] )
[ WITH { [ ENCRYPTION ]
        [ , SCHEMABINDING ]
        [ , RETURNS NULL ON NULL INPUT | CALLED ON NULL INPUT ]
        [ , EXECUTE_AS_Clause ]
      } ]
[ AS ]
BEGIN
    SQL_Statements
    RETURN
END

```

The types of SQL statements allowed in a function include the following:

- ▶ DECLARE statements to define variables and cursors that are local to the function.
- ▶ Assignments of values to variables that are local to the function, using the SET command or an assignment select.
- ▶ Cursor operations on local cursors that are declared, opened, closed, and de-allocated within the function. FETCH statements must assign values to local variables by using the INTO clause.
- ▶ Control-of-flow statements such as IF, ELSE, WHILE, GOTO, and so on, excluding the TRY...CATCH statements.
- ▶ UPDATE, INSERT, and DELETE statements that modify table variables defined within the function.
- ▶ EXECUTE statements that call an extended stored procedure. (Any results returned by the extended stored procedure are discarded.)
- ▶ Other user-defined functions, up to a maximum nesting level of 32.

If you specify the ENCRYPTION option, the SQL statements used to define the function are stored encrypted in the syscomments table. This prevents anyone from viewing the function source code in the database.

NOTE

If you choose to encrypt the function code, you should be sure to save a copy of the script used to create the function to a file outside the database, in case you ever need to modify the function or re-create it. After the source code for the function is encrypted, you cannot extract the original unencrypted source code from the database.

If a function is created with the SCHEMABINDING option, the database objects that the function references cannot be altered or dropped unless the function is dropped first or the schema binding of the function is removed, using the ALTER FUNCTION command and without specifying the SCHEMABINDING option. A CREATE FUNCTION statement with the SCHEMABINDING option specified fails unless all the following conditions are met:

- ▶ Any user-defined functions and views referenced within the function are also schema bound.
- ▶ Any objects referenced by the function are referenced using a two-part name (*schema.object_name*).
- ▶ The function and the objects it references belong to the same database.
- ▶ The user executing the CREATE FUNCTION statement has REFERENCES permission on all database objects that the function references.

You can specify the `SCHEMABINDING` option only for T-SQL functions. The following example modifies the `AveragePricebyType2` function by specifying the `SCHEMABINDING` option:

```
ALTER FUNCTION AveragePricebyType2 (@price money = 0.0)
RETURNS @table table (type varchar(12) null, avg_price money null)
with schemabinding
AS
begin
    insert @table
        SELECT type, avg(price) as avg_price
            FROM dbo.titles
            group by type
            having avg(price) > @price
    return
end
```

The following example shows what happens if you try to modify a column in the `titles` table referenced by the function:

```
alter table titles alter column price smallmoney null
go
```

Msg 5074, Level 16, State 1, Line 1

The object 'AveragePricebyType2' is dependent on column 'price'.

Msg 5074, Level 16, State 1, Line 1

The statistics 'price' is dependent on column 'price'.

Msg 4922, Level 16, State 9, Line 1

ALTER TABLE ALTER COLUMN price failed because one or more objects access this column.

If the `RETURNS NULL ON NULL INPUT` option is specified, the function automatically returns `NULL` as a result, without invoking the function body. If this option is not specified, the default option of `CALLED ON NULL INPUT` is applied. The following example shows the difference between these two options:

```
CREATE FUNCTION striptime (@datetimeval datetime)
RETURNS datetime
AS
BEGIN
    DECLARE @dateval datetime
    SELECT @dateval = convert(date, isnull(@datetimeval, getdate()))
    RETURN @dateval
END
GO
```

```

CREATE FUNCTION striptime2(@datetimeval datetime)
RETURNS datetime
WITH RETURNS NULL ON NULL INPUT
AS
BEGIN
    DECLARE @dateval datetime
    SELECT @dateval = convert(date, isnull(@datetimeval, getdate()))
    RETURN @dateval

END
GO

select dbo.striptime(NULL), dbo.striptime2(NULL)

```

```

-----
2006-06-05 00:00:00.000 NULL

```

The `EXECUTE AS` clause allows you to specify the security context under which the user-defined function will execute. This way, you can control which user account SQL Server uses to validate permissions on any database objects referenced by the function. This option cannot be specified for inline table-valued functions.

Another key restriction on user-defined functions is that SQL statements within a function cannot generate side effects; that is, a user-defined function cannot generate permanent changes to any resource whose scope extends beyond the function. For example, a function cannot modify data in a table, operate on cursors not local to the function, create or drop database objects, issue transaction control statements, or generate a result set other than the defined function result via a `SELECT` statement or an extended stored procedure that would be returned to the user. The only changes that can be made by the SQL statements in a function are to the objects local to the function, such as local cursors or variables.

A new feature in SQL Server 2008 is that you can now include most built-in system functions within a user-defined function, even ones that are nondeterministic (that is, functions that can return different data values on each call). For example, the `getdate()` function is considered nondeterministic because even though it is always invoked with the same argument, it returns a different value each time it is executed. However, the following nondeterministic built-in functions are still not allowed in user-defined functions:

- ▶ `newid()`
- ▶ `newsequentialid()`
- ▶ `rand()`
- ▶ `textptr()`

User-defined functions can also call other user-defined functions, with a limit of 32 levels of nesting. Nesting of functions can help improve the modularity and reusability of

function code. For example, the following version of the `getonlydate()` function uses the `striptime()` function example shown earlier in this chapter:

```
CREATE FUNCTION dbo.getonlydate()
RETURNS datetime
as
BEGIN
DECLARE @date datetime
SET @date = dbo.striptime( getdate())
RETURN @date
end
```

Using SSMS to Create Functions

To create a function by using SSMS, open the Object Explorer to the database in which you want to create the function. Then select the Programmability node, right-click the Functions node, select New, and then choose one of the three available options as shown in Figure 29.1:

- ▶ Inline Table-Valued Function
- ▶ Multistatement Table-Valued Function
- ▶ Scalar-Valued Function

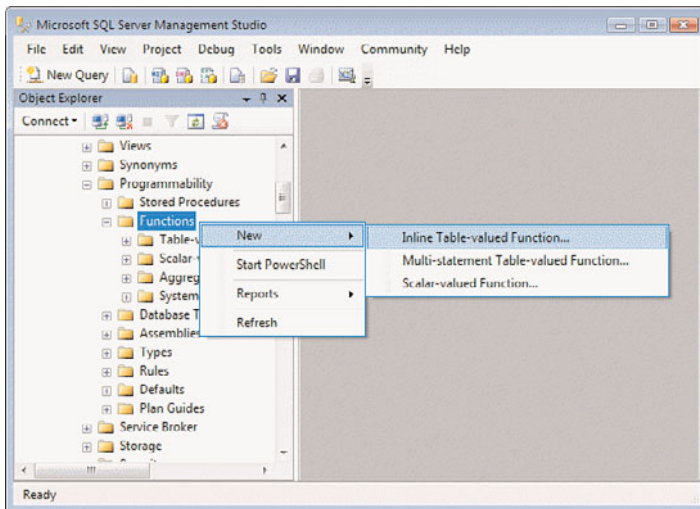

FIGURE 29.1 Creating a new function from the Object Browser in SSMS.

SSMS opens a new query window populated with a template for that type of function. Listing 29.1 shows an example of the default template code for an inline table-valued function that would be opened into a new query window.

LISTING 29.1 An Example of a New Function Creation Script Generated by SSMS

```

.. =====
-- Template generated from Template Explorer using:
-- Create Inline Function (New Menu).SQL
--
-- Use the Specify Values for Template Parameters
-- command (Ctrl-Shift-M) to fill in the parameter
-- values below.
--
-- This block of comments will not be included in
-- the definition of the function.
.. =====
SET ANSI_NULLS ON
GO
SET QUOTED_IDENTIFIER ON
GO
.. =====
-- Author:          <Author,,Name>
-- Create date:    <Create Date,,>
-- Description:    <Description,,>
.. =====
CREATE FUNCTION <Inline_Function_Name, sysname, FunctionName>
(
    -- Add the parameters for the function here
    <@param1, sysname, @p1> <Data_Type_For_Param1, , int>,
    <@param2, sysname, @p2> <Data_Type_For_Param2, , char>
)
RETURNS TABLE
AS
RETURN
(
    -- Add the SELECT statement with parameter references here
    SELECT 0
)

GO

```

You can modify the template code as necessary to name the function and to specify the parameters, return value, and function body. When you are finished, you execute the

contents of the query window to create the function. After you create a function successfully, you should save the source code to a file by choosing File, Save or File, Save As. This way, you can re-create the function from the file if it is accidentally dropped from the database.

One thing you might notice about the function templates is that they contain template parameters for parameter names and function names, for example. These template parameters are in the format `<parameter_name, data_type, value>`:

- ▶ *parameter_name* is the name of the template parameter in the script.
- ▶ *data_type* is the optional data type of the template parameter.
- ▶ *value* is the default value to be used to replace every occurrence of the template parameter in the script.

You can automatically substitute values for template parameters by selecting Query, Specify Values for Template Parameters or by pressing Ctrl+Shift+M. The Specify Values for Template Parameters dialog, shown in Figure 29.2, appears.

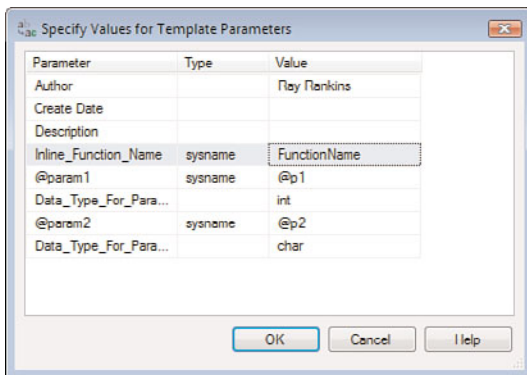

FIGURE 29.2 Using the Specify Values for Template Parameters dialog with functions in SSMS.

Enter the values for the template parameters in the Value column and then click OK. SSMS then substitutes any values you specified wherever the template parameter is defined within the template.

An alternative way to create a function from a template is to use the Template Explorer in SSMS. You can open the Template Explorer by selecting View, Template Explorer in SSMS (see Figure 29.3) or by pressing Ctrl+Alt+T. The Template Explorer window appears in SSMS (which is also shown in Figure 29.3).

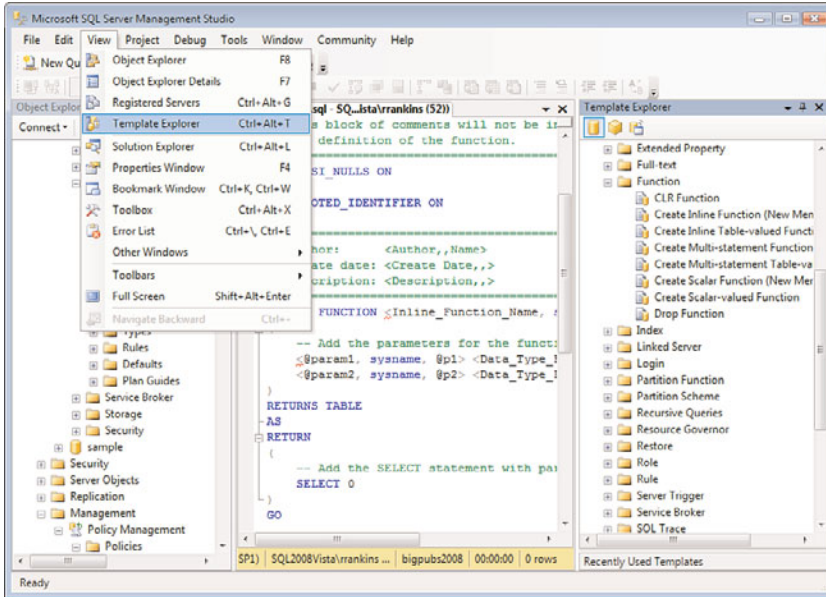

FIGURE 29.3 Opening the Template Explorer to create functions in SSMS.

You can double-click the template for the type of function you want to create or right-click the desired template and then select Open. SSMS opens a new query window populated with the template code.

NOTE

You are also able to edit the provided function templates available in the Template Explorer by right-clicking them and selecting Edit. You can then customize the templates to include code fragments, comments, or a structure that is more to your preferences and save the changes to the template file. However, it is generally recommended that you not modify the provided templates alone and instead create your own custom templates.

Creating Custom Function Templates

To create a custom function template, right-click the Function folder in the Template Explorer and select New. SSMS then creates an entry in the Template Explorer, and you can specify the name for the template, as shown in Figure 29.4.

To begin adding code to the template, you double-click it or right-click and select Open. A blank query window appears, and you can use it to enter the new template code. Probably the best way to get started is to copy the template code from one of the templates provided with SQL Server 2008.

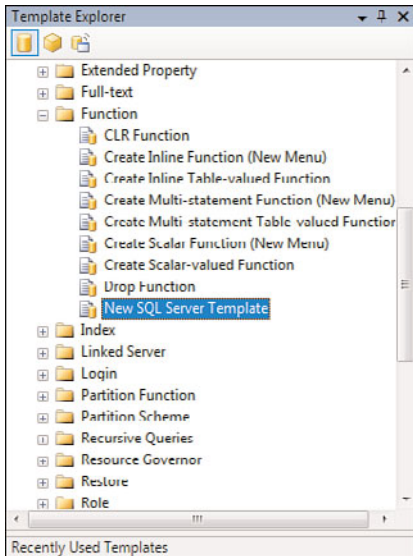

FIGURE 29.4 Creating a new function template in SSMS.

Listing 29.2 shows an example of a new function template.

LISTING 29.2 An Example of Custom Function Template

```

=====
-- SQL Server 2008 Unleashed Sample
-- Create scalar-valued function template
=====

USE <database_name, sysname, bigpubs2008>
GO

IF OBJECT_ID (N'<schema_nm, sysname, dbo>.<func_nm, sysname, fn_myfunc>')
    IS NOT NULL
    DROP FUNCTION <schema_nm, sysname, dbo>.<func_nm, sysname, fn_myfunc>
GO

CREATE FUNCTION <schema_nm, sysname, dbo>.<func_nm, sysname, fn_myfunc>
    (<parameter1, sysname, @param1> <parameter1_datatype,, int>,
     <parameter2, sysname, @param2> <parameter2_datatype,, int>,
     <parameter3, sysname, @param3> <parameter3_datatype,, int>)
    RETURNS <return_value_datatype,,int>
    WITH EXECUTE AS CALLER
AS
-- place the body of the function here

```

```

BEGIN
    DECLARE <variable1, sysname, @var1> <variable1_datatype,, int>,
           <variable2, sysname, @var2> <variable2_datatype,, int>

    select <variable1, sysname, @var1> = isnull(<parameter1, sysname, @param1> )
    <T-SQL_Body,,>

    RETURN <variable1, sysname, @var1>
END
GO

```

After you define a custom function template, you can use it as you do the built-in templates. You can double-click it or right-click and select Open, and SSMS opens a new query window with a new function creation script based on the custom template. If you use the default values for the template parameters, after the parameter substitution, your CREATE FUNCTION script should look like the one in Listing 29.3.

LISTING 29.3 An Example of a **CREATE FUNCTION** Script Generated from a Custom Function Template

```

=====
-- SQL Server 2008 Unleashed Sample
-- Create scalar-valued function template
=====

USE bigpubs2008
GO

IF OBJECT_ID (N'dbo.fn_myfunction') IS NOT NULL
    DROP FUNCTION dbo.fn_myfunction
GO

CREATE FUNCTION dbo.fn_myfunction
    (@param1 int,
     @param2 int,
     @param3 int)
RETURNS int
WITH EXECUTE AS CALLER
AS
-- place the body of the function here
BEGIN
    DECLARE @var1 int,
           @var2 int

```

```

select @var1 = isnull(@param1 )

RETURN @var1
END
GO

```

Viewing and Modifying User-Defined Functions

Besides using T-SQL commands to create functions, you can also use them to view and modify functions. You can get information by using the provided system procedures and queries against the `INFORMATION_SCHEMA.routines` view. The following sections describe these methods.

Using T-SQL to View Functions

To view the source code for a user-defined function, you can use the `sp_helptext` procedure:

```

use bigpubs2008
go
exec sp_helptext getonlydate
go

```

Text

.....

```

CREATE FUNCTION getonlydate ( )
RETURNS datetime
AS
BEGIN RETURN (select convert(datetime, convert(date, getdate())))
END

```

NOTE

To display the source code for the functions clearly, configure the SSMS query window to display results as text rather than in the grid by pressing `Ctrl+T`.

In addition to `sp_helptext`, you can write queries against the `INFORMATION_SCHEMA.routines` view to display the source code for a function:

```

SELECT routine_definition
from INFORMATION_SCHEMA.routines
where routine_name = 'getonlydate'
and specific_schema = 'dbo'

```

```
and specific_catalog = 'bigpubs2008'
```

```
routine_definition
```

```
-----
CREATE FUNCTION getonlydate ()
RETURNS datetime
AS
BEGIN RETURN (select convert(datetime, convert(date, getdate())))
END
```

If you want to display information about the input parameters for a function, you use the `INFORMATION_SCHEMA.parameters` view. For scalar functions, the view also displays information for the return parameter, which has an ordinal position of 0 and no parameter name:

```
select substring(parameter_name,1,20) as parameter_name,
       substring(data_type, 1, 20) as data_type,
       Parameter_mode,
       ordinal_position
from INFORMATION_SCHEMA.parameters
where specific_name = 'striptime'
and specific_schema = 'dbo'
and specific_catalog = 'bigpubs2008'
order by ordinal_position
go
```

parameter_name	data_type	Parameter_mode	ordinal_position
	datetime	OUT	0
@datetimeval	datetime	IN	1

If you want to display information about the result columns returned by a table-valued function, use the `INFORMATION_SCHEMA.routine_columns` view:

```
select substring(column_name, 1, 20) as column_name,
       substring (data_type, 1, 12)
       + case when character_maximum_length is not null
           then '(' + cast(character_maximum_length as varchar(4)) + ')'
           else ''
       end
       as datatype,
       numeric_precision as 'precision',
       numeric_scale as scale,
       ordinal_position
from INFORMATION_SCHEMA.routine_columns
where table_name = 'AveragePricebyType'
order by ordinal_position
go
```

column_name	datatype	precision	scale	ordinal_position
type	char(12)	NULL	NULL	1
avg_price	money	19	4	2

In addition, SQL Server provides the `OBJECTPROPERTY` function, which you can use to get information about functions. One of the things you can find out is whether a function is a multistatement table function, an inline function, or a scalar function. The `OBJECTPROPERTY` function accepts an object ID and an object property parameter, and it returns the value 1 if the property is true, 0 if it is false, or NULL if an invalid function ID or property parameter is specified. The following property parameters are appropriate for functions:

- ▶ **IsTableFunction**—Returns 1 if the function is a table-valued function but not an inline function.
- ▶ **IsInlineFunction**—Returns 1 if the function is an inline table-valued function.
- ▶ **IsScalarFunction**—Returns 1 if the function is a scalar function.
- ▶ **IsSchemaBound**—Returns 1 if the function was created with the `SCHEMABINDING` option.
- ▶ **IsDeterministic**—Returns 1 if the function is deterministic (that is, it always returns the same result each time it is called with a specific set of input values).

The following example demonstrates a possible use of the `OBJECTPROPERTY` function with the `INFORMATION_SCHEMA.routines` view:

```
select convert(varchar(10), specific_schema) as 'schema',
       convert(varchar(20), specific_name) as 'function',
       case objectproperty(object_id(specific_name), 'IsScalarFunction')
         when 1 then 'Yes' else 'No' end as IsScalar,
       case objectproperty(object_id(specific_name), 'IsTableFunction')
         when 1 then 'Yes' else 'No' end as IsTable,
       case objectproperty(object_id(specific_name), 'IsInlineFunction')
         when 1 then 'Yes' else 'No' end as IsInline,
       case objectproperty(object_id(specific_name), 'IsSchemaBound')
         when 1 then 'Yes' else 'No' end as IsSchemaBnd,
       case objectproperty(object_id(specific_name), 'IsDeterministic')
         when 1 then 'Yes' else 'No' end as IsDtrmnstc
from information_schema.routines
where routine_type = 'FUNCTION'
order by specific_name
go
```

schema	function	IsScalar	IsTable	IsInline	IsSchemaBnd	IsDtrmnstc
dbo	AverageBookPrice	Yes	No	No	No	No

dbo	AverageBookPrice2	Yes	No	No	No	No
dbo	AveragePricebyType	No	Yes	Yes	No	No
dbo	AveragePricebyType2	No	Yes	No	Yes	Yes
dbo	getdateonly	Yes	No	No	No	No
dbo	getonlydate	Yes	No	No	No	No
dbo	striptime	Yes	No	No	No	No
dbo	striptime2	Yes	No	No	No	No

Using T-SQL to Modify Functions

You can use the ALTER FUNCTION command to change a function's definition without having to drop and re-create it. The syntax for the ALTER FUNCTION command is identical to the syntax for CREATE FUNCTION, except that you replace the CREATE keyword with the ALTER keyword. The following example modifies the AveragePricebyType2 function:

```
ALTER FUNCTION AveragePricebyType2 (@price money = 0.0)
RETURNS @table table (type varchar(12) null, avg_price money null)
with schemabinding
AS
begin
    insert @table
        SELECT type, avg(price) as avg_price
        FROM dbo.titles
        group by type
        having avg(price) > @price
        order by avg(price) desc
    return
end
```

Using the ALTER FUNCTION command has a couple advantages over dropping and re-creating a function to modify it. The main advantage, as mentioned earlier, is that you don't have to drop the function first to make the change. The second advantage is that, because you don't have to drop the function, you don't have to worry about reassigning permissions to the function. To determine whether a function has been altered since it was created, you can query the LAST_ALTERED column in the INFORMATION_SCHEMA.routines view for that function.

One limitation of the ALTER FUNCTION command is that you cannot use this command to change a table-valued function to a scalar function or to change an inline function to a multistatement function. You have to drop and re-create the function.

Using SSMS to View and Modify Functions

To view or edit a function within SSMS, open the Object Explorer to the database in which you want to create the function. Then select the Programmability node, right-click the Functions node, and then select either the Table-Valued Functions folder or the Scalar-Valued Functions folder. SSMS then displays a list of the functions of that type defined in that database within the Object Explorer as well as in the Summary window.

NOTE

If the function you want to view or edit is not shown in the list, it was probably created after the list of functions in the Object Explorer was populated. You might need to refresh the function list in Object Explorer. To do this, you right-click the Functions folder and choose Refresh.

When you right-click a function name in either the Object Explorer or the Summary window, you are presented with a number of options for viewing or modifying the function, as shown in Figure 29.5.

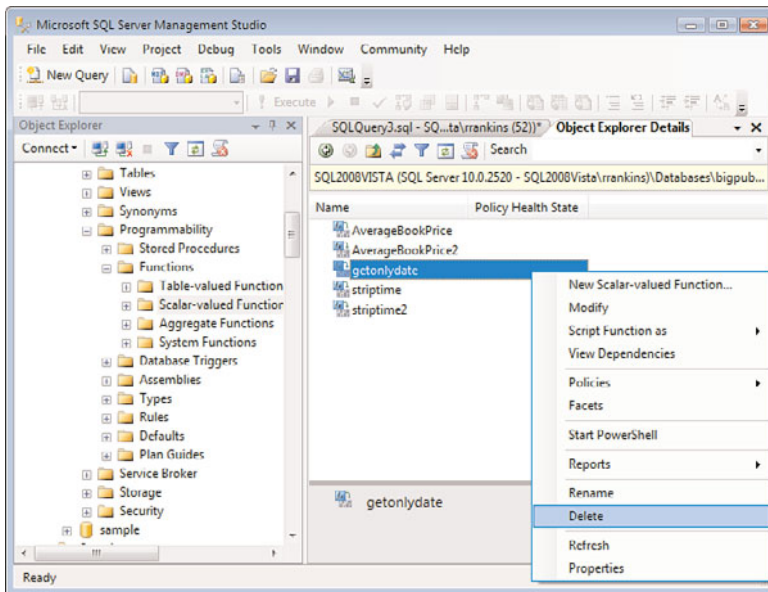

FIGURE 29.5 The Options menu for viewing and editing functions in SSMS.

You can view or edit the function properties, view the function dependencies, delete the function, rename it, modify it, or script the function definition. If you choose to edit the function by clicking **Modify**, SSMS opens a new query window with the source code of the function extracted from the database as an `ALTER FUNCTION` command. You can edit the function as needed and execute the code in the query window to modify the function.

There are also options for scripting a function as a `CREATE`, `ALTER`, `DROP`, or `SELECT` command to either a new query window, a file, or the Clipboard, as shown in Figure 29.6.

You can also view the function properties by selecting the **Properties** option from the context menu. The Properties dialog appears, as shown in Figure 29.7. Unfortunately, except for the function permissions and extended properties, the properties shown are read-only.

For more information on the features and options for SSMS and for scripting objects, see Chapter 4, “SQL Server Management Studio.”

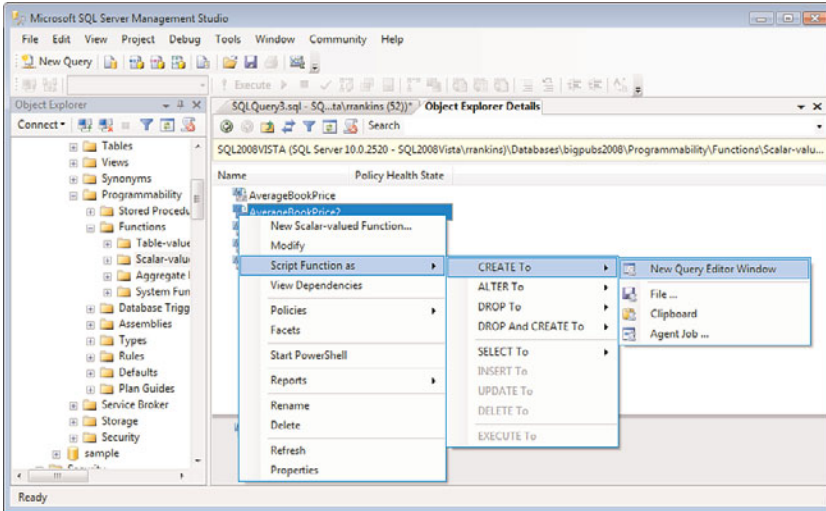

FIGURE 29.6 Options for scripting functions in SSMS.

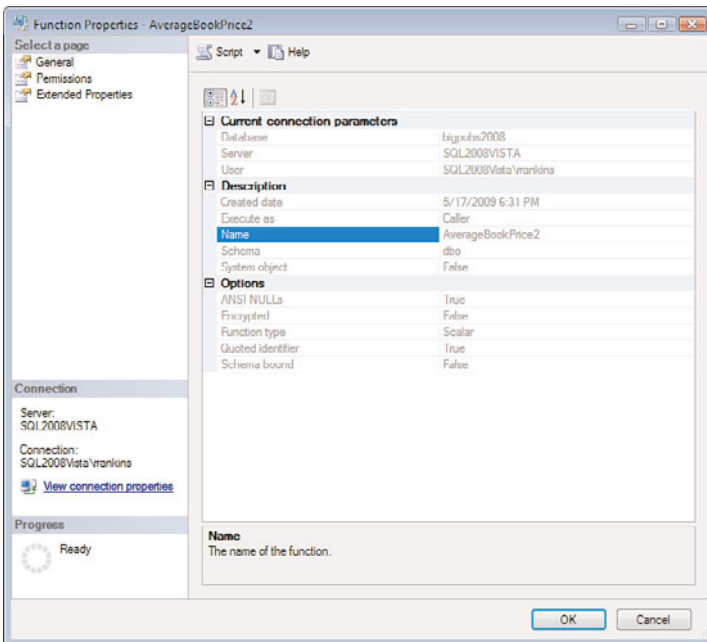

FIGURE 29.7 The Function Properties dialog in SSMS.

Managing User-Defined Function Permissions

When a function is initially created, the only user who has permission to execute the function is the user who created it. To allow other users to execute a scalar function, you need to grant EXECUTE permission on the function to the appropriate user(s), group(s), or

role(s). For a table-valued function, you need to grant SELECT permission to the user(s), group(s), or role(s) that will need to reference it. The following example grants EXECUTE permission on the `getonlydate()` function to everyone and SELECT permission on the `AveragePriceByType` function to the database user `fred`:

```
GRANT EXECUTE on dbo.getonlydate to public
GRANT SELECT on AveragePricebyType to fred
```

For more detailed information on granting and revoking permissions, see Chapter 11, “Security and User Administration.”

In SQL Server 2008, you can also specify the execution context of scalar-valued and multi-statement, table-valued, user-defined functions. Essentially, this capability allows you to control which user account is used to validate permissions on objects referenced by the function, regardless of what user is actually executing the function. This provides additional flexibility and control in managing permissions for user-defined functions and the objects they reference. Only EXECUTE or SELECT permissions need to be granted to users on the function itself; you do not have to grant them explicit permissions on the referenced objects. Only the user account defined as the execution context for the function by the EXECUTE AS clause must have the necessary permissions on the objects the function accesses.

For example, in the following SQL script, the `AverageBookPrice2` function is modified to run within the context of the `dbo` user. Any user who invokes this function essentially inherits the permissions of the `dbo` user on any objects accessed within the scope of the function temporarily for the execution of the function:

```
ALTER FUNCTION [dbo].[AverageBookPrice2](@booktype varchar(12) = '%')
RETURNS money
WITH EXECUTE AS 'dbo'
AS
BEGIN
    RETURN ( SELECT avg(price)
            FROM titles
            WHERE type like @booktype)
END
GO
```

Rewriting Stored Procedures as Functions

In releases of SQL Server prior to SQL Server 2000, if you wanted to do custom processing within SQL code, your only real option was to create stored procedures to do things that often would have worked much better as functions. For example, you couldn't use the result set of a stored procedure in a WHERE clause or to return a value as a column in a select list. Using a stored procedure to perform calculations on columns in a result set often required using a cursor to step through each row in a result set and pass the column

values fetched, one at a time, to the stored procedure as parameters. This procedure then typically returned the computed value via an output parameter, which had to be mapped to another local variable. Another alternative was to retrieve the initial result set into a temporary table and then perform additional queries or updates against the temporary table to modify the column values, which often required multiple passes. Neither of these methods was an efficient means of processing the data, but prior to SQL Server 2000, few alternatives existed. If you needed to join against the result set of a stored procedure, you had to insert the result set into a temporary table first and then join against the temporary table, as shown in the following code fragment:

```
...
insert #results exec result_proc
select * from other_Table
    join #results on other_table.pkey = #results.keyfield
...
```

Now that SQL Server supports user-defined functions, you might want to consider rewriting some of your old stored procedures as functions to take advantage of the capabilities of functions and improve the efficiency of your SQL code. You mainly want to do this in situations in which you would like to be able to invoke a stored procedure directly from within a query. If the stored procedure returns a result set, it is a candidate for being written as a table-valued function. If it returns a scalar value, usually via an output parameter, it is a candidate for being written as a scalar function. However, the following criteria also are indications that a procedure is a good candidate for being rewritten as a function:

- ▶ The procedure logic is expressible in a single `SELECT` statement; however, it is written as a stored procedure, rather than a view, because of the need for it to be parameter driven.
- ▶ The stored procedure does not perform update operations on tables, except against table variables.
- ▶ There are no dynamic SQL statements executed via the `EXECUTE` statement or `sp_executesql`.
- ▶ The stored procedure returns no more than a single result set.
- ▶ If the stored procedure returns a result set, its primary purpose is to build an intermediate result that is typically loaded into a temporary table, which is then queried in a `SELECT` statement.

The `result_proc` stored procedure, used earlier in this section, could possibly be rewritten as a table-valued function called `fn_result()`. The preceding code fragment could then be rewritten as follows:

```
SELECT *
    FROM fn_results() fn
    join other_table o.pkey = fn.keyfield
```

Creating and Using CLR Functions

Prior to SQL Server 2005, the only way to extend the functionality of SQL Server beyond what was available using the T-SQL language was to create extended stored procedures or Component Object Model (COM) components. The main problem with these types of extensions was that if not written very carefully, they could have an adverse impact on the reliability and security of SQL Server. For example, extended stored procedures are implemented as DLLs that run in the same memory space as SQL Server. An access violation raised in a poorly written extended stored procedure could crash SQL Server itself.

In addition, neither extended stored procedures nor COM components allow you to create custom user-defined functions that can be written in any programming language other than T-SQL, which has a limited command set for operations such as complex string comparison and manipulation and complex numeric computations.

In SQL Server 2008, you can write custom user-defined functions in any Microsoft .NET Framework programming language, such as Microsoft Visual Basic .NET or Microsoft Visual C#. SQL Server supports both scalar and table-valued CLR functions, as well as CLR user-defined aggregate functions. These extensions written in the CLR are much more secure and reliable than extended stored procedures or COM components.

For information on the methods and tools to actually create and compile CLR user-defined functions, see Chapter 46. This chapter focuses only on how to install and use CLR functions in a SQL Server database.

NOTE

The CLR function examples presented in the following sections are provided as illustrations only. The sample code will not execute successfully because the underlying CLR assemblies have not been provided.

Adding CLR Functions to a Database

If you've already created and compiled a CLR function, your next task is to install that CLR function in the database. The first step in this process is to copy the .NET assembly to a location that SQL Server can access, and then you need to load it into SQL Server by creating an assembly. The syntax for the CREATE ASSEMBLY command is as follows:

```
CREATE ASSEMBLY AssemblyName [AUTHORIZATION Owner_name]
FROM { <client_assembly_specifier> | <assembly_bits> [ , ...n ] }
[WITH PERMISSION_SET = (SAFE | EXTERNAL_ACCESS | UNSAFE) ]
```

AssemblyName is the name of the assembly. *client_assembly_specifier* specifies the local path or network location where the assembly being uploaded is located, and also the manifest filename that corresponds to the assembly. It can be expressed as a fixed string or an expression evaluating to a fixed string, with variables. The path can be a local path, but often the path is a network share. *assembly_bits* is the list of binary values that make up the assembly and its dependent assemblies.

The WITH clause is optional, and it defaults to SAFE. Marking an assembly with the SAFE permission set indicates that no external resources (for example, the Registry, Web services, file I/O) are going to be accessed.

The CREATE ASSEMBLY command fails if it is marked as SAFE and assemblies like System.IO are referenced. Also, if anything causes a permission demand for executing similar operations, an exception is thrown at runtime.

Marking an assembly with the EXTERNAL_ACCESS permission set tells SQL Server that it will use resources such as networking, files, and so forth. Assemblies such as System.Web.Services (but not System.Web) can be referenced with this set. To create an EXTERNAL_ACCESS assembly, the creator must have EXTERN ACCESS_permission.

Marking an assembly with the UNSAFE permission set tells SQL Server that not only might external resources be used, but unmanaged code may be invoked from managed code. An UNSAFE assembly can potentially undermine the security of either SQL Server or the CLR. Only members of the sysadmin role can create UNSAFE assemblies.

After the assembly is created, the next step is to associate the method within the assembly with a user-defined function. You do this with the CREATE FUNCTION command, using the following syntax:

```
CREATE FUNCTION [ schema_name. ] function_name
    ( [ { @parameter_name [AS] [ schema_name.]scalar_datatype [ = default ] }
      [ ,...n ] ] )
RETURNS { return_data_type | TABLE ( { column_name data_type } [ ,...n ] ) }
[ WITH { [ , RETURNS NULL ON NULL INPUT | CALLED ON NULL INPUT ]
        [ , EXECUTE_AS_Clause ] } ]
[ AS ] EXTERNAL NAME assembly_name.class_name.method_name
```

After creating the CLR function successfully, you can use it just as you would a T-SQL function. The following example shows how to manually deploy a table-valued CLR function:

```
CREATE ASSEMBLY fn_EventLog
FROM 'F:\assemblies\fn_EventLog\fn_eventlog.dll'
WITH PERMISSION_SET = SAFE
GO
CREATE FUNCTION ShowEventLog(@logname nvarchar(100))
RETURNS TABLE (logTime datetime,
                Message nvarchar(4000),
                Category nvarchar(4000),
                InstanceId bigint)
AS
EXTERNAL NAME fn_EventLog.TabularEventLog.InitMethod
GO
SELECT * FROM dbo.ReadEventLog(N'System') as T
go
```

NOTE

The preceding examples show the steps involved in manually registering an assembly and creating a CLR function. If you use Visual Studio's Deploy feature, the CREATE/ALTER ASSEMBLY and CREATE FUNCTION commands are issued automatically by Visual Studio. For more details on using Visual Studio to create and deploy user-defined CLR functions, see Chapter 46.

Deciding Between Using T-SQL or CLR Functions

One question that often comes up regarding user-defined functions is whether it's better to develop functions in T-SQL or in the CLR. The answer really depends on the situation and what the function will be doing.

The general rule of thumb is that if the function will be performing data access or large set-oriented operations with little or no complex procedural logic, it's better to create that function in T-SQL to get the best performance. The reason is that T-SQL works more closely with the data and doesn't require multiple transitions between the CLR and SQL Server engine.

On the other hand, most benchmarks have shown that the CLR performs better than T-SQL for functions that require a high level of computation or text manipulation. The CLR offers much richer APIs that provide capabilities not available in T-SQL for operations such as text manipulation, cryptography, I/O operations, data formatting, and invoking of web services. For example, T-SQL provides only rudimentary string manipulation capabilities, whereas the .NET Framework supports capabilities such as regular expressions, which are much more powerful for pattern matching and replacement than the T-SQL `replace()` function.

Another good candidate for CLR functions is user-defined aggregate functions. User-defined aggregate functions cannot be defined in T-SQL. To compute an aggregate value over a group in T-SQL, you would have to retrieve the values as a result set and then enumerate over the result set, using a cursor to generate the aggregate. This results in slow and complicated code. With CLR user-defined aggregate functions, you need to implement the code only for the accumulation logic. The query processor manages the iteration, and any user-defined aggregates referenced by the query are automatically accumulated and returned with the query result set. This approach can be orders of magnitude faster than using cursors, and it is comparable to using SQL Server built-in aggregate functions. For example, the following shows how you might use a user-defined aggregate function that aggregates all the authors for a specific BookId into a comma-separated list:

```
use bigpubs2008
go
SELECT t.Title_ID, count(*), dbo.CommaList(a.au_lname) as AuthorNames
FROM Authors a
JOIN titleauthor ta on a.au_id = ta.au_id
```

```

JOIN Titles t on ta.title_id = t.title_id
GROUP BY t.title_id
having count(*) > 2
go

```

```

Title_ID AuthorNames
-----

```

```

TC7777  O'Leary, Gringlesby, Yokomoto

```

NOTE

The preceding example will not execute successfully because we have not created the `CommaList()` CLR function. It is provided merely as an example showing how such a function could be used if it was created.

In a nutshell, performance tests have generally shown that T-SQL generally performs better for standard CRUD (create, read, update, delete) operations, whereas CLR code performs better for complex math, string manipulation, and other tasks that go beyond data access.

Summary

User-defined functions in SQL Server 2008 allow you to create reusable routines that can help make your SQL code more straightforward and efficient.

In this chapter, you saw how to create and modify scalar functions and inline and multi-statement table-valued functions and how to invoke and use them in queries. Scalar functions can be used to perform more complex operations than those provided by the built-in scalar functions. Table-valued functions provide a way to create what are essentially parameterized views, and you can include them inline in your queries, just as you would in a table or view.

With the introduction of CLR-based functions, SQL Server 2008 greatly increases the power and capabilities of user-defined functions, and CLR functions can also provide performance improvements over T-SQL functions that need to perform complex computations or string manipulations.

In the next chapter, you learn how to create and manage triggers in SQL Server 2008.

This page intentionally left blank

CHAPTER 30

Creating and Managing Triggers

A *trigger* is a special type of stored procedure executed automatically based on the occurrence of a database event. Prior to SQL Server 2005, the database events that fired triggers were based only on data manipulations, such as insertions, updates, or deletions. Triggers in SQL Server 2005 and SQL Server 2008 can also fire on events related to the definition of database objects. The two types of triggering events are referred to as Data Manipulation Language (DML) and Data Definition Language (DDL) events.

Most of the benefits derived from triggers are based on their event-driven nature. Once created, triggers automatically fire (without user intervention) based on an event in the database. This differs from other database code, which must be called explicitly in order to execute.

Say, for example, that you would like to keep track of historical changes to the data in several key tables in a database. Whenever a change is made to the data in the tables, you would like to put a copy of the data in a historical table before the change is made. You could accomplish this via the application code that is making the change to the data. The application code could copy the data to the history table before the change occurs and then execute the actual change. You could also manage this in other ways, such as by using stored procedures that are called by the application and subsequently insert records into the history tables.

These solutions work, but a trigger-based solution has some distinct advantages over them. With a trigger-based solution, a trigger can act on any modifications to the key tables. In the case of the history table example, triggers would automatically insert records into the history table whenever a modification was made to the data. This would

IN THIS CHAPTER

- ▶ What's New in Creating and Managing Triggers
- ▶ Using DML Triggers
- ▶ Using DDL Triggers
- ▶ Using CLR Triggers
- ▶ Using Nested Triggers
- ▶ Using Recursive Triggers

all happen within the scope of the original transaction and would write history records for any changes made to these tables, including ad hoc changes that may have been made directly to the tables outside the application.

This is just one example of the benefits and uses of triggers. This chapter discusses the different types of triggers and further benefits they can provide.

What's New in Creating and Managing Triggers

The features and methods available for creating and managing triggers are essentially the same in SQL Server 2008 as they were in SQL Server 2005. The upside to this is that you can take the knowledge and skills that you have with SQL Server 2005 and apply them directly to SQL Server 2008.

One area that has had some minor changes in SQL Server 2008 relates to events captured by DDL triggers. In SQL Server 2008 more system stored procedures that perform DDL-like operations fire DDL triggers and event notification. In SQL Server 2005 certain system stored procedures would fire DDL triggers, but there are many more included in SQL Server 2008. For example, the execution of the `sp_rename` stored procedure would not fire a DDL trigger in SQL Server 2005, but it does in SQL Server 2008. Refer to the “Using DDL Triggers” section later in this chapter for a complete list of DDL statements and system stored procedures that DDL triggers respond to.

Using DML Triggers

DML triggers are invoked when a DML event occurs in the database. DML events manipulate or modify the data in a table or view. These events include insertions, updates, and deletions.

DML triggers are powerful objects for maintaining database integrity and consistency. They are able to evaluate data before it has been committed to the database. During this evaluation period, these triggers can perform a myriad of actions, including the following:

- ▶ Compare before and after versions of data.
- ▶ Roll back invalid modifications.
- ▶ Read from other tables, including those in other databases.
- ▶ Modify other tables, including those in other databases.
- ▶ Execute local and remote stored procedures.

Based on the nature of these actions, triggers were originally used in many cases to enforce referential integrity. Triggers were used when foreign key columns in one table had to be validated against primary keys or unique index values in another table. The triggers could fire when data was modified, and validations could be performed to ensure that referential integrity was maintained.

The advent of declarative referential integrity (DRI) diminished the need for referential integrity triggers. DRI is now generally implemented with database objects such as foreign key constraints that perform the referential integrity validation internally. Because of this, triggers generally handle more complex integrity concepts and enforce restrictions that cannot be handled through data types, constraints, defaults, or rules. Following are some examples of trigger uses:

- ▶ **Maintenance of duplicate and derived data**—A denormalized database generally introduces data duplications (that is, redundancy). Instead of exposing this redundancy to end users and programmers, you can keep the data in sync by using triggers. If the derived data is allowed to be out of sync, you might want to consider handling refreshes through batch processing or some other method instead.
- ▶ **Complex column constraints**—If a column constraint depends on other rows within the same table or rows in other tables, using a trigger is the best method for that column constraint.
- ▶ **Complex defaults**—You can use a trigger to generate default values based on data in other columns, rows, or tables.
- ▶ **Inter-database referential integrity**—When related tables are found in two different databases, you can use triggers to ensure referential integrity across the databases.

You can use stored procedures for all these tasks, but the advantage of using triggers is that they fire on all data modifications. Stored procedure code or SQL in application code is executed only when it makes the data modifications. With triggers, all data modifications are subject to the trigger code, except for bulk copy and a few other nonlogged actions. Even if a user utilizes an ad hoc tool, such as SQL Server Management Studio (SSMS) to make changes to the database, the integrity rules cannot be bypassed after the trigger is in place.

NOTE

Triggers and stored procedures are not mutually exclusive. You can have both triggers and stored procedures that perform modifications and validation on that same table. If desired, you can perform some tasks via triggers and other tasks via stored procedures.

Creating DML Triggers

You can create and manage triggers in SQL Server Management Studio or directly via Transact-SQL (T-SQL) statements. The Object Explorer in SSMS provides a simple means of creating triggers that you can use to generate the underlying T-SQL code. You expand the Object Explorer tree to the user table level and then right-click the Triggers node. When you select the New Trigger option, as shown in Figure 30.1, the trigger template shown in the right pane of Figure 30.1 appears.

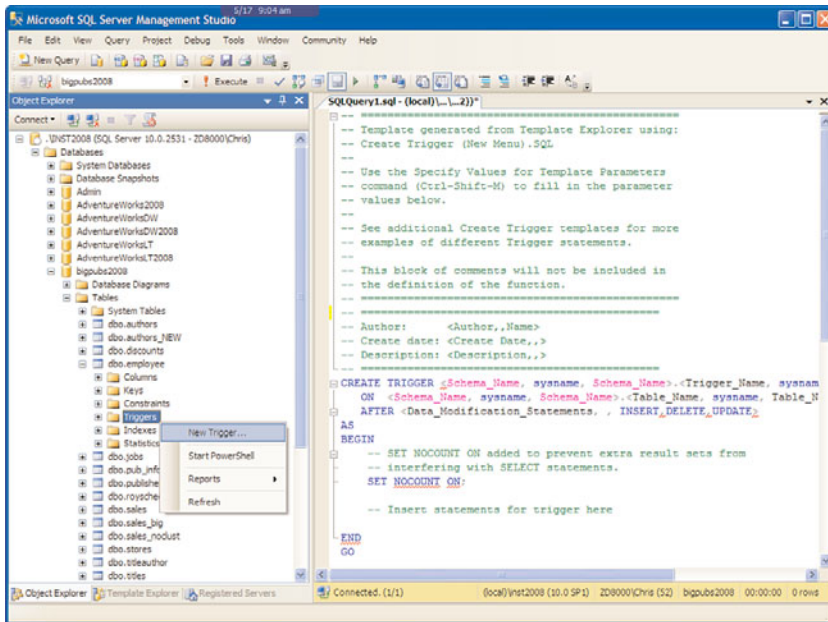

FIGURE 30.1 Using SSMS to create triggers.

You can populate the trigger template by manually editing it, or you can select the Query menu option Specify Values for Template Parameters. When you select Specify Values for Template Parameters, a screen appears, allowing you to fill in the basic values for the trigger, including the table that the trigger will be on and the events to respond to.

You can launch the New Trigger template and other templates related to triggers via the Template Explorer, which you open by selecting View, Template Explorer in SSMS. Figure 30.2 shows a partial list of the available templates, including those related to triggers.

All the trigger templates provide a basic framework for you to create a trigger, but the core logic is up to you. Existing triggers or sample triggers are often good alternatives to the templates because they offer more of the core logic. You can right-click a trigger in the Object Explorer and select the Script Trigger As option. This option contains several different methods to script the trigger. After you script a trigger, you can modify it as necessary to meet your needs.

TIP

Using the `sys.triggers` catalog view is a good way to list all the triggers in a database. To use it, you simply open a new query editor window in SSMS and select all the rows from the view as shown in the following example:

```
SELECT * FROM sys.triggers
```

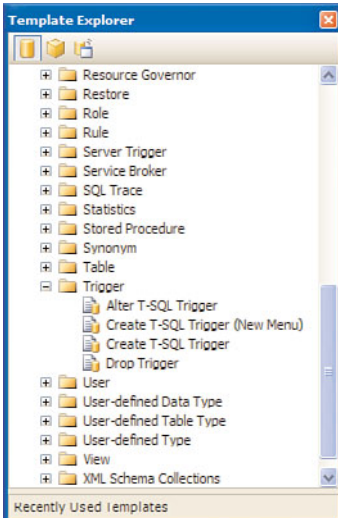

FIGURE 30.2 The Template Explorer.

After you have a basic trigger template, you can code the trigger, with limited restrictions. Almost every T-SQL statement you would use in a SQL batch or stored procedure is also available for use in the trigger code. However, you cannot use the following commands in a DML trigger:

- ▶ ALTER DATABASE
- ▶ CREATE DATABASE
- ▶ DISK RESIZE
- ▶ DROP DATABASE
- ▶ LOAD DATABASE and LOAD LOG
- ▶ RECONFIGURE
- ▶ RESTORE DATABASE and RESTORE LOG

The following sections describe the different types of DML triggers that can be coded and some of their common uses.

Using AFTER Triggers

An AFTER trigger is the original mechanism that SQL Server created to provide an automated response to data modifications. Prior to the release of SQL Server 2000, the AFTER trigger was the only type of trigger, and the word AFTER was rarely used in its name. Any trigger written for prior versions of SQL Server or documentation referring to these triggers is for AFTER triggers.

SQL Server 2000 introduced a new type of trigger called an INSTEAD OF trigger. This trigger is discussed later in the section titled “INSTEAD OF Triggers.” The introduction of that new

trigger and inclusion of the word **AFTER** in the name of the old trigger have helped accentuate the behavior of the **AFTER** trigger: the **AFTER** trigger executes *after* a data modification has taken place.

NOTE

Throughout the rest of this chapter, if the trigger type is not specified, you can assume that it is an **AFTER** trigger.

The fact that an **AFTER** trigger fires *after* a data modification might seem to be a simple concept, but it is critical to understanding how it works. The **AFTER** trigger fires after the data modification statement completes but before the statement's work is committed to the databases. The statement's work is captured in the transaction log but not committed to the database until the trigger has executed and performed its actions.

The trigger has the capability to roll back its actions as well as the actions of the modification statement that invoked it. This is possible because an implicit transaction exists that includes both the modification statement and trigger it fires. If the trigger does not issue a rollback, an implicit **COMMIT** of all the work is issued when the trigger completes.

The basic syntax for creating an **AFTER** trigger is as follows:

```
CREATE TRIGGER trigger_name
ON table_name
AFTER { INSERT | UPDATE | DELETE }
AS
SQL statements
```

The **AFTER** trigger is the default type of DML trigger, so the **AFTER** keyword is optional.

Listing 30.1 shows the code you use to create a trigger in the **BigPubs2008** database. (You can find instructions for creating the **BigPubs2008** database in the introduction chapter at the beginning of this book.) This new trigger prints a message, stating the number of rows updated by an **UPDATE** statement. You then execute a couple of **UPDATE** statements to see whether the trigger works.

LISTING 30.1 An Example of a Simple **AFTER** Trigger

```
CREATE TRIGGER tr_au_upd ON authors
AFTER UPDATE
AS
PRINT 'TRIGGER OUTPUT: ' + CONVERT(VARCHAR(5), @@ROWCOUNT)
+ ' rows were updated.'
GO

UPDATE authors
SET au_fname = au_fname
```

```

WHERE state = 'UT'
GO
--TRIGGER OUTPUT: 1 rows were updated.

UPDATE authors
SET au_fname = au_fname
WHERE state = 'CA'
GO
--TRIGGER OUTPUT: 37 rows were updated.

```

Even though you do not actually change the contents of the `au_fname` column (because you set it to itself), the trigger fires anyway. Listing 30.1 does not show the typical use of a trigger, but it gives you some insight into how and when a trigger fires. The fact that the trigger fires, regardless of what is updated, causes many developers to test the `@@rowcount` value at the beginning of the trigger code. If `@@rowcount` is equal to zero, the trigger can return without executing the remainder of the trigger code. This is a good tactic for optimizing the performance of triggers.

NOTE

Triggers are meant to guarantee the integrity of data. Although you can return result sets and messages in triggers, doing so is not recommended. The programmers who write applications that perform modifications on a table are probably not prepared to get unexpected result sets or messages when they submit data modification statements.

The exception is returning an error with the `RAISERROR` command. If a trigger performs `ROLLBACK TRAN`, it should also execute `RAISERROR` to communicate the failure to the application.

Executing AFTER Triggers

You know that the `AFTER` trigger fires when a data modification (such as an insertion, an update, or a deletion) takes place. What about the trigger's execution in relationship to other events, including the execution of constraints? The following events take place before an `AFTER` trigger executes:

- ▶ **Constraint processing**—This includes `CHECK` constraints, `UNIQUE` constraints, and `PRIMARY KEY` constraints.
- ▶ **Declarative referential actions**—These actions are defined by `FOREIGN KEY` constraints that ensure the proper relationships between tables. This includes cascading `FOREIGN KEY` constraints.
- ▶ **Triggering action**—This data modification caused the trigger to fire. The action occurs before the trigger fires, but the results are not committed to the database until the trigger completes.

You need to consider this execution carefully when you design triggers. For example, if you have a constraint and trigger defined on the same column, any violations to the

constraint about the statement, and the trigger execution does not occur. For example, if you have a foreign key constraint on a table that ensures referential integrity and a trigger that does some validation on that same foreign key column then the trigger validation will only execute if the foreign key validation is successful.

Specifying Trigger Firing Order

You can create more than one trigger on a table for each data modification action. In other words, you can have multiple triggers responding to an INSERT, an UPDATE, or a DELETE command. This can be useful in certain situations, but it can generate confusion because you might not know the order in which the triggers fire for the particular action.

Some of the confusion has been alleviated by the fact that SQL Server 2008 allows you to specify the first and last trigger that fire for a particular action. If you have four triggers responding to updates on a given table, you can set the order for two of the triggers (first and last), but the order of the remaining two triggers remains unknown.

The `sp_settriggerorder` procedure is the tool you use to set the trigger order. This procedure takes the trigger name, order value (FIRST, LAST, or NONE), and action (INSERT, UPDATE, or DELETE) as parameters. For example, you could use the following to set the firing order on the trigger used in this chapter's simple example:

```
sp_settriggerorder tr_au_upd, FIRST, 'UPDATE'
```

The execution of this command sets the `tr_au_upd` trigger as the first trigger to fire when an update happens to the table on which this trigger has been placed. If an ALTER statement is executed against the trigger after the trigger order has been defined, the firing order is lost. The `sp_settriggerorder` procedure must be run again to reestablish the firing order.

NOTE

It is recommended that you avoid defining multiple triggers for the same event on the same table when possible. Often, it is possible to include all the logic in one trigger defined for an action. This can simplify your database and avoid the uncertainty of the firing order.

Special Considerations with AFTER Triggers

Following are a few other considerations for AFTER triggers:

- ▶ AFTER triggers can be used on tables that also have cascading referential integrity constraints. The cascading feature, which was new to SQL Server 2000, allows you to define cascading actions when a user updates or deletes a primary key to which a foreign key points. This new feature is discussed in more detail in Chapter 24, "Creating and Managing Tables."
- ▶ WRITETEXT and TRUNCATE TABLE do not fire triggers. BCP, by default, does not fire triggers either, but the FIRE_TRIGGERS bulk copy hint can be specified to cause both AFTER and INSTEAD OF triggers to execute.

- ▶ Triggers are objects, so they must have unique names within the database. If you try to add a trigger with a name that already exists, you get an error message. You can, however, use ALTER on an existing trigger.

The following restrictions apply to AFTER triggers:

- ▶ AFTER triggers can be placed only on tables, not on views.
- ▶ A single AFTER trigger cannot be placed on more than one table.
- ▶ The text, ntext, and image columns cannot be referenced in the AFTER trigger logic.

Using inserted and deleted Tables

In most trigger situations, you need to know what changes were made as part of the data modification. You can find this information in the `inserted` and `deleted` tables. For the AFTER trigger, these temporary memory-resident tables contain the rows modified by the statement. With the `INSTEAD OF` trigger, the `inserted` and `deleted` tables are actually temporary tables created on-the-fly.

The `inserted` and `deleted` tables have identical column structures and names as the tables that were modified. Consider running the following statement against the `BigPubs2008` database:

```
UPDATE titles
  SET price = $15.05
  WHERE type LIKE '%cook%'
```

When this statement is executed, a copy of the rows to be modified is recorded, along with a copy of the rows after the modification. These copies are available to the trigger in the `deleted` and `inserted` tables.

If you want to be able to see the contents of the `deleted` and `inserted` tables for testing purposes, you can create a copy of the table and then create a trigger on that copy (see Listing 30.2). You can perform data modification statements and view the contents of these tables without the modification actually taking place.

LISTING 30.2 Viewing the Contents of the **inserted** and **deleted** Tables

```
--Create a copy of the titles table in the BigPubs2008 database
SELECT *
  INTO titles_copy
  FROM titles
GO
--add an AFTER trigger to this table for testing purposes
CREATE TRIGGER tc_tr ON titles_copy
  FOR INSERT, UPDATE, DELETE
  AS
  PRINT 'Inserted:'
  SELECT title_id, type, price FROM inserted
```

```

PRINT 'Deleted:'
SELECT title_id, type, price FROM deleted
ROLLBACK TRANSACTION

```

The inserted and deleted tables are available within the trigger after INSERT, UPDATE, and DELETE. Listing 30.3 shows the contents of inserted and deleted, as reported by the trigger when executing the preceding UPDATE statement.

LISTING 30.3 Viewing the Contents of the **inserted** and **deleted** Tables When Updating the **titles_copy** Table

```

UPDATE titles_copy
SET price = $15.05
WHERE type LIKE '%cook%'

```

Inserted:

title_id	type	price
TC7777	trad_cook	15.05
TC4203	trad_cook	15.05
TC3218	trad_cook	15.05
MC3021	mod_cook	15.05
MC2222	mod_cook	15.05

Deleted:

title_id	type	price
TC7777	trad_cook	14.3279
TC4203	trad_cook	14.595
TC3218	trad_cook	0.0017
MC3021	mod_cook	15.894
MC2222	mod_cook	14.9532

NOTE

In SQL Server 2008, an error message is displayed after a rollback is initiated in a trigger. The error message indicates that the transaction ended in the trigger and that the batch has been aborted. Prior to SQL Server 2005, an error message was not displayed when a rollback was encountered in the trigger.

The nature of the inserted and deleted tables enables you to determine the action that fired the trigger. For example, when an INSERT occurs, the deleted table is empty because there were no previous values prior to the insertion. Table 30.1 shows the DML triggering events and the corresponding contents in the deleted and inserted tables.

TABLE 30.1 Determining the Action That Fired a Trigger

Statement	Contents of inserted	Contents of deleted
INSERT	Rows added	Empty
UPDATE	New rows	Old rows
DELETE	Empty	Rows deleted

NOTE

Triggers do not fire on a row-by-row basis. One common mistake in coding triggers is to assume that only one row is modified. However, triggers are set-based. If a single statement affects multiple rows in the table, the trigger needs to handle the processing of all the rows that were affected, not just one row at a time.

One common approach to dealing with the multiple rows in a trigger is to place the rows in a cursor and then process each row that was affected, one at a time. This approach works, but it can have an adverse effect on the performance of the trigger. To keep your trigger execution fast, you should try to use rowset-based logic instead of cursors in triggers when possible.

Rowset-based logic will typically join to the inserted or deleted table that are available to a trigger. You can join these tables to other tables that are being manipulated by the trigger. For example, a trigger on a Job table can update a related employee table with rowset-based logic such as :

```
UPDATE employee
   SET employee.job_lvl = i.min_lvl
   FROM inserted i
  WHERE employee.emp_id = i.emp_id
```

This kind of logic will allow the trigger update to work correctly if one job record is changed or many job rows are changed at once. This is much more efficient than loading all of the rows from the inserted table into a cursor which updates the employee records one at a time within the cursor loop.

Checking for Column Updates

The UPDATE() function is available inside INSERT and UPDATE triggers. UPDATE() allows a trigger to determine whether a column was affected by the INSERT or UPDATE statement that fired the trigger. By testing whether a column was actually updated, you can avoid performing unnecessary work.

For example, suppose a rule mandates that you cannot change the city for an author (a silly rule, but it demonstrates a few key concepts). Listing 30.4 creates a trigger for both INSERT and UPDATE that enforces this rule on the authors table in the BigPubs2008 database.

LISTING 30.4 Using the **UPDATE()** Function in a Trigger

```

CREATE TRIGGER tr_au_ins_upd ON authors
FOR INSERT, UPDATE
AS
IF UPDATE(city)
BEGIN
RAISERROR ('You cannot change the city.', 15, 1)
ROLLBACK TRAN
END
GO
UPDATE authors
SET city = city
WHERE au_id = '172-32-1176'

```

```

Server: Msg 50000, Level 15, State 1, Procedure
tr_au_ins_upd, Line 5
You cannot change the city.

```

Listing 30.4 shows how you generally write triggers that verify the integrity of data. If the modification violates an integrity rule, an error message is returned to the client application, and the modification is rolled back.

The `UPDATE()` function evaluates to `TRUE` if you update the column in the `UPDATE` statement. As shown in the preceding example, you do not have to change the value in the column for the `UPDATE()` function to evaluate to `TRUE`, but the column must be referenced in the `UPDATE` statement. For example, with the author update, the `city` column was set it to itself (the value does not change), but the `UPDATE()` function still evaluates to `TRUE`.

NOTE

If you created the `tr_au_upd` trigger on the `authors` table as part of the `AFTER` trigger example earlier in this chapter, you might have also seen the `TRIGGER OUTPUT: 1 rows were updated` message. This trigger was set to be the first trigger to fire, and it executes in addition to the new `ins_upd` trigger added in the example from this section.

Now you can add a couple of `INSERT` statements on the `authors` table:

```

INSERT authors (au_id, au_lname, au_fname, city, contract)
VALUES('111-11-1111', 'White', 'Johnson', 'Menlo Park', 1)

```

```

--Results from the previous insert
Server: Msg 50000, Level 15, State 1
You cannot change the city.

```

The `UPDATE()` function evaluates to `TRUE` and displays the error message. This outcome is expected because the trigger was created for `INSERT` as well, and the `IF UPDATE` condition is evaluated for both insertions and updates.

Now you can see what happens if you change the `INSERT` statement so that it does not include the `city` column in the `INSERT`:

```
INSERT authors (au_id, au_lname, au_fname, contract)
VALUES('111-11-2222', 'White', 'Johnson', 1)
```

```
Server: Msg 50000, Level 15, State 1
You cannot change the city.
```

The error message is still displayed, even though the insertion was performed without the `city` column. This process might seem counterintuitive, but the `IF UPDATE` condition always returns a `TRUE` value for `INSERT` actions. The reason is that the columns have either explicit default values or implicit (`NULL`) values inserted, even if they are not specified. The `IF UPDATE` conditions see this as a change and evaluate to `TRUE`.

If you change the `tr_au_ins_upd` trigger to be for `UPDATE` only (not `INSERT` and `UPDATE`), the insertions can take place without error.

Enforcing Referential Integrity by Using DML Triggers

Several options, including foreign key constraints and stored procedures, are available to enforce referential integrity, but using a trigger is still a viable alternative. A trigger provides a great deal of flexibility and allows you to customize your referential integrity solution to fit your needs. Some of the other alternatives, such as foreign keys, do not provide the same degree of customization.

TIP

In a database environment in which multiple databases are used with related data, a trigger can be invaluable for enforcing referential integrity. The trigger can span databases, and it can ensure that data rows inserted into a table in one database are valid based on rows in another database.

Listing 30.5 shows how to re-create and populate the `customers` and `orders` tables in the sample `BigPubs2008` database.

LISTING 30.5 Creating and Populating the `customers` and `orders` Tables

```
if exists (select * from sysobjects
  where id = object_id('orders') and sysstat & 0xf = 3)
  drop table orders
GO
if exists (select * from sysobjects
```

```

where id = object_id('customers') and sysstat & 0xf = 3)
drop table customers

GO

CREATE TABLE customers
(customer_id INT PRIMARY KEY NOT NULL,
customer_name NVARCHAR(25) NOT NULL,
customer_comments NVARCHAR(22) NULL)
CREATE TABLE orders
(order_id INT PRIMARY KEY NOT NULL,
customer_id INT,
order_date DATETIME,
CONSTRAINT FK_orders_customers
FOREIGN KEY (customer_id) REFERENCES customers (customer_id))

INSERT customers (customer_id, customer_name, customer_comments)
VALUES(1, 'Hardware Suppliers AB', 'Stephanie is contact.')
INSERT customers (customer_id, customer_name, customer_comments)
VALUES(2, 'Software Suppliers AB', 'Elisabeth is contact.')
INSERT customers (customer_id, customer_name, customer_comments)
VALUES(3, 'Firmware Suppliers AB', 'Mike is contact.')

INSERT orders (order_id, customer_id, order_date)
VALUES(100, 1, GETDATE())
INSERT orders (order_id, customer_id, order_date)
VALUES(101, 1, GETDATE())
INSERT orders (order_id, customer_id, order_date)
VALUES(102, 1, GETDATE())

SELECT * FROM customers
SELECT * FROM orders
customer_id customer_name          customer_comments
-----
1           Hardware Suppliers AB   Stephanie is contact.
2           Software Suppliers AB    Elisabeth is contact.
3           Firmware Suppliers AB    Mike is contact.

order_id  customer_id order_date
-----
100       1           2009-06-17 05:16:49.233
101       1           2009-06-17 05:16:49.233
102       1           2009-06-17 05:16:49.233

```

When foreign key constraints are used to enforce referential integrity, they prohibit several different types of changes to the data in the related tables. These restrictions

ensure that the integrity of the relationships is maintained. For example, the FOREIGN KEY constraint `FK_orders_customers` on the `orders` table prohibits the following:

- ▶ Inserting rows into the `orders` table for customer numbers that don't exist in the `customers` table
- ▶ Updating the `orders` table by changing the customer number to values that don't exist in the `customers` table
- ▶ Deleting rows in the `customers` table for which orders exist
- ▶ Updating the `customers` table by changing the customer number for which orders exist

You might want a cascading action instead of prohibiting the deletion or update of rows on the `customers` table. This would include automatically cascading the `DELETE` or `UPDATE` statement executed on the `customers` table to the related `orders` table. You can do this by using triggers.

Cascading Deletes

A cascading delete is relatively simple to create. Listing 30.6 shows a cascading delete trigger for the `customers` table.

TIP

SQL Server 2000 added a feature that allows you to define cascading actions on a FOREIGN KEY constraint. When defining the constraints on a table, you can use the `ON UPDATE CASCADE` or `ON DELETE CASCADE` clause, which causes changes to the primary key of a table to cascade to the related foreign key tables. Refer to Chapter 26, "Implementing Data Integrity," for further information on this option.

LISTING 30.6 A Cascading Delete for the **customers** Table

```
CREATE TRIGGER cust_del_orders ON customers
FOR DELETE
AS
IF @@ROWCOUNT = 0
RETURN
DELETE orders
FROM orders o , deleted d
WHERE o.customer_id = d.customer_id
IF @@ERROR <> 0
BEGIN
RAISERROR ('ERROR encountered in cascading trigger.', 16, 1)
```

```

ROLLBACK TRAN
RETURN
END

```

The following DELETE statement deletes the row for Customer 1, so all three rows for that customer in the orders table should be deleted by the trigger:

```
DELETE customers WHERE customer_id = 1
```

```

Server: Msg 547, Level 16, State 1
The DELETE statement conflicted with COLUMN REFERENCE
constraint 'FK_orders_customers'.
The conflict occurred in database 'BigPubs2008',
table 'orders', column 'customer_id'.
The statement has been terminated.

```

This result might not be what you expected. The FOREIGN KEY constraint here restricts the DELETE statement, so the trigger never fires. The trigger in this example is an AFTER trigger. Therefore, the trigger does not fire, and the cascading action never takes place. You have several options to get around this situation:

- ▶ Remove the FOREIGN KEY constraint from orders to customers.
- ▶ Disable the FOREIGN KEY constraint from orders to customers.
- ▶ Keep the FOREIGN KEY constraint and perform all cascading actions in stored procedures.
- ▶ Keep the FOREIGN KEY constraint and perform all cascading actions in the application.
- ▶ Use an INSTEAD OF trigger in place of the AFTER trigger.
- ▶ Use the new cascading referential integrity constraints.

Listing 30.7 shows how you can disable the FOREIGN KEY constraint so that a cascading delete can occur.

LISTING 30.7 Disabling the **FOREIGN KEY** Constraint to the **customers** Table So That a Cascading Delete Can Occur

```

ALTER TABLE orders
  NOCHECK CONSTRAINT FK_orders_customers
GO

GO

DELETE customers WHERE customer_id = 1
SELECT * FROM customers
SELECT * FROM orders
customer_id customer_name          customer_comments

```

```

-----
2          Software Suppliers AB      Elisabeth is contact.
3          Firmware Suppliers AB      Mike is contact.

```

```

order_id  customer_id order_date
-----

```

In Listing 30.7, the cascading deletes occur via the trigger because the FOREIGN KEY constraint is disabled. Compared to a trigger for cascading deletes, a trigger for cascading updates is more complex and not as common. This issue is discussed in more detail in the next section.

If you disable the FOREIGN KEY constraint, you have a potential integrity problem. If rows are inserted or updated in the orders table, there are no constraints to ensure that the customer number exists in the customer table. You can take care of this situation by using an INSERT and UPDATE trigger on the orders table (see Listing 30.8). The trigger in Listing 30.8 tests for the existence of a customer before the order is inserted or updated.

LISTING 30.8 Handling a Restriction by Using a Trigger on the **orders** Table

```

if exists (select * from sysobjects where id = object_id('dbo.ord_ins_upd_cust')
          and sysstat & 0xf = 8)
    drop trigger dbo.ord_ins_upd_cust
GO

CREATE TRIGGER ord_ins_upd_cust ON orders
FOR INSERT, UPDATE
AS
IF EXISTS (SELECT * FROM inserted
          WHERE customer_id NOT IN
          (SELECT customer_id FROM customers))
BEGIN
    RAISERROR('No customer with such customer number', 16, 1)
    ROLLBACK TRAN
    RETURN
END

```

Cascading Updates

A cascading update with a trigger is a bit tricky to achieve. Modifying a primary key, per definition, really involves deleting a row and inserting a new row. The problem is that you lose the connection between the old row and new row in the customers table. How do you know which changes to cascade to which rows?

This situation is simpler if you can restrict the changes to one row (see Listing 30.9) because you have only one row in the deleted and inserted tables. You know the customer number before and after the modification.

LISTING 30.9 A Cascading Update in a Trigger

```

if exists (select * from sysobjects where id = object_id('dbo.cust_upd_orders')
          and sysstat & 0xf = 8)
    drop trigger dbo.cust_upd_orders
GO

CREATE TRIGGER cust_upd_orders ON customers
FOR UPDATE
AS
DECLARE @rows_affected int, @c_id_before int, @c_id_after int
SELECT @rows_affected = @@ROWCOUNT
IF @rows_affected = 0
    RETURN -- No rows changed, exit trigger
IF UPDATE(customer_id)
BEGIN
    IF @rows_affected = 1
    BEGIN
        SELECT @c_id_before = customer_id FROM deleted
        SELECT @c_id_after = customer_id FROM inserted
        UPDATE orders
        SET customer_id = @c_id_after
        WHERE customer_id = @c_id_before
    END
ELSE
    BEGIN
        RAISERROR ('Cannot update more than 1 row.', 16, 1)
        ROLLBACK TRAN
        RETURN
    END
END
END

```

If several rows are updated, it's not easy to know which order belongs to which customer. You can easily modify the trigger shown in Listing 30.9 to handle a situation in which several rows change to the same value; however, this is not allowed because of the primary key on the customers table. Instances in which several rows are modified and the primary key value is changed are rare, and you are not likely to encounter such situations.

NOTE

The cascading FOREIGN KEY constraints are an excellent alternative to triggers, and they are efficient. If you choose not to use the cascading feature, you might still want to enjoy the simplicity of constraints. Then you need to handle cascading actions only in stored procedures or in client applications.

Stored procedures are often a good choice because they essentially give application developers a function-based interface for modifications. If the implementation details (for example, the table structure or rules) change, client applications can be isolated from the changes, as long as the interfaces to the stored procedures stay the same. The question of how to handle a cascade is a matter of personal preference, however.

Handling cascading updates in a client application or stored procedure is a chicken-and-egg situation: you cannot change the primary key table first because other tables reference it. You also cannot change the referencing table because no row exists in the primary key table with a corresponding value. The solution is to insert in the referenced table a new row that contains the new primary key value, change the referencing rows, and then delete the old row from the referenced table.

INSTEAD OF Triggers

SQL Server 2000 introduced a type of trigger called an INSTEAD OF trigger. This type of trigger extends SQL Server's trigger capabilities and provides an alternative to the AFTER trigger that was heavily utilized in prior versions of SQL Server.

The name of the trigger gives you some insight into how this trigger operates: this trigger performs its actions *instead of* the action that fired it. This is much different from the AFTER trigger, which performs its actions *after* the statement that caused it to fire has completed. This means you can have an INSTEAD OF update trigger on a table that successfully completes but does not include the actual update to the table.

The basic syntax for creating an INSTEAD OF trigger is as follows:

```
CREATE TRIGGER trigger_name
ON table_name
INSTEAD OF { INSERT | UPDATE | DELETE }
AS
SQL statements
```

Listing 30.10 shows how to create a trigger that prints a message stating the number of rows updated by an UPDATE statement. It then executes an UPDATE against the table that has the trigger on it. Finally, it selects the rows from the table for review.

LISTING 30.10 A Simple **INSTEAD OF** Trigger

```

if exists (select * from sysobjects where id = object_id('dbo.cust_upd_orders')
           and sysstat & 0xf = 8)
    drop trigger dbo.cust_upd_orders
GO
CREATE TRIGGER trI_au_upd ON authors
INSTEAD OF UPDATE
AS
PRINT 'TRIGGER OUTPUT: '
+CONVERT(VARCHAR(5), @@ROWCOUNT) + ' rows were updated.'
GO

UPDATE authors
SET au_fname = 'Rachael'
WHERE state = 'UT'
GO
TRIGGER OUTPUT: 1 rows were updated.

SELECT au_fname, au_lname FROM authors
WHERE state = 'UT'
GO
au_fname          au_lname
-----
Johann Wolfgang  von Goethe

```

As you can see from the results of the `SELECT` statement, the first name (`au_fname`) column is not updated to 'Rachael'. The `UPDATE` statement is correct, but the `INSTEAD OF` trigger logic does not apply the update from the statement as part of its `INSTEAD OF` action. The only action the trigger carries out is to print its message.

The important point to realize is that after you define an `INSTEAD OF` trigger on a table, you need to include all the logic in the trigger to perform the actual modification as well as any other actions that the trigger might need to carry out.

Executing **INSTEAD OF** Triggers

To gain a complete understanding of the `INSTEAD OF` trigger, you must understand its execution in relationship to the other events that are occurring. The following key events are important when the `INSTEAD OF` trigger fires:

- ▶ **Triggering action**—The `INSTEAD OF` trigger fires *instead of* the triggering action. As shown earlier, the actions of the `INSTEAD OF` trigger replace the actions of the original data modification that fired the trigger.
- ▶ **Constraint processing**—Constraint processing—including `CHECK` constraints, `UNIQUE` constraints, and `PRIMARY KEY` constraints—happens *after* the `INSTEAD OF` trigger fires.

Listing 30.11 demonstrates the trigger execution order.

LISTING 30.11 **INSTEAD OF** Trigger Execution

```

CREATE TRIGGER employee_insInstead
ON employee
INSTEAD OF insert
AS

DECLARE @job_id smallint

--Insert the jobs record for the employee if it does not already exist
IF NOT EXISTS
(SELECT 1
 FROM jobs j, inserted i
 WHERE i.job_id = j.job_id)
BEGIN
    INSERT jobs
        (job_desc, min_lvl, max_lvl)
    SELECT 'Automatic Job Add', i.job_lvl, i.job_lvl
    FROM inserted i

--Capture the identify value for the job just inserted
--This will be used for the employee insert later
    SELECT @job_id = @@identity

    PRINT 'NEW job_id ADDED FOR NEW EMPLOYEE:' + convert(char(3),@job_id)

END

--Execute the original insert action with the newly added job_id
INSERT employee
    (emp_id, fname, minit, lname, job_id, job_lvl, pub_id, hire_date)
SELECT emp_id, fname, minit, lname, @job_id, job_lvl, pub_id, hire_date
FROM Inserted

GO

```

The trigger in Listing 30.11 can be created in *BigPubs2008*. The key feature of this **INSTEAD OF** trigger is that it can satisfy a referential integrity constraint that was not satisfied before the **INSERT** was executed. Note the **FOREIGN KEY** constraint on the *employee* table that references *job_id* on the *jobs* table. The trigger first checks whether the *jobs* record associated with the *job_id* of the employee being inserted exists. If the *jobs* record does not

exist for the inserted employee's `job_id`, the trigger inserts a new jobs record and uses it for the insertion of the employee record.

If you execute the following `INSERT` statement, which has a `job_id` that does not exist, it succeeds:

```
INSERT EMPLOYEE
    (emp_id, fname, minit, lname, job_id, job_lvl, pub_id, hire_date)
VALUES ('KNN33333F', 'Kayla', 'N', 'Nicole', 20, 100, 9952, getdate())
Go
```

This statement succeeds because the constraint processing happens after the `INSTEAD OF` trigger completes its actions. Conversely, if you were to create the same trigger as an `AFTER` trigger, the `FOREIGN KEY` constraint would execute before the `AFTER` trigger, and the following error message would be displayed:

```
INSERT statement conflicted with COLUMN FOREIGN KEY constraint
'FK_employee_job_id_1BFD2C07'. The
conflict occurred in database 'BigPubs2008', table 'jobs', column 'job_id'.
-->The statement has been terminated.
```

Notice with the previous `INSTEAD OF` trigger example that the last action the trigger performs is the actual insertion of the employee record. The trigger was created to fire when an employee was inserted, so the trigger must perform the actual insertion. This insertion occurs in addition to any other actions that justify the trigger's creation.

Using `AFTER` Versus `INSTEAD OF` Triggers

Now that you have seen some of the key differences between `AFTER` and `INSTEAD OF` triggers, you need to decide which trigger to use. In the previous example (Listing 30.11), the `INSTEAD OF` trigger is the only trigger option for this kind of functionality. However, you can often use either trigger type to attain the same result.

Something you should consider when choosing one of these triggers is the efficiency of the overall modification. For example, if you have a modification that will cause a trigger to fire and often reject the modification, you might want to consider using the `INSTEAD OF` trigger. The rationale is that the `INSTEAD OF` trigger does not perform the actual modification until after the trigger completes, so you do not need to undo the modification. If you were to use an `AFTER` trigger in the same scenario, any modifications that were rejected would need to be rolled back because they have already been written to the transaction log by the time the `AFTER` trigger fires.

Conversely, if you have a situation in which the vast majority of the updates are not rejected, the `AFTER` trigger might be your best choice.

The particular situation dictates the preferred trigger, but you should keep in mind that `INSTEAD OF` triggers tend to be more involved than `AFTER` triggers because an `INSTEAD OF` trigger must perform the actual data modification that fired it.

Using AFTER and INSTEAD OF Triggers Together

An important consideration when coding an INSTEAD OF trigger is that it can exist on the same table as an AFTER trigger. INSTEAD OF triggers can also execute based on the same data modifications as AFTER triggers.

Consider, for example, the INSTEAD OF trigger from Listing 30.11 that you placed on the employee table in the BigPubs2008 database. An AFTER trigger already existed on the employee table. Listing 30.12 shows the code for the existing AFTER trigger on the employee table.

LISTING 30.12 An **AFTER** Trigger Placed on the Same Table as an **INSTEAD OF** Trigger

```

if exists (select * from sysobjects where id = object_id('dbo.employee_insupd')
          and sysstat & 0xf = 8)
    drop trigger dbo.employee_insupd
GO

CREATE TRIGGER employee_insupd
ON employee
FOR INSERT, UPDATE
AS
--Get the range of level for this job type from the jobs table.
declare @min_lvl tinyint,
        @max_lvl tinyint,
        @emp_lvl tinyint,
        @job_id smallint
select @min_lvl = min_lvl,
       @max_lvl = max_lvl,
       @emp_lvl = i.job_lvl,
       @job_id = i.job_id
from employee e, jobs j, inserted i
where e.emp_id = i.emp_id AND i.job_id = j.job_id
IF (@job_id = 1) and (@emp_lvl <> 10)
begin
    raiserror ('Job id 1 expects the default level of 10.',16,1)
    ROLLBACK TRANSACTION
end
ELSE
IF NOT (@emp_lvl BETWEEN @min_lvl AND @max_lvl)
begin
    raiserror ('The level for job_id:%d should be between %d and %d.',
              16, 1, @job_id, @min_lvl, @max_lvl)
    ROLLBACK TRANSACTION
end
End
go

```

This AFTER trigger checks whether the job level assigned to the employee falls within a valid range for the `job_id` assigned to the employee. It is fired for both insertions and updates, and it can exist on the same table as the `employee_ins` INSTEAD OF trigger described earlier. The combined effect on an employee insertion with both the triggers on the `employee` table is to have the following actions happen:

1. The INSERT data modification is executed.
2. The INSTEAD OF trigger fires, completes its validation, and ultimately does the employee insertion that is written to the transaction log.
3. Constraint processing completes.
4. The AFTER trigger fires, performing its actions on the employee record inserted by the INSTEAD OF trigger.
5. The AFTER trigger completes and commits the transaction to the database.

One of the key points in this example is that the AFTER trigger performs its actions on the row inserted by the INSTEAD OF trigger. It does not use the record from the original INSERT that started the trigger execution. Therefore, in this chapter's example, where the INSTEAD OF trigger generates a new `job_id`, the new `job_id` value—not the `job_id` that was originally inserted—is used in the AFTER trigger.

You need to consider rollback and recovery in this scenario as well, but they are beyond the scope of this discussion. This example simply shows that INSTEAD OF and AFTER triggers can be combined and that you need to consider the order of execution when designing a trigger solution.

Using Views with INSTEAD OF Triggers

One of the most powerful applications of an INSTEAD OF trigger is to a view. The INSTEAD OF trigger, unlike the AFTER trigger, can be applied to a view and triggered based on modifications to the view. For more information on views, see Chapter 27, "Creating and Managing Views."

The creation of INSTEAD OF triggers on views is important because data modifications against views have many restrictions. The list is extensive, but following are a few examples:

- ▶ You cannot use data modification statements that apply to more than one table in the view in a single statement.
- ▶ All columns defined as NOT NULL in the underlying tables that are being inserted must have the column values specified in the INSERT statement.
- ▶ If the view was defined with the WITH CHECK OPTION clause, rows cannot be modified in a way that will cause them to disappear from the view.

You can use the INSTEAD OF trigger to overcome some of these restrictions. In particular, the first restriction (related to making a single table modification) can be addressed with the INSTEAD OF trigger. The INSTEAD OF trigger fires before the actual modification takes place, so it can resolve the modifications to the underlying tables associated with the view. It can then execute the modification directly against those base tables. The following example demonstrates this capability:

```

Use BigPubs2008
go
CREATE VIEW employeeJobs
AS
select j.min_lvl, j.max_lvl, j.job_id, j.job_desc, e.job_lvl, e.emp_id
  from employee e, jobs j
 where e.job_id = j.job_id
GO

```

This example creates a view in the `BigPubs2008` database that joins data from the `employee` and `jobs` tables. It retrieves the job types and the associated levels, the employees assigned to the job types, and each employee's current job level. Following is a sample set of rows from the view:

min_lvl	max_lvl	job_id	job_desc	job_lvl	emp_id
25	100	14	Designer	35	ENL44273F
25	100	14	Designer	89	PSA89086M
25	100	14	Designer	100	KFJ64308F
25	100	12	Editor	32	Y-L77953M
25	100	12	Editor	35	H-B39728F
25	100	12	Editor	100	HAS54740M

Let's say you want to change the minimum job level (`min_lvl`) for the `Designer` job to 40 and at the same time set the job level (`job_lvl`) for any employees who have this job to 40. If you execute the following update—without an `INSTEAD OF` trigger—against the view, you get the message shown:

```

UPDATE employeeJobs
  SET min_lvl = 40,
      job_lvl = 40
 WHERE job_id = 12
GO

```

View or function 'employeeJobs' is not updateable
because the modification affects multiple base tables.

To get around this problem, you can use an `INSTEAD OF` trigger. The trigger can decipher the update to the view and apply the updates to the base table without causing the error. This functionality is demonstrated in the `INSTEAD OF` trigger shown in Listing 30.13.

LISTING 30.13 A Basic View with an **INSTEAD OF** Trigger

```

CREATE TRIGGER employeeJobs_updInstead
ON employeeJobs
INSTEAD OF UPDATE
AS
IF @@ROWCOUNT = 0 RETURN

```

```
--update the data related to the jobs table
UPDATE jobs
  SET jobs.min_lvl = i.min_lvl,
      jobs.max_lvl = i.max_lvl,
      jobs.job_desc = i.job_desc
  FROM inserted i
 WHERE jobs.job_id = i.job_id
       AND (jobs.min_lvl <> i.min_lvl
           OR jobs.max_lvl <> i.max_lvl
           OR jobs.job_desc <> i.job_desc)

--update the data related to the employee table
UPDATE employee
  SET employee.job_lvl = i.min_lvl
  FROM inserted i
 WHERE employee.emp_id = i.emp_id
GO
```

A section in Listing 30.13 checks the fields related to the jobs table and updates the base table if any of the values have changed. Another section updates the employee table for the employee fields that have been changed in the view.

NOTE

You could enhance the trigger in Listing 30.13 to include logic to check for specific updates or to update only those employees who are assigned to the job and have a job level below the new minimum. These enhancements are not included in the listing to keep the example simple.

If you now execute the same UPDATE statement, you don't get an error message:

```
UPDATE employeeJobs
  SET min_lvl = 40,
      job_lvl = 40
 WHERE job_id = 12
GO
```

The following results show values selected from the employeeJobs view after the update is executed successfully:

min_lvl	max_lvl	job_id	job_desc	job_lvl	emp_id
25	100	14	Designer	35	ENL44273F
25	100	14	Designer	89	PSA89086M

25	100	14	Designer	100	KFJ64308F
25	100	13	Sales Representative	35	PMA42628M
25	100	13	Sales Representative	64	CGS88322F
25	100	13	Sales Representative	100	TP055093M
40	100	12	Editor	40	Y-L77953M
40	100	12	Editor	40	H-B39728F
40	100	12	Editor	40	HAS54740M

Notice that the Editor job now has a minimum level (`min_lvl`) equal to 40 and that all the employees who have that job level (`job_lvl`) are also set to 40.

You can see the added flexibility that you get by using the `INSTEAD OF` trigger on a basic view. This flexibility is also applicable to a more sophisticated view called a *distributed partitioned view*. With this type of view, data for the view can be partitioned across different servers. Partitioning this way enables you to scale a database solution and still have a single view of the data that appears as one table.

You can make data modifications via a distributed partitioned view, but some restrictions exist. If you do not meet the requirements for updating the view, you can use the `INSTEAD OF` trigger to bypass these restrictions; this is similar to adding an `INSTEAD OF` trigger on a nonpartitioned view.

INSTEAD OF Trigger Restrictions

`INSTEAD OF` triggers have many capabilities, but they also have limitations. Following are some of them:

- ▶ `INSTEAD OF` triggers do not support recursion. This means they cannot call themselves, regardless of the setting of the `Recursive Triggers` database option. For example, if an `INSERT` is executed on a table that has an `INSTEAD OF` trigger, and the `INSTEAD OF` trigger performs an `INSERT` on this same table, the `INSTEAD OF` trigger for this `INSERT` does not fire a second time. Any `AFTER` triggers defined on the same table for `INSERT` fire based on the `INSTEAD OF` trigger `INSERT`.
- ▶ You can define only one `INSTEAD OF` trigger for each action on a given table. Therefore, you can have a maximum of three `INSTEAD OF` triggers for each table: one for `INSERT`, one for `UPDATE`, and one for `DELETE`.
- ▶ A table cannot have an `INSTEAD OF` trigger and a `FOREIGN KEY` constraint with `CASCADE` defined for the same action. For example, you cannot have an `INSTEAD OF` trigger defined for `DELETE` on a given table as well as a foreign key with a `CASCADE DELETE` definition. You get an error if you attempt to do this. In this situation, you could have `INSTEAD OF` triggers defined on `INSERT` and `UPDATE` without receiving errors.

Using DDL Triggers

DDL triggers were introduced in SQL Server 2005. These triggers focus on changes to the definition of database objects as opposed to changes to the actual data. The definition of database objects is dictated by the DDL events that these triggers respond to.

The DDL events that these triggers fire on can be broken down into two main categories. The first category includes DDL events that are scoped at the database level and affect the definition of objects such as tables, indexes, and users. The second category of DDL triggers is scoped at the server level. These triggers apply to server objects, such as logins.

The number of DDL events at the database level far exceeds the number at the server level. Table 30.2 lists the DDL statements and system stored procedures that DDL triggers can fire on.

CREATE_LINKED_SERVER (sp_addlinkedserver)	ALTER_LINKED_SERVER (sp_serveroption)	DROP_LINKED_SERVER (sp_dropserver)
CREATE_LINKED_SERVER_LOGIN (sp_addlinkedsrvlogin)		DROP_LINKED_SERVER_LOGIN (sp_droplinkedsrvlogin)
CREATE_LOGIN (sp_addlogin and sp_grantlogin) (xp_grantlogin and sp_denylogin)	ALTER_LOGIN (sp_defaultdb and sp_defaultlanguage) (sp_password, sp_change_users_login)	DROP_LOGIN (sp_droplogin and sp_revokelogin) (xp_revokelogin)
CREATE_MESSAGE (sp_addmessage)	ALTER_MESSAGE (sp_altermessage)	DROP_MESSAGE (sp_dropmessage)
CREATE_REMOTE_SERVER (sp_addserver)	ALTER_REMOTE_SERVER (sp_setnetname)	DROP_REMOTE_SERVER (sp_dropserver)
GRANT_SERVER	DENY_SERVER	REVOKE_SERVER
ADD_SERVER_ROLE_MEMBER		DROP_SERVER_ROLE_MEMBER

System stored procedures are enclosed in parentheses.

Triggers created on the DDL events are particularly important for auditing purposes. In the past, it was very difficult to isolate changes to the definition of a database or to secure them from change. With DDL triggers, you have the tools necessary to manage these changes.

Creating DDL Triggers

The basic syntax for creating a DDL trigger follows:

```
CREATE TRIGGER trigger_name
ON { ALL SERVER | DATABASE }
[ WITH <ddl_trigger_option> [ ,...n ] ]
{ FOR | AFTER } { event_type | event_group } [ ,...n ]
AS { sql_statement [ ; ] [ ...n ] | EXTERNAL NAME <method_specifier> [ ; ] }
```

The best way to illustrate the use of the DDL trigger syntax and power of these triggers is to look at a few examples. The example shown in Listing 30.14 illustrates the creation of a DDL trigger that is scoped at the database level and prevents table-level changes.

LISTING 30.14 A Database-Scoped DDL Trigger for Tables

```
CREATE TRIGGER tr_TableAudit
ON DATABASE
FOR CREATE_TABLE, ALTER_TABLE, DROP_TABLE
AS
    PRINT 'You must disable the TableAudit trigger in order
        to change any table in this database'
    ROLLBACK
GO
```

This trigger is fired whenever the CREATE, ALTER, or DROP TABLE statements are executed. Consider, for example, the following statements that can be run against the BigPubs2008 database:

```
ALTER table titles
    add new_col int null
alter table titles
    drop column new_col
```

You must disable the TableAudit trigger in order to change any table in this database

```
Msg 3609, Level 16, State 2, Line 1
```

```
The transaction ended in the trigger. The batch has been aborted.
```

These ALTER statements add a column to the titles table and then remove the column. With the tr_TableAudit trigger in place on the BigPubs2008 database, the error message is displayed after the first ALTER statement is executed.

This type of trigger is useful for controlling development and production database environments. It goes beyond the normal security measures and helps manage unwanted change. For development environments, this type of trigger enables the database administrator to lock down an environment and focus all changes through that person.

The previous examples include events scoped at the database level. Let's look at an example that applies to server-level events. The script in Listing 30.15 creates a trigger scoped at the server level. It prevents changes to the server logins. When this trigger is installed, it displays a message and rolls back any login changes that are attempted.

LISTING 30.15 A Server-Scoped DDL Trigger for Logins

```
CREATE TRIGGER tr_LoginAudit
ON ALL SERVER
FOR CREATE_LOGIN, ALTER_LOGIN, DROP_LOGIN
AS
    PRINT 'You must disable the tr_LoginAudit trigger before making login changes'
    ROLLBACK
```

The DDL trigger examples we have looked at thus far have targeted specific events listed in Table 30.2. These individual events can also be referenced via an event group. Event groups are hierarchical in nature and can be referenced in DDL triggers instead of the individual events. For example, the table-level trigger from Listing 30.14 can be changed as shown in Listing 30.16 to accomplish the same result. In Listing 30.16, the `DDL_TABLE_EVENTS` group reference replaces the individual event references to `CREATE_TABLE`, `ALTER_TABLE`, and `DROP_TABLE`.

LISTING 30.16 An Example of a DDL Trigger Referencing an Event Group

```
USE [BigPubs2008]
IF EXISTS (SELECT * FROM sys.triggers
    WHERE name = N'tr_TableAudit' AND parent_class=0)
DROP TRIGGER [tr_TableAudit] ON DATABASE
go

CREATE TRIGGER tr_TableAudit
ON DATABASE
FOR DDL_TABLE_EVENTS
AS
    PRINT 'You must disable the TableAudit trigger in
    order to change any table in this database'
    ROLLBACK
GO
```

SQL Server Books Online has an excellent diagram listing all the event groups that can be used to fire DDL triggers. Refer to the “DDL Event Groups” topic in Books Online, which shows the event groups and related DDL events they contain. Event groups simplify administration and allow for auditing at a high level.

The DDL trigger examples we have looked at thus far have executed simple print statements. To further extend the functionality of DDL triggers, you can code them to capture event information related to the DDL trigger execution. You do this by using the EVENTDATA function. The EVENTDATA function returns an XML string that includes the time of the event, server process ID (SPID), and type of event that fired the trigger. For some events, additional information, such as the object name or T-SQL statement, is included in the XML string as well.

The EVENTDATA function is essentially the replacement for the inserted and deleted tables available with DML triggers but not available with DDL triggers. It gives you information you can use to implement an auditing solution that captures changes to a data definition. This function is particularly useful in situations in which you do not want to prevent changes to your definition, but you want a record of the changes that occur.

Listing 30.17 shows an auditing solution with a DDL trigger that utilizes the EVENTDATA function to capture any changes to indexes in the BigPubs2008 database. Several event data elements are selected from the EVENTDATA XML string and displayed whenever a change is made to an index.

LISTING 30.17 An Example of a DDL Trigger That References an Event Group

```
CREATE TRIGGER tr_ddl_IndexAudit
ON DATABASE
FOR CREATE_INDEX, ALTER_INDEX, DROP_INDEX
AS
    DECLARE @EventData XML
-- Capture event data from the EVENTDATA function
SET @EventData = EVENTDATA()
-- Select the auditing info from the XML stream
SELECT  @EventData.query ('data(/EVENT_INSTANCE/PostTime)')
        AS [Event Time],
        @EventData.query ('data(/EVENT_INSTANCE/EventType)')
        AS [Event Type],
        @EventData.query ('data(/EVENT_INSTANCE/ServerName)')
        AS [Server Name],
        @EventData.query ('data(/EVENT_INSTANCE/TSQLCommand/CommandText)')
        AS [Command Text]
GO
```

To test the DDL trigger in Listing 30.17, you can run the following statement to create an index on the titles table in the BigPubs2008 database:

```
CREATE NONCLUSTERED INDEX [nc_titles_type] ON [dbo].[titles] ( [type] ASC )
```

The INDEX CREATE statement completes successfully, and the event-specific information appears in the Results pane.

You can further extend the auditing capabilities of this type of DDL trigger by writing the results to an audit table. This would give you a quick way of tracking changes to database objects. This type of approach dramatically improves change control and reporting on database changes.

NOTE

DDL triggers can also execute managed code based on the CLR. This topic is discussed in the section “Using CLR Triggers,” later in this chapter.

Managing DDL Triggers

The administration of DDL triggers is similar to the administration of DML triggers, but DDL triggers are located in a different part of the Object Explorer tree. The reason is that DDL triggers are scoped at the server or database level, not at the table level. Figure 30.3 shows the Object Explorer tree and the nodes related to DDL triggers at both the server and database levels. The `tr_TableAudit` trigger you created earlier in this chapter is shown under the Database Triggers node. Figure 30.3 shows the options available when you right-click a database trigger in the Object Explorer tree.

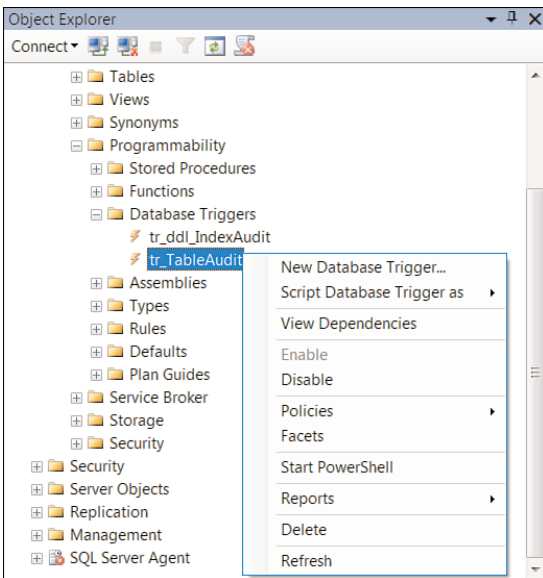

FIGURE 30.3 Using SSMS to manage DDL triggers.

The DDL triggers scoped at the server level are found in the Triggers node under the Server Objects node of the Object Explorer tree. (The Server Objects node is near the bottom of Figure 30.3.)

You can obtain information about DDL triggers by using catalog views. These views provide a convenient and flexible means for querying database objects, including DDL triggers. Table 30.3 lists the catalog views that relate to triggers. The table includes the scope of the trigger that the view reports on and a brief description of what it returns.

TABLE 30.3 Catalog Views for DDL Triggers

Catalog View	Description
<i>Statements with Database-Level Scope</i>	
sys.triggers	All triggers, including DDL database-scoped triggers
sys.trigger_events	All trigger events, including those that fire DDL database-scoped triggers
sys.sql_modules	All SQL-defined modules, including trigger definitions
sys.assembly_modules	All CLR-defined modules, including database-scoped triggers
<i>Statements with Server-Level Scope</i>	
sys.server_triggers	Server-scoped DDL triggers
sys.server_trigger_events	Events that fire server-scoped triggers
sys.sql_modules	DDL trigger definitions for server-scoped triggers
sys.server_assembly_modules	CLR trigger definitions for server-scoped triggers

Listing 30.18 shows sample SELECT statements that utilize the catalog views. These statements use the sys.triggers and sys.server_triggers views. The SELECT against the sys.triggers table uses a WHERE clause condition that checks the parent_class column to retrieve only DDL triggers. The SELECT from sys.server_triggers does not need a WHERE clause because it inherently returns only DDL triggers. The results of each statement are shown below each SELECT in the listing.

LISTING 30.18 Viewing DDL Triggers with Catalog Views

```
--DATABASE SCOPED DDL TRIGGERS
select left(name,20) 'Name', create_date, modify_date, is_disabled
from sys.triggers
where parent_class = 0
```

```
--Name                create_date                modify_date                is_disabled
-----
--tr_TableAudit      2009-06-18 12:48:43.140 2009-06-18 12:48:43.140 0
--tr_ddl_IndexAudit  2009-06-22 06:35:10.233 2009-06-22 06:35:10.233 0
```

```
--SERVER SCOPED DDL TRIGGERS
```

```
select left(name,20) 'Name', create_date, modify_date, is_disabled
from sys.server_triggers
```

```
--Name                create_date                modify_date                is_disabled
-----
--tr_LoginAudit      2009-06-18 12:13:46.077 2005-06-18 12:13:46.077 0
```

Using CLR Triggers

CLR triggers are triggers based on the CLR. CLR integration, which was added with SQL Server 2008, allows for database objects (such as triggers) to be coded in one of the supported .NET languages, including Visual Basic .NET and C#.

The decision to code triggers and other database objects by using the CLR depends on the type of operations in the trigger. Typically, objects that have heavy computations or require references to objects outside SQL are coded in the CLR. Triggers strictly geared toward database access should continue to be coded in T-SQL.

You can code both DDL and DML triggers by using a supported CLR language. Generally speaking, it is much easier to code a CLR trigger in the Visual Studio .NET Integrated Development Environment (IDE), but you can create them outside the IDE as well. Visual Studio .NET provides a development environment that offers IntelliSense, debugging facilities, and other user-friendly capabilities that come with a robust IDE. The .NET Framework and development environment are discussed in more detail in Chapter 4, “SQL Server and the .NET Framework.”

The following basic steps are required to create a CLR trigger:

1. Create the CLR class. You code the CLR class module with references to the namespaces required to compile CLR database objects.
2. Compile the CLR class into an assembly or a DDL file, using the appropriate language compiler.
3. Load the CLR assembly into SQL Server so that it can be referenced.
4. Create the CLR trigger that references the loaded assembly.

The following listings provide examples of each of these steps.

NOTE

The CLR must be enabled on your server before you can add CLR components. The CLR option is disabled by default. To enable the CLR, you use the `sp_configure 'clr enabled', 1` T-SQL command followed by the `RECONFIGURE` command. You can also enable CLR integration by using SQL Server 2008 Surface Area Configuration and then choosing the Surface Area Configuration for Features and selecting the Enable CLR Integration option.

Listing 30.19 contains C# code that can be used for the first step: creating the CLR class. This simple example selects rows from the inserted table.

LISTING 30.19 A CLR Trigger Class Created with C#

```
using System;
using System.Data;
using System.Data.Sql;
using Microsoft.SqlServer.Server;
using System.Data.SqlClient;
using System.Data.SqlTypes;
using System.Xml;
using System.Text.RegularExpressions;

public class clrtriggertest
{
    public static void showinserted()
    {
        SqlTriggerContext triggContext = SqlContext.TriggerContext;
        SqlConnection conn = new SqlConnection ("context connection = true");
        conn.Open();
        SqlCommand sqlComm = conn.CreateCommand();
        SqlPipe sqlP = SqlContext.Pipe;
        SqlDataReader dr;
        sqlComm.CommandText = "SELECT pub_id, pub_name from inserted";
        dr = sqlComm.ExecuteReader();
        while (dr.Read())
            sqlP.Send((string)dr[0] + ", " + (string)dr[1]);
    }
}
```

The CLR class in Listing 30.19 needs to be compiled so that SQL Server can use it. The compiler for C# is located in the .NET Framework path, which is

C:\WINDOWS\Microsoft.NET\Framework*version* by default. The last part of the path, *version*, is the number of the latest version installed on your machine. For simplicity's sake, you can add the full .NET Framework path to your path variable in the Advanced tab of your System Properties dialog. If you add the .NET Framework path to your path variable, you can run the executable for the compiler without navigating to that location.

You can save the code from Listing 30.19 in a text file named `clrtriggertesting.cs`. Then you can open a command prompt window and navigate to the folder where you saved the `clrtriggertesting.cs` file. The command shown in Listing 30.20 compiles the `clrtriggertesting.cs` file into `clrtriggertesting.dll`. This command can be run from any directory if you have added the .NET Framework path (for example, C:\WINDOWS\Microsoft.NET\Framework\v3.5) to your path variable. Without the additional path entry, you need to navigate to the .NET Framework path prior to executing the command.

LISTING 30.20 A CLR Trigger Class Compilation

```
csc /target:library clrtriggertesting.cs
```

After compiling `clrtriggertesting.dll`, you need to load the assembly into SQL Server. Listing 30.21 shows the T-SQL command you can execute to create the assembly for `clrtriggertesting.dll`.

LISTING 30.21 Using **CREATE ASSEMBLY** in SQL Server

```
CREATE ASSEMBLY triggertesting
from 'c:\clrtrigger\clrtriggertesting.dll'
WITH PERMISSION_SET = SAFE
```

The final step is to create the trigger that references the assembly. Listing 30.22 shows the T-SQL commands to add a trigger on the `publishers` table in the `BigPubs2008` database.

LISTING 30.22 Creating a CLR Trigger

```
CREATE TRIGGER tri_publishers_clr
ON publishers
FOR INSERT
AS
EXTERNAL NAME triggertesting.clrtriggertest.showinserted
```

Listing 30.23 contains an `INSERT` statement to the `publishers` table that fires the newly created CLR trigger.

LISTING 30.23 Using an INSERT Statement to Fire a CLR Trigger

```
INSERT publishers
  (pub_id, pub_name)
  values ('9922', 'Sams Publishing')
```

The trigger simply echoes the contents of the inserted table. The output from the trigger based on the insertion in Listing 30.23 is as follows:

```
9922, Sams Publishing
```

The `tri_publishers` trigger demonstrates the basic steps for creating a CLR trigger. The true power of CLR triggers lies in performing more complex calculations, string manipulations and things of this nature that can be done much more efficiently with CLR programming languages than they can in T-SQL.

NOTE

For more detailed information and examples of CLR triggers, see Chapter 45.

Using Nested Triggers
